Leptin / neurohumoral	Leptin (an adipocyte hormone) normally stimulates ventilation; serum leptin is <i>high</i> in obesity, so central leptin resistance is proposed as a key contributor to the diminished ventilatory responsiveness and CO_2 retention.

- ▶ **Rapid, shallow breathing pattern** (higher frequency, lower tidal volume than simple obesity) minimises elastic work but **increases dead-space fraction**, worsening alveolar hypoventilation and CO_2 retention.
- ▶ **Gas exchange**: hypoventilation alone causes hypoxaemia with a *normal* A–a gradient; superimposed **V/Q mismatch and shunt from premature airway closure** widen the A–a gradient and deepen hypoxaemia, which is **worse supine**.

- ▶ **Renal compensation:** chronic respiratory acidosis drives **bicarbonate retention** (metabolic compensation) — an elevated serum HCO_3^- is the bedside footprint of chronic hypoventilation.
- ▶ **Reversibility:** central drive defects **improve once sleep-disordered breathing is treated** (CPAP/NIV) or weight is lost — confirming that blunted responsiveness is a **consequence, not the primary cause**, of OHS.

Clinical features

- ▶ **Sleep-related:** loud habitual snoring, witnessed apnoeas, **excessive daytime somnolence**, poor-quality unrefreshing sleep, **early-morning headaches** (from nocturnal CO_2 retention).
- ▶ **Cardiorespiratory:** exertional **dyspnoea**, orthopnoea, fatigue; signs of **cor pulmonale** — raised JVP, peripheral oedema, loud P_2 (chronic hypoxaemia/hypercapnia → pulmonary vasoconstriction → **pulmonary hypertension and right heart failure**).
- ▶ **Examination:** central obesity, plethora/cyanosis, possible secondary erythrocytosis (polycythaemia from chronic hypoxaemia), features of metabolic syndrome.
- ▶ **Acute presentation:** decompensated **acute-on-chronic hypercapnic respiratory failure** with CO_2 narcosis (drowsiness, asterixis, papilloedema), often precipitated by sedatives, infection or an acute cardiac event.

Diagnosis and investigations

Diagnosis follows a stepwise evaluation of daytime hypercapnia (history/exam → PFTs + chest imaging → BMI → polysomnography), excluding parenchymal, chest-wall, neuromuscular and drive disorders first.

Test	Expected finding / role
Arterial blood gas (ABG)	Diagnostic hallmark — $\text{PaCO}_2 \geq 45$ mmHg with near-normal pH (compensated chronic respiratory acidosis); hypoxaemia common. A <i>normal</i> pH distinguishes chronic from acute hypoventilation.
Serum bicarbonate	Sensitive screen: $\text{HCO}_3^- < 27$ mmol/L makes OHS very unlikely; $\text{HCO}_3^- \geq 27$ mmol/L should trigger an ABG to confirm hypercapnia.
Polysomnography (PSG)	Confirms and grades OSA (AHI) and detects nocturnal hypoventilation ; essential as ~90% have OSA.
Pulmonary function tests	Restrictive pattern with reduced ERV/FRC, <i>normal</i> FEV_1/FVC ; used to exclude obstructive/restrictive lung disease as the cause of hypercapnia.
CXR / CT, ECG, echocardiography	Exclude parenchymal disease; assess for RV hypertrophy / pulmonary hypertension / cor pulmonale.

Test	Expected finding / role
TFTs, drug history	Exclude hypothyroidism and sedative/opioid-induced hypoventilation .
FBC	Secondary erythrocytosis supports chronic hypoxaemia.

- **Screening questionnaires** for OSA (Epworth Sleepiness Scale, *Berlin*, **STOP-Bang**) raise suspicion but are insufficiently specific — PSG remains the standard.
- *Distinguish from* **congenital central hypoventilation syndrome** (**Ondine's curse**, **PHOX2B mutation**) and primary alveolar hypoventilation, where the lungs and habitus are normal and drive is absent.

Management

Treatment targets *all* contributors — sleep-disordered breathing, the mechanical load (weight), and comorbidities.

Modality	Detail
Positive airway pressure (first line)	CPAP is first-line for OHS with concomitant severe OSA — it corrects upper-airway obstruction and improves daytime PaCO ₂ /PaO ₂ in >half of patients. <i>*RCT evidence (e.g. Pickwick/Masa, Lancet 2019) shows CPAP and NIV are broadly equivalent*</i> for long-term PaCO ₂ , symptoms, cardiovascular and overall mortality in OHS + severe OSA.
Non-invasive ventilation / BiPAP	Preferred when hypoventilation predominates or there is no significant OSA , in acute decompensated OHS , and when hypercapnia persists despite adherent CPAP or obstructive events persist at maximum CPAP (20 cmH ₂ O). Use BiPAP with a backup rate (ST mode) or volume-assured pressure support ; BiPAP-spontaneous (no backup) is reserved for CPAP-intolerant patients.
Weight reduction	Substantial weight loss (≈20–25% of body weight) can normalise PaCO₂ . Diet, activity, behavioural therapy; bariatric surgery gives the most durable loss (indicated BMI ≥40, or ≥35 with serious comorbidity) and improves comorbidities. PaO ₂ rises ~1 mmHg per 5 kg lost.
Supplemental oxygen	Use cautiously for persistent hypoxaemia/pulmonary hypertension — may worsen hypercapnia even at low flow; <i>not</i> a substitute for ventilatory support.

Modality	Detail
Avoid respiratory depressants	Sedative-hypnotics, opioids and alcohol are contraindicated/avoided.
Respiratory stimulants	Medroxyprogesterone, acetazolamide improve $\text{PaCO}_2/\text{PaO}_2$ but are poorly evidenced, carry side-effects, and must not replace PAP or weight loss.
Comorbidities / perioperative	Aggressively treat decompensating events (ACS, PE, pneumonia, heart failure). OHS patients have high perioperative risk (respiratory failure, re-intubation, heart failure) — recognition is a key safety measure.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ “Load vs Strength” balance diagram (Harrison Fig 307-1B): a beam/see-saw labelled — *Respiratory load* (chest-wall elastic load, **Obesity**, abdominal distension, lung resistive load) on one side **greater than** *Respiratory muscle strength + Respiratory drive*; arrow to “Alveolar hypoventilation $\rightarrow \uparrow \text{PaCO}_2$ ”. Add the three OHS contributors as input arrows: **OSA, blunted central drive (leptin resistance), increased work of breathing**.
- ▶ Obesity volume–pressure curve (Murray Fig 131.13): label axes **Volume (y) vs Pressure cmH_2O (x)**; show CW, L, RS curves; mark FRC reset to a lower, less compliant point and TLC, illustrating tidal breathing on the stiff portion of the curve.

Clinical / Diagnostic significance

- ▶ OHS confers **higher morbidity and mortality** than equally obese eucapnic patients — driven by pulmonary hypertension, cor pulmonale, cardiovascular disease and recurrent respiratory failure; effective PAP therapy reduces this.
- ▶ Always **measure an ABG in an obese, sleepy, hypercapnic-appearing patient** with a raised serum bicarbonate — OHS is frequently missed until a crisis.
- ▶ In acute decompensation, **NIV is the cornerstone**; intubate for failure, but plan early NIV weaning because these patients are difficult to extubate.
- ▶ **Treating OSA/hypoventilation can reverse the “blunted drive”** — demonstrating the syndrome’s potential reversibility and the priority of CPAP/NIV plus weight loss.

High-yield exam pointers

- ▶ **Definition triad**: BMI ≥ 30 + awake $\text{PaCO}_2 \geq 45$ mmHg + sleep-disordered breathing, **excluding other causes** = OHS (Pickwickian).
- ▶ **~90% have OSA, ~70% severe OSA**; severe obesity (BMI > 40) and AHI $> 30/\text{h}$ are risk factors.
- ▶ Serum $\text{HCO}_3^- < 27$ mmol/L makes OHS unlikely; ≥ 27 mmol/L $\rightarrow$ **do an ABG**.
- ▶ ABG shows **chronic compensated respiratory acidosis** ($\uparrow \text{PaCO}_2$, near-normal pH, $\uparrow \text{HCO}_3^-$).

- ▶ Pathophysiology = ↑mechanical load + blunted central drive + leptin resistance + OSA; work of breathing up to ~250% of normal.
- ▶ CPAP first-line if severe OSA; NIV (BiPAP-ST/VAPS) if hypoventilation predominates, no OSA, or acute decompensation. CPAP and NIV broadly equivalent (*Pickwick* trial).
- ▶ Weight loss of 20–25% can normalise PaCO₂; bariatric surgery most durable.
- ▶ Oxygen can worsen hypercapnia; avoid sedatives/opioids/alcohol; respiratory stimulants are adjuncts only.
- ▶ Complications: pulmonary hypertension, cor pulmonale, secondary polycythaemia, high perioperative risk.

Obstructive Sleep Apnea

Asked in: Paper IV May 2019 — RGUHS MD General Medicine

Definition / Introduction — Obstructive sleep apnea (OSA) is the most common sleep-related breathing disorder, characterised by recurrent episodes of complete (apnea) or partial (hypopnea) collapse of the **pharyngeal airway during sleep**, occurring despite persistent respiratory effort. Each event terminates in arousal and/or oxyhemoglobin desaturation, producing sleep fragmentation, intermittent hypoxemia and sympathetic surges. The term **obstructive sleep apnea/hypopnea syndrome (OSAHS)** denotes OSA accompanied by symptoms, classically excessive daytime sleepiness (EDS). Diagnosis rests on objective sleep study quantification using the **apnea-hypopnea index (AHI)**: ≥5 events/h with symptoms, or ≥15 events/h irrespective of symptoms.

Pathophysiology

- ▶ The pharynx lacks rigid bony/cartilaginous support, so patency depends on **pharyngeal dilator muscle** tone (genioglossus the principal). During inspiration, intraluminal pressure becomes negative (“suction”); dilator activation must counteract this.

- ▶ At **sleep onset**, neuromuscular output to dilators falls. In a person with an anatomically narrow/collapsible airway, this transient loss of compensation causes pharyngeal collapse (apnea) or near-collapse (hypopnea). Common collapse sites: **soft palate (most common)**, **tongue base**, **lateral pharyngeal walls**, and **epiglottis**.
- ▶ Collapse is worst in **REM sleep** (lowest skeletal-muscle tone) and in the **supine position** (gravity). Low lung volume in recumbency/obesity reduces caudal tracheal traction, decreasing pharyngeal-wall stiffness.
- ▶ **Starling resistor model** — collapsibility is expressed as the **critical closing pressure (Pcrit)**; a more negative Pcrit = less collapsible airway: normal < -10 cmH₂O, non-apneic snoring -10 to -5 , obstructive hypopnea -5 to 0 , obstructive apnea > 0 cmH₂O.
- ▶ **Non-anatomic (“ventilatory control”) traits** also contribute: high loop gain (oversensitive chemoresponsiveness to CO₂ causing unstable breathing), a low arousal threshold (premature awakening prevents dilator compensation), and poor dilator muscle responsiveness. These define individual OSA endotypes/phenotypes.

Predisposing risk factors

- ▶ **Obesity** — the dominant modifiable factor; accounts for ~40–60% of cases. A 10% weight gain raises AHI by ~30% and confers a sixfold risk of developing AHI ≥ 15 ; obese persons have ≥ 4 -fold risk.
- ▶ **Male sex** (2–3× more prevalent; android fat distribution, longer/more collapsible pharynx); **older age**; **postmenopausal** state in women (loss of protective sex-hormone effect on ventilatory drive).
- ▶ **Craniofacial**: retrognathia, micrognathia, high-arched palate; genetic syndromes — *Down syndrome*, *Treacher-Collins*, *Pierre-Robin sequence*.
- ▶ **Adenotonsillar hypertrophy** (chief cause in children, peak age 3–8 yr), **macroglossia**, nasal obstruction (septal deviation, polyps).
- ▶ **Endocrine**: hypothyroidism (25–35%), acromegaly (~70% have SDB), PCOS; also **family history** (first-degree relative risk $\sim 2\times$), East-Asian ancestry (craniofacial), alcohol, sedative-hypnotics and opioids, and smoking.

Clinical features

Nocturnal symptoms	Daytime symptoms
Loud habitual snoring , witnessed apneas, gasping/choking, nocturnal restlessness/diaphoresis, nocturia , GERD, morning headache, unrefreshing sleep, insomnia (more in women)	Excessive daytime sleepiness (cardinal), fatigue, impaired concentration/memory, irritability, mood/depressive symptoms, reduced libido/impotence

- ▶ **Physical findings**: central obesity, large **neck circumference**, hypertension; crowded oropharynx with **Mallampati class III–IV**, low-lying soft palate, bulky uvula, enlarged tonsils, macroglossia, retro-/micrognathia, nasal obstruction.

- ▶ Sex differences: women report more insomnia/fatigue/depression and less heavy snoring; apneas shorter and REM-predominant — a cause of under-recognition.

Diagnosis and investigations

- ▶ **Screening tools** (estimate pretest probability; sensitive but not specific): **STOP-Bang** (Snoring, Tiredness, Observed apnea, Pressure/HTN, BMI >35, Age >50, Neck >40 cm, male Gender), Berlin and NoSAS questionnaires. The **Epworth Sleepiness Scale** quantifies sleepiness (8 situations, 0–3 each; **score ≥11 = excessive sleepiness**).
- ▶ **Polysomnography (PSG)** is the **gold standard** (Level 1, attended, in-laboratory): records EEG, EOG, chin/leg EMG, ECG, oronasal airflow (thermistor + nasal pressure), thoraco-abdominal effort bands, oximetry, body position, snoring. **Home sleep apnea testing (Level 3)** is acceptable for high-pretest-probability patients without major comorbidity; a negative home study in a high-probability patient should be followed by PSG.
- ▶ **Respiratory event scoring (AASM)**:

Event	Definition
Apnea	≥90% fall in airflow ≥10 s; <i>obstructive</i> = effort persists (thoraco-abdominal paradox), <i>central</i> = effort absent, <i>mixed</i> = central then obstructive
Hypopnea	≥30% airflow reduction ≥10 s with ≥3% desaturation or an arousal (def 1A); or ≥4% desaturation (def 1B)
RERA	Increasing effort/flow-limitation terminating in arousal, not meeting hypopnea criteria

- ▶ **AHI** = (apneas + hypopneas)/hour of sleep; **RDI** adds RERAs. Severity grading:

Severity	AHI (events/h)
Normal	<5
Mild	5–14
Moderate	15–29
Severe	≥30

- ▶ Adjuncts: serum TSH/FT₄ (exclude hypothyroidism); erythrocytosis from chronic hypoxemia; ABG normal in pure OSA (waking hypercapnia suggests **obesity hypoventilation syndrome [OHS]** — BMI >30 with daytime PaCO₂ >45 mmHg; OSA coexists in ~90%). Overnight BP often shows a “**non-dipping**” pattern. MSLT/MWT help distinguish narcolepsy and quantify sleepiness.

Health consequences / complications

- ▶ **Hypertension** — OSA is an identifiable secondary cause; produces nocturnal non-dipping, and **resistant/uncontrolled HTN** via sympathetic activation and RAAS/fluid effects. CPAP lowers 24-h BP modestly (~2–4 mmHg, more in sleepy/resistant patients).
- ▶ **Cardio-/cerebrovascular**: coronary artery disease, heart failure (HFrEF and HFpEF), **atrial fibrillation** and ventricular arrhythmias, stroke; OSA does not by itself cause right-heart failure (cor pulmonale implies coexisting cardiopulmonary disease).
- ▶ **Metabolic**: insulin resistance/type 2 diabetes, pro-inflammatory and prothrombotic state.
- ▶ **Neurobehavioural**: EDS, cognitive impairment, depression; 2–3× **risk of motor-vehicle and occupational accidents**; reduced quality of life. (Large RCTs of CPAP have not shown reduced cardiovascular event rates, likely from exclusion of sleepy patients and poor adherence.)

Management

- ▶ **General / behavioural**: weight reduction (even bariatric surgery), adequate sleep duration (7–9 h), **avoid supine sleep** (positional/vibrotactile therapy can cut AHI ~50% in positional OSA), treat nasal allergy, increase activity, **avoid alcohol within 3 h of bed**, and minimise sedatives/opioids.
- ▶ **CPAP** — *standard first-line therapy with the highest evidence*; a pneumatic splint maintaining airway patency. Titrated by sleep study or auto-titrating **APAP** (5–20 cmH₂O). Improves sleepiness, mood, BP and insulin sensitivity; adherence is the limiting factor (~50–80%; ~75% still using at 1 year). Side effects (nasal congestion, claustrophobia, aerophagia) are managed with humidification, mask change, or bilevel PAP.
- ▶ **Mandibular advancement (oral) appliances** — advance the mandible/tongue; reduce AHI by ≥50% in two-thirds; best for **mild–moderate OSA** or CPAP-intolerant patients; side effects: TMJ pain, tooth movement.
- ▶ **Surgery**: **uvulopalatopharyngoplasty (UPPP)** (removes uvula + ~15 mm of soft-palate margin) helps ~50%, better for snoring than apneas; often part of **multilevel surgery**. Nasal septoplasty aids CPAP tolerance. **Tracheostomy** is definitive but reserved for refractory severe disease. **Bariatric surgery** for obese patients.
- ▶ **Hypoglossal (upper-airway) nerve stimulation** — implanted stimulator for CPAP-intolerant moderate–severe OSA (AHI 15–65, per CMDT up to 100), BMI <35, and **absence of complete concentric collapse at the velum** on drug-induced sleep endoscopy.
- ▶ **Pharmacotherapy**: no FDA-approved drug historically; **tirzepatide** (dual GLP-1/GIP agonist) achieved ~16–17% weight loss with reduction in AHI (*NEJM* 2024) — a major recent advance; noradrenergic-antimuscarinic combinations (enhancing dilator tone) are in trials. Supplemental O₂ alone is **not** recommended (may prolong apneas).

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Upper-airway sagittal section** showing collapse sites — label: *nasal cavity, soft palate, uvula, tongue base, lateral pharyngeal walls, epiglottis, genioglossus muscle*; arrows for negative inspiratory (“suction”) pressure causing collapse.
- ▶ **Polysomnography tracing of an obstructive apnea** — label channels: *EEG (arousal), nasal-pressure & thermistor airflow (cessation ≥ 10 s), chest and abdomen effort bands showing paradoxical/thoraco-abdominal paradox, SaO_2 (desaturation dip)*; contrast with a central apnea (flat effort channels).

Clinical / Diagnostic significance

- ▶ Consider OSA in any patient with resistant hypertension, recurrent AF, nocturnal angina/arrhythmia, type 2 diabetes, unexplained pulmonary hypertension, or pre-operative obese patients (use STOP-Bang).
- ▶ Pre-operative recognition reduces perioperative airway/cardiac complications; OHS carries the highest risk.
- ▶ Confirm with PSG/HSAT and grade by AHI before committing to lifelong CPAP; reassess residual sleepiness and adherence at follow-up.

High-yield exam pointers

- ▶ AHI defines and grades OSA: mild 5–14, moderate 15–29, severe ≥ 30 ; diagnostic threshold ≥ 5 with symptoms or ≥ 15 without.
- ▶ **Apnea** = $\geq 90\%$ airflow drop ≥ 10 s; obstructive = effort present (thoraco-abdominal paradox); **hypopnea** = $\geq 30\%$ drop with $\geq 3\%$ desat or arousal.
- ▶ Major risk factors: **obesity, male sex, older age**; collapse site most often the **soft palate**; worst in REM and supine.
- ▶ **Epworth ≥ 11** = excessive sleepiness; **STOP-Bang** for screening; **Mallampati III–IV** on exam.
- ▶ **PSG is gold standard**; **CPAP is first-line treatment**; oral appliance for mild–moderate/CPAP-intolerant.
- ▶ **Pcrit** (Starling resistor) >0 cmH₂O = frank obstructive apnea.
- ▶ OSA is a secondary cause of **resistant hypertension** and is linked to **AF, stroke, CAD, diabetes**.
- ▶ Newer options: **hypoglossal nerve stimulation** (AHI 15–65, BMI <35 , no concentric velar collapse) and **tirzepatide** for weight-driven OSA.

SOURCE & COVERAGE

Pneumothorax

Asked in: Paper III Jul 2021 — RGUHS MD General Medicine

Definition / Introduction — Pneumothorax is the presence of air (gas) in the pleural space, with consequent partial or complete collapse of the underlying lung. The normal pleural space is a potential space holding only a thin film of fluid at a sub-atmospheric pressure of about **−3 to −5 cmH₂O**, generated by the balance between the inward elastic recoil of the lung and the outward recoil of the chest wall; entry of air abolishes this negative pressure and the lung recoils inward. It is classified by mechanism into **spontaneous** (primary or secondary), **traumatic**, and **iatrogenic**, with **tension pneumothorax** being a life-threatening physiological emergency in any category.

Classification

Type	Definition / Setting	Typical patient & common causes
Primary spontaneous (PSP)	Occurs <i>without</i> antecedent trauma and <i>without</i> clinically apparent lung disease	Tall, thin, young (<45 y), male, smoker; rupture of apical subpleural blebs/bullae + "pleural porosity"
Secondary spontaneous (SSP)	Spontaneous but on a background of known lung disease; BTS labels pneumothorax in patients >50 y or with significant smoking history as SSP	COPD (commonest in the West), pulmonary TB (commonest worldwide), cystic fibrosis, lung cancer, necrotizing pneumonia, <i>Pneumocystis jirovecii</i> , ILD (IPF, sarcoid), LAM and pulmonary Langerhans cell histiocytosis
Traumatic	Penetrating or blunt (non-penetrating) chest injury; air enters via chest-wall wound or visceral pleural laceration	Rib-fracture laceration, or alveolar rupture from sudden chest compression; often a hemopneumothorax
Iatrogenic	A subset of traumatic, from an invasive procedure	Transthoracic/CT-guided needle biopsy (leading cause),

Type	Definition / Setting	Typical patient & common causes
		thoracentesis, subclavian/IJ central line, transbronchial biopsy, barotrauma of positive-pressure ventilation, CPR
Tension	Pleural pressure positive throughout the respiratory cycle via a one-way (check) valve	Usually during mechanical ventilation, resuscitation, or trauma
Catamenial	Pneumothorax temporally linked to menstruation	Women of childbearing age; thoracic/diaphragmatic endometriosis

Pathogenesis

- ▶ **Blebs vs bullae (Miller 1947)**: a **bleb** is an outpouching of the *visceral pleura* caused by air dissecting between the **lamina elastica interna and externa**, typically <1 cm diameter; a **bull** is an air space >1 cm sharply demarcated by a thin wall (≤ 1 mm). *Reid (1967)* subdivided bullae into **type I** (narrow/pedunculated, no parenchyma), **type II** (broad/sessile), and **type III** (broad-based, extending to the hilum with minimal parenchyma).
- ▶ **PSP — “pleural porosity”**: the historical view that bleb/bulla rupture creates an alveolar–pleural communication is challenged. *Noppen’s* fluorescein-enhanced autofluorescence thoracoscopy showed air leakage from areas of **porosity** (disrupted mesothelium replaced by an inflammatory fibroelastic layer) rather than from the visible blebs themselves. PSP lungs are therefore **not truly “normal”** — they show distal airway inflammation (respiratory bronchiolitis), emphysema-like change and over-expression of **matrix metalloproteinases (MMP-2, MMP-9)**.
- ▶ **Familial / genetic causes (~10%)**: *Marfan syndrome* (**FBN1** / fibrillin-1), *Birt-Hogg-Dubé syndrome* (**FLCN** / folliculin — skin fibrofolliculomas, lung cysts, renal cancer), α_1 -*antitrypsin deficiency*, *homocystinuria*, *Ehlers-Danlos syndrome*. A strong family history warrants genetic referral and surveillance.
- ▶ **Tension physiology**: the visceral defect acts as a **one-way valve** — air enters on inspiration but cannot escape; rising intrapleural pressure progressively collapses the lung, shifts the mediastinum, and **reduces venous return**, lowering left-ventricular filling and cardiac output → obstructive shock.

Clinical features

- ▶ **Symptoms**: acute, usually unilateral, **pleuritic chest pain** and **dyspnoea** in nearly all; cough is common. Magnitude of symptoms correlates poorly with radiographic size.
- ▶ **Signs (affected hemithorax)**: reduced movement/expansion, **hyperresonant (tympanitic) percussion**, **diminished breath sounds**, decreased tactile/vocal fremitus, and ipsilateral chest

enlargement. Findings may be subtle in small pneumothoraces or against a background of emphysema.

- ▶ **Tension pneumothorax (emergency):** enlarged hemithorax with **no breath sounds**, **hyperresonance**, **tracheal/mediastinal shift to the contralateral side**, severe **tachycardia**, **hypotension**, **distended neck veins and cyanosis**. High peak inspiratory pressures (volume-cycled) or falling tidal volume (pressure-cycled) on a ventilator strongly suggest it. *Diagnosis is clinical — treatment must NOT await a chest X-ray.*

Investigations

- ▶ **Erect frontal CXR (first-line):** a **visceral pleural line** with absence of lung markings peripheral to it; the line has air on both sides, no vessels beyond it, and runs continuous and sharply demarcated — distinguishing it from a **skin-fold** (edge, lucent on one side only, vessels traceable across it).
- ▶ **Supine film (trauma/ICU):** look for the **deep sulcus sign** (abnormally deep, lucent costophrenic angle as air collects anteriorly).
- ▶ **Chest CT:** most accurate; clarifies size, detects **occult pneumothorax** (~40% of traumatic, seen on CT not CXR), distinguishes pneumothorax from **giant bullae** (avoids inadvertent intubation of a bulla and bronchopleural fistula), and screens for SSP causes (cystic lung disease/LAM).
- ▶ **Thoracic ultrasound:** absence of **lung sliding** and **B-lines** (with a “lung point”) diagnoses pneumothorax with high sensitivity/specificity in the supine trauma patient; beware false positives over emphysematous bullae.
- ▶ **ABG/ECG:** ABG usually unnecessary but may show hypoxaemia and respiratory alkalosis; left-sided PSP can mimic **acute MI** with QRS-axis/precordial T-wave changes.
- ▶ **Size estimation (no global consensus):** BTS “large” = **>2 cm** interpleural distance at the level of the **hilum** (~50% hemithorax volume by the *Light index*); ACCP “large” = **≥3 cm** from apex to cupola. Size guides—but does not dictate—the decision to intervene.

Management

- ▶ **General principle:** decide first *whether* intervention is needed (symptoms, size, underlying lung disease, ventilation status), then *how*.
- ▶ **PSP:** stable, small, minimally symptomatic patients → **observation** (many resolve as air is reabsorbed; the 2020 *Brown et al.* conservative-vs-interventional RCT showed conservative management is non-inferior even for moderate–large PSP in reliable patients). Symptomatic/large → **needle aspiration** with a 16–18-gauge cannula (aspirate up to 2.5 L); if aspiration fails, place a **small-bore chest tube (7–14F)**, optionally with a **Heimlich one-way valve** for ambulatory/outpatient management.

- ▶ **SSP:** admit for ≥ 24 h with **supplemental oxygen**; **most require a chest tube** because the diseased lung tolerates collapse poorly and spontaneous resolution is less likely. Early surgical/recurrence-prevention referral.
- ▶ **Supplemental oxygen:** high-flow/100% O_2 speeds reabsorption ~**fourfold** by washing out pleural nitrogen and widening the nitrogen gradient.
- ▶ **Tension pneumothorax:** immediate **needle decompression** — large-bore cannula into the **2nd intercostal space, mid-clavicular line** (Harrison: 2nd anterior intercostal space); a rush of gas confirms it. Leave the cannula until a definitive **chest tube** is placed.
- ▶ **Traumatic:** large/symptomatic $\rightarrow$ tube thoracostomy; if hemopneumothorax, an apical tube for air and a basal tube for blood. Small/occult may be observed.
- ▶ **Iatrogenic:** often resolves with observation/oxygen or simple aspiration; tube only if these fail or the patient is ventilated.
- ▶ **Failure of medical management / prolonged air leak (PAL = leak $>5-7$ days):** definitive treatment is **VATS** (preferred over open thoracotomy) — bleb/bullae resection (stapling) **plus pleurodesis** (talc poudrage, pleural abrasion, or pleurectomy). **Medical (chemical) pleurodesis** via the tube (talc slurry, tetracycline/minocycline) suits the non-surgical candidate; **autologous blood-patch pleurodesis** (1–2 mL/kg) and **endobronchial valves** are options in difficult SSP/COPD with bronchopleural fistula.
- ▶ **Recurrence prevention** is indicated for: **recurrent** (ipsi- or contralateral) pneumothorax, **synchronous bilateral** pneumothorax, PAL, or high-risk occupation (**airline pilot, diver**).
- ▶ **Catamenial pneumothorax:** suspect in any woman with pneumothorax within 24–48 h of menses (usually **right-sided**, recurrent); treat by **suppressing ectopic endometrium** — ovulation suppression with OCPs, or **danazol / GnRH analogues** (medical oophorectomy) — combined with VATS closure of diaphragmatic defects $\pm$ pleurodesis.
- ▶ **Complications:** tension physiology, pneumomediastinum, subcutaneous emphysema, and **re-expansion pulmonary oedema** (unilateral, after rapid re-inflation of a chronically collapsed lung — avoid by draining slowly and limiting suction).

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Labelled CXR / line diagram of a right-sided pneumothorax:** label *visceral pleural (lung) line, collapsed lung, absent lung markings (radiolucent pleural space), chest wall, diaphragm*, and (for tension) *mediastinum/trachea shifted to the contralateral side and depressed/flattened ipsilateral diaphragm*.
- ▶ **Tension pneumothorax pathophysiology schematic:** label *one-way (check) valve at visceral pleural defect, air entering on inspiration, rising positive intrapleural pressure, collapsed lung, mediastinal shift, kinked great veins $\rightarrow$ reduced venous return $\rightarrow$ fall in cardiac output*.

Clinical / Diagnostic significance

- ▶ A young, tall, thin male smoker with sudden pleuritic pain and dyspnoea = classic **PSP**; a similar event in COPD/TB/ILD = **SSP** and is far less benign.
- ▶ Recurrent pneumothorax in a **young woman** must trigger thought of **LAM**, **catamenial pneumothorax**, or **Birt-Hogg-Dubé** — consider low-dose CT chest.
- ▶ **Tension pneumothorax is a clinical diagnosis**; needle decompression precedes imaging and saves life.
- ▶ Distinguishing a **giant bulla** from a pneumothorax on CXR is critical — wrongly draining a bulla causes a persistent air leak/bronchopleural fistula; CT resolves the doubt.
- ▶ **Counselling**: mandatory smoking cessation (reduces recurrence), **no air travel until 7 days after radiographic resolution** (cabin depressurisation expands undrained air — an untreated pneumothorax is an absolute contraindication to flying), and **lifelong avoidance of scuba diving** unless definitive surgical pleurodesis has been performed.

High-yield exam pointers

- ▶ **Recurrence**: ~30% after a first PSP (observation or simple drainage); up to 50% for SSP if no surgery — surgery/pleurodesis greatly lowers this (talc poudrage recurrence $\approx$ 1.8%).
- ▶ **Bleb <1 cm vs bulla >1 cm**; *Reid* type I/II/III bullae; *Miller* first described blebs (1947).
- ▶ **Light's criteria** distinguish exudate/transudate in pleural *effusion*; do not confuse with **Light index** for pneumothorax *size*.
- ▶ **BTS large** = >2 cm at hilum; **ACCP large** = $\geq$ 3 cm at apex.
- ▶ Needle aspiration cannula 16–18 G, **up to 2.5 L**; tension decompression at **2nd ICS, mid-clavicular line**.
- ▶ **100% oxygen accelerates resorption** $\sim$ 4 $\times$.
- ▶ Familial mnemonics: **Marfan** (FBN1), **Birt-Hogg-Dubé** (FLCN), α_1 -antitrypsin deficiency, homocystinuria.
- ▶ **Pneumothorax ex vacuo** occurs when a trapped (unexpandable) lung cannot re-expand after fluid drainage.
- ▶ Left-sided pneumothorax can mimic **acute MI** on ECG; tension pneumothorax can mimic and coexist with shock.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Disorders of the Pleura” (pneumothorax classification, pleural mechanics, tension pneumothorax decompression).
- ▶ **Murray & Nadel's Textbook of Respiratory Medicine, 7e** — “Pneumothorax” (epidemiology; bleb/bulla and Reid classification; pleural-porosity pathogenesis; MMPs; familial genetics; sizing — BTS/ACCP/Light index; needle-aspiration vs chest-tube and

conservative-management RCTs; VATS/pleurodesis; blood-patch and endobronchial-valve therapy; traumatic, iatrogenic and catamenial pneumothorax).

Pulmonary Function Tests

Asked in: Paper I Dec 2023 — RGUHS MD General Medicine

Definition / Introduction — Pulmonary function tests (PFTs) are objective, reproducible, non-invasive measurements of the mechanical and gas-exchange properties of the respiratory system, interpreted against predicted values derived from height, age and sex. They quantify how the three functionally independent components of the system — the **lung and airways**, the **neuromuscular pump** and the **chest wall** — handle volume (statics) and flow (dynamics). PFTs serve to **detect and classify disease** (**obstructive vs restrictive vs mixed vs vascular**), grade severity, follow progression and response to therapy, and assess fitness for surgery. For most measures, **85–115% of the predicted value is normal**, and in health the various volumes tend to scale together.

Components of a complete PFT battery

- ▶ **Spirometry** — FVC, FEV₁, FEV₁/FVC ratio and the **flow-volume loop** (the core, effort-independent test of airflow).
- ▶ **Static lung volumes** — TLC, FRC, RV (require gas dilution or plethysmography; spirometry alone cannot measure them).
- ▶ **Diffusing capacity (DLCO)** — integrity of the alveolar-capillary membrane and gas transfer.
- ▶ **Respiratory muscle strength** — maximal inspiratory/expiratory pressures; supine spirometry.
- ▶ **Arterial blood gases (ABG) / pulse oximetry** — efficiency of gas exchange.
- ▶ **Bronchodilator reversibility** (pre- vs post-bronchodilator spirometry) and bronchoprovocation in selected cases.

Lung volumes and capacities (Spirogram, Fig. 296-2)

- ▶ **Tidal volume (TV)** — air moved in a normal quiet breath.
- ▶ **Inspiratory reserve volume (IRV)** and **expiratory reserve volume (ERV)** — extra air inhaled/exhaled beyond tidal breathing.
- ▶ **Residual volume (RV)** — air remaining after maximal exhalation; *cannot be exhaled, hence not measurable by spirometry*.
- ▶ **Inspiratory capacity (IC)** = TV + IRV; **functional residual capacity (FRC)** = ERV + RV, the volume at the end of a normal tidal breath.

- ▶ **Vital capacity (VC)** = TLC – RV, the maximal excursion of the respiratory system.
- ▶ **Total lung capacity (TLC)** — volume at full inflation.

Measuring absolute volumes — Because spirometry discloses only *relative* volume change, FRC (and hence RV and TLC) must be measured by one of two methods:

- ▶ **Inert gas (helium or neon) dilution** — a known volume of non-absorbable gas is diluted by resident lung gas; poorly ventilated regions (e.g., airflow obstruction) receive little gas, so this method **underestimates true lung volume**.
- ▶ **Body plethysmography** — the patient pants against a closed shutter; pressure/volume fluctuations give thoracic gas volume via **Boyle's law** ($P_1V_1 = P_2V_2$). More accurate when air-trapping is present.

Spirometry, airflow and the flow-volume loop

- ▶ In an **FVC manoeuvre** the patient inhales fully to TLC then exhales rapidly and forcefully to RV. Maximal expiratory flow is **effort-independent** (flow-limited) because of dynamic airway compression (*Bernoulli effect*), so results are reproducible.
- ▶ **FVC** = total volume exhaled; **FEV₁** = volume exhaled in the first second (a flow rate); **FEV₁/FVC ratio** is the key discriminator of obstruction.
- ▶ Data are displayed two ways — the **spirogram** (volume vs time) and the **flow-volume loop** (flow vs volume).
- ▶ **Pitfall:** airflow obstruction can lower FVC by raising RV, sometimes rendering the FEV₁/FVC ratio “*artificially normal*” and falsely implying obstruction is absent.

Flow-volume loop (Fig. 296-4)	Characteristic shape	Typical cause
A. Normal	Rapid rise then near-linear declining expiratory limb	—
B. Lower-airway obstruction	“Scooping” (concave) expiratory limb; flows fall faster at low volumes	Asthma, emphysema/COPD
C. Fixed central airway obstruction	Plateau of both inspiratory and expiratory limbs	Tracheal stenosis, large goitre
D. Variable extrathoracic (upper, above thoracic inlet)	Inspiratory plateau	Tracheal adenoma, post-tracheostomy stricture
E. Variable intrathoracic (lower, below thoracic inlet)	Expiratory plateau	Intrathoracic tracheal/bronchial lesion

Obstructive vs restrictive patterns

Feature	Obstructive	Restrictive
Defining defect	Reduced FEV ₁ /FVC ratio	Reduced TLC (FEV ₁ /FVC normal or high)
FEV ₁	Markedly reduced	Reduced proportionate to FVC
TLC, FRC, RV	Often increased (hyperinflation, air-trapping)	Reduced
Flow-volume loop	Scooped expiratory limb	Small loop shifted to low volumes; flows high <i>for the volume</i>
Examples	Asthma, emphysema/COPD, chronic bronchitis, cystic fibrosis	Pulmonary fibrosis (parenchymal), neuromuscular weakness, chest-wall/obesity (extraparenchymal)

Diffusing capacity (DLCO), muscle strength and ABG

- ▶ DLCO uses a small, safe amount of **carbon monoxide** with a **10-second breath-hold**; CO crossing the alveolar membrane combines with capillary haemoglobin (*single-breath diffusing capacity*). It rises with diffusion surface area and capillary haemoglobin and falls with membrane thickening.
 - **Low DLCO:** membrane thickening/destruction (**pulmonary fibrosis, emphysema**), curtailed pulmonary vasculature (**pulmonary hypertension**), reduced alveolar-capillary haemoglobin (**anaemia**). An isolated low DLCO with normal volumes should prompt evaluation for **pulmonary vascular disease**.
 - **High DLCO:** asthma, polycythaemia, pulmonary (alveolar) haemorrhage.
- ▶ **Respiratory muscle strength** — maximal inspiratory/expiratory pressure against a closed shutter; pressures $>\pm 60$ cmH₂O at FRC are **adequate** and exclude weakness as a cause of dysfunction. A sensitive bedside test is **supine spirometry**: normal FVC falls only 3–8% from upright to supine, but diaphragmatic weakness/paralysis or neuromuscular disease causes decrements of 10 to >25%.
- ▶ **ABG / oximetry** — measure Pao₂ and Paco₂. A widened (A–a)Do₂ indicates V/Q mismatch or shunt; **hypercarbia** accompanies severe obstruction (e.g., COPD) or advanced restriction. Oxygen content Cao₂ = $1.39 \times [\text{Hb}] \times \% \text{O}_2 \text{Sat} + 0.003 \times \text{Pao}_2$; saturation alone is followed non-invasively by **pulse oximetry**.

Characteristic PFT patterns in common disorders (Fig. 296-6)

Disorder (mechanism)	TLC / FRC / RV	FEV ₁ & FVC	Airway resistance	DLCO
Idiopathic pulmonary fibrosis (restriction, ↑ recoil)	All ↓	↓ (flows high for volume)	Normal	Markedly ↓
Moderate obesity (restriction, chest wall)	FRC ↓; TLC/RV usually normal	Near normal	Normal	Normal
Myasthenia gravis (restriction, muscle weakness)	TLC ↓, RV ↑	↓ (as “innocent bystanders”)	Normal	Normal
Acute asthma (obstruction, ↓ airway diameter)	FRC dynamically ↑, RV ↑, TLC usually normal	↓, reversible post-bronchodilator	↑	Normal or mildly ↑
Severe emphysema (obstruction, ↓ recoil)	TLC ↑ (hyperinflation), FRC ↑↑, RV ↑↑↑	↓, largely irreversible	Normal in “pure” emphysema	↓

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Spirogram (lung volumes & capacities)** — a tracing of volume vs time over a slow vital-capacity manoeuvre, with horizontal reference lines and brackets labelled: *Tidal volume (TV)*, *Inspiratory reserve volume (IRV)*, *Expiratory reserve volume (ERV)*, *Residual volume (RV)*, *Inspiratory capacity (IC)*, *Functional residual capacity (FRC)*, *Vital capacity (VC)*, *Total lung capacity (TLC)*.
- ▶ **Flow-volume loops** — axes labelled *Flow* (expiratory above zero, inspiratory below) and *Volume* (from TLC on left to RV on right); draw and label five loops: *A Normal*, *B Lower-airway obstruction (scooped)*, *C Fixed central obstruction (both limbs plateau)*, *D Variable extrathoracic (inspiratory plateau)*, *E Variable intrathoracic (expiratory plateau)*.

Clinical / Diagnostic significance

- ▶ **Diagnosis and classification:** FEV₁/FVC defines obstruction; reduced TLC defines restriction; combined defects suggest mixed disease.
- ▶ **Bronchodilator reversibility** (pre- vs post-bronchodilator FEV₁) distinguishes reversible asthma from largely fixed COPD/emphysema and guides therapy.
- ▶ **Isolated low DLCO** with normal spirometry/volumes is a clue to **pulmonary vascular disease** (e.g., **pulmonary hypertension**) or early emphysema/ILD; high DLCO suggests alveolar haemorrhage or polycythaemia.

- ▶ **Severity grading and monitoring:** serial FEV₁ tracks COPD/asthma progression and treatment response; falling FVC (especially supine) signals neuromuscular respiratory failure (e.g., GBS, myasthenia, ALS) and the need for ventilatory support.
- ▶ **Preoperative risk assessment** (lung resection, major surgery) and **disability/occupational evaluation** rely on spirometry and DLCO.
- ▶ **Localising airway lesions:** plateaued inspiratory/expiratory limbs flag upper-airway/tracheal obstruction often missed on routine spirometry numbers.

High-yield exam pointers

- ▶ **Obstruction** = low FEV₁/FVC; **restriction** = low TLC — TLC, not spirometry, confirms restriction.
- ▶ RV, FRC and TLC **cannot be measured by spirometry** — need **helium dilution** (underestimates in obstruction) or **body plethysmography** (Boyle's law, more accurate with air-trapping).
- ▶ **Scooped expiratory limb** = lower-airway obstruction; **biphasic plateau** = fixed central; **inspiratory plateau** = variable extrathoracic; **expiratory plateau** = variable intrathoracic.
- ▶ A reduced FVC from air-trapping can make FEV₁/FVC look **falsely normal** — always check TLC/RV.
- ▶ **DLCO low** in fibrosis, emphysema, pulmonary hypertension, anaemia; **high** in asthma, polycythaemia, alveolar haemorrhage.
- ▶ **MIP/MEP >±60 cmH₂O** is adequate; supine FVC fall >10% indicates diaphragmatic weakness (normal 3–8%).
- ▶ **Hallmark of emphysema** = ↑TLC (**hyperinflation**) with very high RV and reduced DLCO but normal airway resistance in “pure” disease.
- ▶ Normal range is **85–115% of predicted**; predictions depend on **height, age, sex**.

SOURCE & COVERAGE

Harrison 22e — Ch 296 “Disturbances of Respiratory Function” (lung volumes, airflow, flow-volume loops, disease patterns Fig. 296-2/296-4/296-6) and Ch 297 “Diagnostic Procedures in Respiratory Disease” (body plethysmography, DLCO, respiratory muscle testing, ABG). **Coverage note:** Specific quantitative reversibility thresholds (e.g., ATS ≥12% and ≥200 mL rise in FEV₁), **methacholine/bronchoprovocation testing**, **cardiopulmonary exercise testing** and the **6-minute walk test** are standard textbook PFT adjuncts but are *not described in the provided Harrison chapters*; they are mentioned only in outline and should be cross-checked against CMDT / ATS-ERS standards before use.

Pulmonary infiltrates with eosinophilia

Asked in: Paper III Nov 2020 — RGUHS MD General Medicine

Definition / Introduction — *Pulmonary infiltrates with eosinophilia* (PIE), or the **eosinophilic lung diseases**, are a heterogeneous group of disorders characterised by the combination of **radiographic pulmonary opacities** (infiltrates) and **eosinophilia**, demonstrated either in peripheral blood, in sputum, or — preferably — in the lung itself (bronchoalveolar lavage [BAL] or tissue). Eosinophilic pneumonia is defined pathologically as a pneumonia in which **eosinophils are the predominant inflammatory cell** in the alveoli and interstitium. By consensus, **blood eosinophilia is $>0.5 \times 10^9/L$ ($500/\mu L$)** and **hypereosinophilia $>1.5 \times 10^9/L$ ($1500/\mu L$)** on two examinations ≥ 1 month apart and/or tissue hypereosinophilia. The unifying effector cell is the **eosinophil**, whose differentiation and lung recruitment are driven by **IL-5, IL-3, GM-CSF and eotaxins** (Th2-/ILC2-derived), making the IL-5 axis a central therapeutic target.

Classification (primary/idiopathic vs secondary)

The first step is to separate **primary (idiopathic)** eosinophilic lung disease from disease that is **secondary** to an identifiable cause (drug, parasite, fungus, malignancy or another lung condition). A practical bedside algorithm asks three questions: (1) *extrapulmonary involvement?* (2) *identifiable cause/trigger?* (3) *acute or chronic onset?*

Category	Disorders
Primary (idiopathic) eosinophilic lung disease	Acute eosinophilic pneumonia (AEP); Chronic eosinophilic pneumonia (CEP); Eosinophilic granulomatosis with polyangiitis (EGPA / Churg-Strauss); Hypereosinophilic syndromes (HES)
Known cause associated with eosinophilia	Asthma & eosinophilic bronchitis; Allergic bronchopulmonary aspergillosis (ABPA); Bronchocentric granulomatosis; Drug/toxin reaction; Infection — parasitic/helminthic & nonparasitic (Löffler, tropical eosinophilia)
Lung diseases with eosinophilia	Cryptogenic organising pneumonia; Hypersensitivity pneumonitis; Idiopathic pulmonary fibrosis; Pulmonary Langerhans cell histiocytosis
Malignancy / systemic	Leukaemia, lymphoma, lung & other carcinomas; post-radiation pneumonitis; RA, sarcoidosis, Sjögren's

Diagnostic approach

- **History is paramount** — onset/timing/precipitants of symptoms; drug, occupational, environmental, **travel and immigration** history; family history; and a systems review for cardiac, GI, neurological, dermatological, sinus and renal clues (point to EGPA or HES).

- ▶ **Blood** — absolute eosinophil count, ESR/CRP, **total IgE**, *Aspergillus*-specific IgE/IgG, ANCA (MPO), stool for ova/parasites, filarial serology. Peripheral eosinophilia may be **absent at presentation in AEP** and is **suppressed by prior corticosteroids**.
- ▶ **BAL** — the noninvasive surrogate for tissue diagnosis. Normal BAL eosinophils <1%; a count >25% (**predominant cell**) strongly supports eosinophilic pneumonia, and >40% is characteristic of CEP. Lower counts (3–25%) are nonspecific (ILD, HP, sarcoid, drug, infection).
- ▶ **Imaging** — chest radiograph + **HRCT** to define distribution (peripheral upper-zone in CEP; diffuse in AEP; migratory in EGPA; central bronchiectasis/finger-in-glove in ABPA).
- ▶ **Biopsy** (transbronchial, cryobiopsy or surgical) is seldom required but resolves difficult cases; *Charcot-Leyden crystals* (composed of the eosinophil protein **galectin-10**) may be seen in tissue/sputum.

Idiopathic eosinophilic pneumonias — AEP vs CEP

Feature	Acute eosinophilic pneumonia (AEP/IAEP)	Chronic eosinophilic pneumonia (CEP/ICEP)
Onset	Acute febrile illness <1 month	Subacute over weeks–months
Demographics	Males 20–40 yr; no asthma	Females ~2:1, mean age ~45; nonsmokers ; asthma/atopy in majority
Trigger	Recent-onset smoking / vaping , inhaled dust	Often none; allergy in ~half
Course	Hypoxaemic respiratory failure, often needs ventilation; no other organ failure	Indolent; respiratory failure rare
Blood eosinophilia	Often absent at onset (appears day 7–30, mean ~1700/ μ L)	Present in ~90%; mean >30% of WBC
BAL eosinophils	$\geq 25\%$	~60% ($\geq 40\%$)
Chest imaging	Bilateral patchy ground-glass/consolidation, septal thickening, small effusions	Peripheral upper-zone consolidation — “ <i>photographic negative of pulmonary oedema</i> ” (pathognomonic but seen in <25%)
Steroid response / relapse	Dramatic; complete recovery, no relapse	Dramatic; >50% relapse , often needs prolonged steroids

AEP diagnostic criteria (Harrison/Philit): acute febrile respiratory illness <1 month; hypoxaemic respiratory failure ($\text{PaO}_2 \leq 60$ mmHg, $\text{PaO}_2/\text{FiO}_2 \leq 300$, or $\text{SpO}_2 < 90\%$ on room air); diffuse bilateral infiltrates; **BAL eosinophilia** >25%; absence of infection/drug cause; quick corticosteroid response; no relapse after stopping steroids.

Eosinophilic granulomatosis with polyangiitis (EGPA / Churg-Strauss)

- ▶ An ANCA-associated, eosinophil-rich small-vessel vasculitis with extravascular necrotising granulomas, defined by the triad of **asthma + eosinophilia + vasculitis**. Mean age ~48 yr.
- ▶ **Three classic phases:** (1) *prodromal* — asthma + allergic rhinosinusitis (often years); (2) *eosinophilic infiltrative* — blood/tissue eosinophilia (lung, GI); (3) *vasculitic* — constitutional symptoms with multi-organ vasculitis. Mean asthma-to-vasculitis interval ~9 years.
- ▶ **Organ involvement:** lung (migratory infiltrates, alveolar haemorrhage); **mononeuritis multiplex** in >75% (esp. peroneal nerve); skin (palpable purpura, nodules) ~50%; **cardiac** (eosinophilic myocarditis/cardiomyopathy — chief cause of death) up to 50%; GI (eosinophilic gastroenteritis); renal ~25% (usually mild, unlike other AAV).
- ▶ **Labs:** blood **eosinophilia >1000/ μ L (or >10% WBC)** — present in >80%, falls within ~24 h of steroids; **p-ANCA/anti-MPO in ~30–40%**; raised IgE, ESR, RF. ANCA-positive patients have a *vasculitic phenotype* (renal, neuropathy, purpura); ANCA-negative a *tissue/eosinophilic phenotype* (cardiac, lung).
- ▶ ***Cottin/Cordier criteria:** *asthma + blood eosinophilia >1500/ μ L (or BAL >25%) + an extrapulmonary manifestation (systemic feature such as mononeuritis multiplex, cardiomyopathy, or purpura; OR histological vasculitis; OR ANCA positivity). A single extrapulmonary feature = forme fruste*.*
- ▶ **Treatment:** glucocorticoids are the mainstay (prednisone 1 mg/kg/day, taper; IV methylprednisolone pulse 15 mg/kg/day for severe/cardiac disease). For **poor-prognosis (Five-Factor Score)** features — **cardiomyopathy, severe GI involvement, renal insufficiency (creatinine >150 μ mol/L $\approx$ 1.7 mg/dL), proteinuria >1 g/day, CNS involvement** (updated FFS also: age >65 yr, absence of ENT symptoms) — add **cyclophosphamide** (or rituximab). **Mepolizumab (anti-IL-5, 300 mg every 4 weeks)** and benralizumab are steroid-sparing agents that increase remission and reduce relapse. Untreated EGPA carries ~50% 3-month mortality; treated 6-year survival >70%.

Other important entities

- ▶ **Hypereosinophilic syndromes (HES)** — persistent eosinophilia >1500/ μ L with **end-organ damage** and no secondary cause; lung involved in ~40%. **Myeloproliferative variant** carries the **FIP1L1-PDGFR α fusion (4q12 deletion)** — an imatinib-responsive constitutively active tyrosine kinase (raised B12, tryptase, splenomegaly, myelofibrosis); **lymphocytic variant** is driven by clonal **CD3⁺CD4⁺ Th2** cells producing IL-5. Cardiac damage = endomyocardial fibrosis/restrictive cardiomyopathy. **<50% respond to steroids alone**; imatinib is first-line for the myeloproliferative/FIP1L1-PDGFR α variant; mepolizumab is effective.
- ▶ **ABPA** — hypersensitivity to *Aspergillus fumigatus* in **asthma or cystic fibrosis**; brownish mucus plugs, refractory asthma. Diagnosis (ISHAM/Agarwal): predisposing asthma/CF + **obligatory positive *Aspergillus* skin test or raised *A. fumigatus*-specific IgE and total IgE >1000 IU/mL + $\geq$ 2**

of (precipitins/IgG to *A. fumigatus*; ABPA-consistent opacities; eosinophil count $>500/\mu\text{L}$).

HRCT: **central (proximal) bronchiectasis**, high-attenuation mucoid impaction, “*finger-in-glove*” opacities. Treat with **oral corticosteroids + itraconazole** (4–6 months); omalizumab/anti-IL-5 in selected cases.

- ▶ **Infections (helminthic)** — chief cause of PIE in the tropics/developing world. ***Löffler syndrome** = *transient migratory infiltrates with eosinophilia from transpulmonary larval migration, most often Ascaris (also hookworm — Ancylostoma, Necator)*. Strongyloides causes recurrent symptoms and a fatal hyperinfection syndrome in the immunosuppressed. Tropical pulmonary eosinophilia is due to filariae (**Wuchereria bancrofti*, *Brugia malayi*), **common in** southern Asia, Africa, South America, **with very high IgE/eosinophilia, nocturnal cough/wheeze — treated with diethylcarbamazine****.
- ▶ **Drug/toxin-induced** — the commonest cause of PIE in the USA; remember **nitrofurantoin, daptomycin, phenytoin, NSAIDs, sulfasalazine/mesalamine, sulfonamides**; also radiation (breast cancer), particulate metals, illicit inhaled drugs. Management = withdraw the agent $\pm$ steroids. Overlaps with DRESS.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Diagnostic algorithm for eosinophilic pneumonia** (box-and-arrow): start “**Pulmonary infiltrates + eosinophilia**” $\rightarrow$ Q1 *Extrapulmonary involvement?* $\rightarrow$ EGPA / HES / DRESS / parasitic; if No $\rightarrow$ Q2 *Cause/trigger identified?* $\rightarrow$ **drug, smoking/vaping, ABPA, parasite, radiation**; if No $\rightarrow$ Q3 *Onset?* $\rightarrow$ **Acute = IAEP vs Chronic = ICEP**. Label boxes: *IAEP, ICEP, EGPA, HES, ABPA, Löffler, drug-induced*.
- ▶ **AEP vs CEP HRCT cartoon**: lung outline 1 = **bilateral diffuse ground-glass + septal thickening + small pleural effusions (AEP)**; lung outline 2 = **peripheral upper-zone consolidation sparing the centre** labelled “*photographic negative of pulmonary oedema*” (CEP).

Clinical / Diagnostic significance

- ▶ The single most useful discriminator is **BAL eosinophil percentage** ($>25\%$ supports an eosinophilic pneumonia; $>40\%$ suggests CEP) — it avoids lung biopsy in most patients.
- ▶ **AEP mimics ARDS** in a previously well young smoker but lacks multi-organ failure and responds completely to steroids — recognising it prevents unnecessary escalation and prognosticates well.
- ▶ **A new eosinophilic infiltrate in a long-standing asthmatic** demands exclusion of ABPA and EGPA; leukotriene-receptor antagonists/omalizumab/dupilumab and steroid tapering may *unmask* EGPA.
- ▶ **Always exclude Strongyloides/helminths before starting corticosteroids** in PIE (risk of fatal hyperinfection) — stool, serology, empiric ivermectin where appropriate.

- ▶ Steroids rapidly abolish blood and BAL eosinophilia, so investigations are best obtained before treatment.

High-yield exam pointers

- ▶ Blood eosinophilia $>500/\mu\text{L}$; hypereosinophilia $>1500/\mu\text{L}$; BAL $>25\%$ = eosinophilic pneumonia; $>40\%$ = CEP.
- ▶ AEP: young male smoker, ARDS-like, no peripheral eosinophilia at onset, **no relapse**; CEP: middle-aged female asthmatic, “*photographic negative of pulmonary oedema*”, **frequent relapse**.
- ▶ EGPA triad = **asthma + eosinophilia + vasculitis**; mononeuritis multiplex; p-ANCA/MPO $\sim 30\text{--}40\%$; cardiac disease = leading cause of death; **Five-Factor Score** guides cyclophosphamide; **mepolizumab** is steroid-sparing.
- ▶ HES: eosinophilia $>1500/\mu\text{L}$ + end-organ damage; FIP1L1-PDGFR α $\rightarrow$ **imatinib**.
- ▶ ABPA: asthma/CF, IgE >1000 IU/mL, central bronchiectasis, *finger-in-glove*; treat steroids + itraconazole.
- ▶ **Löffler syndrome** = transient infiltrates from *Ascaris* larval migration; **tropical pulmonary eosinophilia** = filariae, treat **diethylcarbamazine**.
- ▶ Commonest drugs: **nitrofurantoin, daptomycin, phenytoin, NSAIDs, sulfasalazine**; commonest cause in the West = **drugs**, in the tropics = **helminths**.
- ▶ **Charcot-Leyden crystals** = galectin-10; eosinophil maturation/recruitment driven by IL-5.

SOURCE & COVERAGE

- ▶ **Harrison’s Principles of Internal Medicine, 22e** — “*Hypersensitivity Pneumonitis and Pulmonary Infiltrates with Eosinophilia*” (classification table 299-2, AEP/CEP, EGPA, HES, ABPA, infectious & drug causes, AEP diagnostic criteria).
- ▶ **Murray & Nadel’s Textbook of Respiratory Medicine, 7e** — “*Eosinophilic Lung Diseases*” (diagnostic algorithm Fig 96.1, eosinophilia/BAL thresholds, ICEP & IAEP criteria tables, Cottin/Cordier EGPA criteria, Five-Factor Score, HES genetics, ISHAM/Agarwal ABPA criteria, treatment regimens) and “*Pulmonary Vasculitis*” for EGPA phenotypes.
- ▶ **CMDT 2026** — “*Eosinophilic Pulmonary Syndromes*” and “*Pulmonary Disorders*” (drug list, Löffler/tropical eosinophilia, current management, IL-5-targeted therapy).

Pulmonary Thromboembolism

Asked in: Paper III 09/2025 — RGUHS MD General Medicine

Definition / Introduction — Pulmonary thromboembolism (PE) is acute obstruction of the pulmonary arterial bed by thrombus, almost always an embolus that has detached from a lower-limb **deep-venous thrombosis (DVT)**; together DVT and PE constitute **venous thromboembolism (VTE)**, manifestations

of one disease process. Roughly 90% of clinically apparent PEs arise from proximal lower-extremity DVT. PE is “the great masquerader” — symptoms and signs are non-specific, so a structured, probability-based diagnostic and risk-stratified therapeutic approach is essential because untreated PE carries a case-fatality higher than that of acute myocardial infarction.

Aetiology & Risk Factors (Virchow’s triad)

- ▶ **Virchow’s triad** (1856): venous stasis, hypercoagulability, and endothelial/intimal injury — usually with an **inflammatory trigger** — drive thrombus formation around a valve cusp; activated platelets recruit neutrophils that form *neutrophil extracellular traps*, promoting thrombin generation in a milieu of stasis and low oxygen tension.
- ▶ **Inherited (hereditary) thrombophilias**: **Factor V Leiden** (commonest; causes resistance to activated protein C), **prothrombin G20210A** gene mutation (raises plasma prothrombin), and the rarer deficiencies of **antithrombin III**, **protein C** and **protein S**; also dysfibrinogenaemia and plasminogen deficiency.
- ▶ **Acquired: antiphospholipid syndrome (APS)** — acquired, predisposes to both venous *and* arterial thrombosis, often warrants lifelong anticoagulation; surgery/trauma, hip-knee arthroplasty, hip fracture, spinal cord injury, immobilisation, prior VTE, advancing age, malignancy, pregnancy and the 6–12-week postpartum period, oestrogen contraceptives/HRT, obesity, nephrotic syndrome, long-haul travel, COPD, CKD, sickle cell disease/trait and cirrhosis.

Type	Examples
Hereditary	Factor V Leiden, prothrombin G20210A, antithrombin/protein C/protein S deficiency
Acquired – surgical	Major thoracic/abdominal/neurosurgery, hip & knee arthroplasty, hip fracture, major trauma, spinal cord injury
Acquired – medical	Cancer, prior VTE, CHF, stroke, nephrotic syndrome, oestrogens, pregnancy/postpartum, obesity, APS, IBD

Pathophysiology

- ▶ **Gas exchange**: arterial **hypoxaemia** (~85% of patients) and a widened **alveolar–arterial O₂ gradient** from V/Q mismatch and shunt; increased **alveolar (physiologic) dead space**; surfactant loss → atelectasis; reflex hyperventilation → **hypocapnia**.
- ▶ **Haemodynamics**: mechanical obstruction plus neurohumoral vasoconstrictors (**serotonin**, **thromboxane A₂**, **endothelin**) raise **pulmonary vascular resistance** and pulmonary artery pressure non-linearly.

- ▶ **The RV-failure cascade (key to mortality):** rising RV wall tension → **RV dilatation and dysfunction** with BNP release → **interventricular septal bowing** into the LV → impaired LV filling → falling cardiac output and systemic pressure → reduced **right coronary perfusion** → RV ischaemia/**microinfarction** (troponin release) → a self-perpetuating spiral to circulatory collapse and death.
- ▶ **Pulmonary infarction** is uncommon (dual bronchial + airway oxygen supply) and, paradoxically, more frequent in young patients without cardiopulmonary disease; it indicates a small, peripheral, pleura-adjacent embolus and is intensely pleuritic.

Classification & Risk Stratification

- ▶ *Hemodynamic effects, not clot burden on imaging, best predict mortality* — even “saddle emboli” are usually hemodynamically stable.

Class	Frequency	Definition	Risk
Massive (high-risk)	5–10%	SBP <90 mmHg (≥ 15 min) / vasopressor / arrest; $\geq \frac{1}{2}$ of pulmonary bed obstructed	High
Submassive (intermediate-risk)	20–25%	Normotensive but RV dysfunction $\pm$ troponin/BNP elevation	Intermediate (may decompensate)
Low-risk	65–75%	Normotensive, no RV dysfunction, normal biomarkers	Excellent prognosis

- ▶ **Simplified PESI (sPESI)** — 1 point each for: **age >80 yr, cancer, chronic cardiopulmonary disease, pulse ≥ 110 /min, SBP <100 mmHg, SaO₂ <90%**. Score 0 = low 30-day mortality (suitable for outpatient therapy); ≥ 1 = high risk. (Full PESI stratifies into classes I–V.)

Clinical Features

- ▶ **DVT:** persisting calf “charley horse”/cramp, unilateral swelling, tenderness, warmth, erythema; classic *Homan’s sign* and *Moses sign* and a “palpable cord” are insensitive and non-specific. Diffuse limb oedema suggests *phlegmasia cerulea dolens*; recurrent left-thigh oedema in young women suggests *May–Thurner syndrome* (right iliac artery compressing left iliac vein); chest-wall collaterals = *Urschel’s sign*.
- ▶ **PE** — **three classic syndromes (PIOPED):** (1) **isolated dyspnoea** (~25%); (2) **pleuritic pain $\pm$ haemoptysis** (~60%, usually small peripheral PE/infarction); (3) **circulatory collapse/syncope** (~10%, massive PE).
- ▶ **Commonest symptom = unexplained dyspnoea; commonest sign = tachypnoea (>20/min);** also tachycardia, accentuated P₂, inspiratory crackles, low-grade fever (rarely >38.3°C), and signs of RV overload (left parasternal heave, raised JVP, S₃/S₄) in massive PE.

Diagnosis (integrated, probability-based)

- **Step 1 – Pretest probability:** Wells score (validated in outpatients) or gestalt; if low/moderate, proceed to D-dimer; if high, skip D-dimer and image directly.

Wells criterion (PE)	Points
Clinical signs/symptoms of DVT	3.0
PE as likely as / more likely than alternative	3.0
Heart rate >100/min	1.5
Immobilisation >3 days / surgery within 4 weeks	1.5
Prior PE or DVT	1.5
Haemoptysis	1.0
Cancer	1.0

(High clinical likelihood if score >4.) The **PERC rule** (age <50, HR <100, SaO₂ ≥95%, no prior VTE, no recent trauma/surgery, no haemoptysis, no oestrogen, no unilateral leg swelling) excludes PE in ED patients already judged low-risk.

- **D-dimer (ELISA):** sensitivity >95% — a normal value **rules out** PE in low/intermediate probability; not specific (raised in MI, sepsis, cancer, pregnancy, post-op), so of little value in hospitalised patients. Use **age-adjusted cut-off** (age × 10 ng/mL FEU) in patients >50 yr.
- **ECG:** sinus tachycardia commonest; **S1Q3T3** (specific, insensitive), **T-wave inversion V1–V4** (RV strain — commonest abnormality), incomplete RBBB, Qr in V1.
- **Chest X-ray** (often near-normal): **Westermarck's sign** (focal oligaemia), **Hampton's hump** (peripheral pleura-based triangular density = infarction), **Palla's sign** (enlarged right descending PA), **Fleischner sign** (prominent central PA).
- **CT pulmonary angiography (CTPA)** — **principal/first-line imaging:** directly visualises emboli to ≤1 mm, gives a four-chamber view (**RV:LV diameter ratio >1** predicts 30-day death) and alternative diagnoses; limited for subsegmental clots and needs iodinated contrast.
- **V/Q scan** — second-line (contrast allergy/renal failure/pregnancy): **normal scan excludes PE;** high-probability scan (≥2 segmental mismatched defects) ~87–90% predictive. **SPECT-V/Q** gives fewer non-diagnostic results.
- **Venous compression ultrasound** — loss of vein compressibility is the key DVT criterion; a positive leg study in suspected PE carries equivalent therapeutic implication.
- **Echocardiography** — not for diagnosis but for **risk stratification:** RV dilatation/hypokinesis, **McConnell's sign** (RV free-wall hypokinesis with apical sparing), reduced TAPSE; also excludes mimics (tamponade, MI, aortic dissection).

Management / Treatment

- ▶ **Anticoagulation is the cornerstone** for all PE; start empirically when suspicion is high and bleeding risk low. **DOACs are first-line** for most patients.

Agent	Regimen
UFH	Bolus 80 U/kg, then 18 U/kg/h; target aPTT 60–80 s (anti-Xa 0.3–0.7 U/mL)
Enoxaparin (LMWH)	1 mg/kg SC 12-hourly (no monitoring unless obese/CKD)
Fondaparinux	Weight-based SC OD; does not cause HIT
Rivaroxaban	15 mg BID × 3 weeks → 20 mg OD (monotherapy)
Apixaban	10 mg BID × 1 week → 5 mg BID (monotherapy)
Dabigatran / Edoxaban	After 5 days parenteral: dabigatran 150 mg BID / edoxaban 60 mg OD
Warfarin	Bridge with parenteral ≥5 days until INR 2.0–3.0 ×2 readings

- ▶ **HIT**: use **argatroban** (hepatic) or **bivalirudin** (renal); fondaparinux is an alternative. **APS and pregnancy** → **not** DOACs (warfarin/LMWH respectively).
- ▶ **Massive (high-risk) PE**: cautious volume (≈500 mL normal saline — over-filling worsens RV strain), **norepinephrine** (pressor of choice) + **dobutamine** (inotrope), and **systemic thrombolysis** — FDA-approved **alteplase 100 mg IV over 2 h** (off-label 50 mg). Major bleeding ~10%, intracranial haemorrhage 2–3%; contraindicated with intracranial disease, recent surgery/trauma, stroke <3 months. **VA-ECMO** for refractory shock.
- ▶ **Submassive (intermediate-risk) PE**: anticoagulate + **monitor closely**; routine thrombolysis is controversial (PEITHO: reduced decompensation but excess major bleeding/ICH, no mortality benefit) — reserve thrombolysis/catheter therapy for clinical deterioration.
- ▶ **Catheter-directed therapy** (pharmacologic, mechanical/suction, or pharmacomechanical/ultrasound-facilitated low-dose lysis) and **surgical embolectomy** — for high-risk PE when thrombolysis fails or is contraindicated.
- ▶ **IVC filter** — only for **active bleeding precluding anticoagulation** or **recurrent VTE despite adequate anticoagulation**; prefer a **retrievable** filter.
- ▶ **Duration (ESC 2019)**: “provoked/unprovoked” terminology de-emphasised; ≥3 months for major transient risk factor; **extended/indefinite** anticoagulation for no identifiable/persistent risk factor, recurrent VTE, active cancer (LMWH or apixaban/edoxaban) or APS, with periodic risk–benefit review.
- ▶ **Long-term sequelae**: post-PE syndrome (persistent dyspnoea/RV dysfunction), postthrombotic syndrome, and **chronic thromboembolic pulmonary hypertension (CTEPH)** in ~2% — treat

with **pulmonary thromboendarterectomy** (mortality 1–5% at expert centres), or balloon pulmonary angioplasty + pulmonary vasodilators if inoperable.

- ▶ **Prevention:** low-dose UFH/LMWH/fondaparinux prophylaxis in at-risk hospitalised and surgical patients; mechanical (IPC/graduated stockings) when anticoagulation is contraindicated.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Integrated diagnostic algorithm** — boxes/arrows: *Suspect PE* → *assess clinical probability (Wells)* → *Low/Moderate: D-dimer (normal = stop; raised = CTPA)* → *High: straight to CTPA* → *CTPA positive = treat; negative = consider V/Q / leg ultrasound*. Labels: **Clinical probability, D-dimer, CTPA, V/Q scan, Venous ultrasound, Risk-stratify (PESI/sPESI, RV function, troponin)**.
- ▶ **Pathophysiology flow-chart of massive PE:** PE → ↑RV afterload → ↑RV wall tension → RV dilatation/dysfunction → septal shift → ↓LV filling → ↓cardiac output/↓systemic BP → ↓RV coronary perfusion → RV ischaemia/microinfarction → circulatory collapse.

Clinical / Diagnostic significance

- ▶ Risk stratification (haemodynamics + sPESI + RV function + troponin) directly determines therapy: low-risk → outpatient anticoagulation; intermediate → admit and monitor; high-risk → reperfusion.
- ▶ A **negative D-dimer** in a low-probability patient safely avoids imaging and radiation; CTPA simultaneously diagnoses PE, assesses RV size, and offers alternative diagnoses.
- ▶ Persisting/initial pulmonary hypertension after PE mandates echocardiographic follow-up at ~6 weeks and 6 months to detect CTEPH, a potentially curable cause of PH.

High-yield exam pointers

- ▶ 90% of PE arise from proximal lower-limb DVT; commonest symptom = dyspnoea, commonest sign = tachypnoea.
- ▶ **Wells score** >4 = high probability → image directly; **age-adjusted D-dimer** = age × 10 ng/mL in >50 yr.
- ▶ CTPA is first-line imaging; **normal V/Q or normal perfusion scan** excludes PE.
- ▶ **S1Q3T3** and **T-inversion V1–V4** on ECG; **McConnell's sign** on echo; **Westermarck/Hampton's hump/Palla's sign** on CXR.
- ▶ **sPESI** = age >80, cancer, cardiopulmonary disease, pulse ≥110, SBP <100, SaO₂ <90% (1 each).
- ▶ **Alteplase 100 mg over 2 h** for massive PE; **norepinephrine + dobutamine** for PE shock; cautious fluids only.
- ▶ **DOACs first-line; warfarin/LMWH (not DOACs)** in APS and pregnancy; HIT → argatroban/bivalirudin.

- ▶ **IVC filter** only if anticoagulation contraindicated or VTE recurs despite it; CTEPH in ~2% → thromboendarterectomy.

Refractory Bronchial Asthma

Asked in: Paper III Jul 2021 — RGUHS MD General Medicine

Definition / Introduction — *Refractory* (severe/difficult-to-treat) asthma is asthma that **remains uncontrolled despite, or requires, the highest-intensity guideline therapy** (GINA Step 4–5: high-dose ICS/LABA ± LAMA) once adherence, inhaler technique, triggers, comorbidities and alternative diagnoses have been optimised. It constitutes only ~5–10% of all asthmatics yet consumes nearly 50% of asthma-related costs and carries the bulk of asthma morbidity and mortality. The modern approach is to first distinguish *true* severe asthma from “difficult-to-treat” asthma, then **phenotype/endotype** the patient (type-2 high vs type-2 low) to target add-on biologic therapy.

Terminology — difficult-to-treat vs severe vs uncontrolled

Term	Definition (ERS/ATS, GINA)
Difficult-to-treat asthma	Uncontrolled despite high-dose ICS + second controller (LABA/LAMA), OR needing this therapy to stay controlled — <i>before</i> modifiable factors are addressed. Chronic OCS dependence is included.
Severe (refractory) asthma	Asthma that remains difficult to treat after correcting adherence, inhaler technique, triggers and comorbidities — i.e. requires GINA Step 4/5 to prevent it becoming uncontrolled, or stays uncontrolled despite this.
Uncontrolled asthma (ERS/ATS — any one of 4)	1. Poor symptom control : ACQ ≥1.5 or ACT ≤19; 2. Frequent severe exacerbations : ≥2 systemic-steroid bursts (≥3 days each) in past year; 3. Serious exacerbation : ≥1 hospitalisation, ICU stay or

Term	Definition (ERS/ATS, GINA)
	mechanical ventilation in past year; 4. Airflow limitation: FEV ₁ <80% predicted (with FEV ₁ /FVC below the lower limit of normal) after withholding bronchodilators.

- ▶ Up to 50% of “poorly controlled” referrals are due to poor adherence or wrong inhaler technique, not truly refractory disease — these must be excluded first.

Step 1 — Confirm the diagnosis and unmask the “fakers”

- ▶ **Re-confirm asthma objectively** — reversible obstruction ($\geq 12\%$ and 200 mL, or the newer $\geq 10\%$ rise in FEV₁ % predicted), peak-flow variability $>20\%$, or airway hyperresponsiveness (methacholine PD₂₀ ≤ 400 μg). $>1/3$ of physician-labelled “asthma” does not meet diagnostic criteria.
- ▶ **Exclude mimics** (overlapping obstructive picture): heart failure, COPD / asthma-COPD overlap, α_1 -antitrypsin deficiency, inducible laryngeal obstruction (vocal-cord dysfunction) — present in up to 75% of asthmatics, diagnosed by truncated/flattened inspiratory flow-volume loop and laryngoscopy showing paradoxical adduction with posterior “chinking”, endobronchial mass/foreign body, bronchiectasis, bronchiolitis obliterans, tracheobronchomalacia.
- ▶ **Identify aggravating comorbidities:** chronic rhinosinusitis $\pm$ nasal polyps, GERD, obesity (blunts steroid response), OSA, anxiety/depression, ongoing smoking and occupational/allergen exposure.
- ▶ **Screen for specific refractory phenotypes:** ABPA (IgE >1000 IU/mL, eosinophils $>500/\mu\text{L}$, positive *Aspergillus* skin test, specific IgE & IgG, central bronchiectasis — treat with itraconazole/voriconazole + OCS) and aspirin-exacerbated respiratory disease (AERD) (asthma + eosinophilia + sinusitis + nasal polyps + COX-1-inhibitor-triggered attacks from leukotriene overproduction).

Step 2 — Phenotype and endotype (the key to refractory asthma)

Type-2 HIGH (eosinophilic/allergic)	Type-2 LOW (non-eosinophilic)
Early-onset allergic asthma; late-onset eosinophilic asthma; AERD; exercise-induced; exacerbation-prone	Obesity-related late-onset; paucigranulocytic (fixed obstruction, little inflammation); neutrophilic; smoking-related
Biomarkers $\uparrow$: blood eos $\geq 300/\mu\text{L}$, sputum eos $>2-3\%$, FeNO $>25-50$ ppb, $\uparrow$ IgE / specific IgE	Biomarkers low/absent; poor steroid response
Responds to ICS and to type-2 biologics	Often steroid-resistant; $\sim 30-50\%$ of asthmatics; consider tiotropium, macrolide (azithromycin 500 mg thrice weekly)

- ▶ FeNO is IL-13-driven: >20–25 ppb on moderate–high ICS in severe asthma indicates persistent type-2 inflammation OR non-adherence (FeNO is steroid-suppressible, so it doubles as an adherence check).
- ▶ Extreme eosinophilia should prompt search for eosinophilic granulomatosis with polyangiitis (EGPA) or hypereosinophilic syndromes.

Step 3 — Pharmacologic escalation (GINA Step 5)

- ▶ **Optimise inhaled therapy: high-dose ICS/LABA** (formoterol-based as both maintenance & reliever — “MART/AIR” strategy), then **add-on LAMA** (tiotropium).
- ▶ **Adjuncts:** leukotriene modifiers (especially in AERD — leukotriene overproduction; and exercise-induced symptoms), **azithromycin** in selected eosinophilic and non-eosinophilic patients.
- ▶ **Chronic OCS** only as a last resort at lowest effective dose (alternate-day if possible) given cumulative toxicity — diabetes, osteoporosis, cataract/glaucoma, hypertension, adrenal suppression; add bone-protection and *Pneumocystis* prophylaxis if ≥ 20 mg prednisone/day chronically.
- ▶ **Bronchial thermoplasty** (radiofrequency ablation of airway smooth muscle over 3 bronchoscopies) — only in trials/registries; sham effect prominent and device now largely withdrawn.

Step 4 — Add-on biologic (“targeted”) therapy for severe type-2 asthma

Biologic	Target / MOA	Selection biomarker	Dose
Omalizumab	Anti-IgE (binds free IgE Cε3 domain)	IgE 30–700 IU/mL + perennial allergen sensitisation	75–375 mg SC every 2–4 wk (by weight & IgE)
Mepolizumab	Anti-IL-5	Blood eos $\geq 150/\mu\text{L}$ (or $\geq 300/\mu\text{L}$ prior yr)	100 mg SC every 4 wk (300 mg for EGPA)
Reslizumab	Anti-IL-5	Blood eos $\geq 400/\mu\text{L}$; age ≥ 18	3 mg/kg IV every 4 wk
Benralizumab	Anti-IL-5Rα (depletes eosinophils)	Blood eos $\geq 300/\mu\text{L}$	30 mg SC $\times 3$ every 4 wk, then every 8 wk
Dupilumab	Anti-IL-4Rα (blocks IL-4 and IL-13)	Blood eos $\geq 300/\mu\text{L}$ or FeNO >25 ppb	200/300 mg SC every 2 wk (caution eos >1500/ μL)
Tezepelumab	Anti-TSLP (upstream epithelial <i>alarmin</i>)	Works even without raised type-2 biomarkers	SC (cuts exacerbations 50–70%)

- ▶ Biologics **reduce exacerbations** by ~50% (tezepelumab up to 70%) and are OCS-sparing (mepolizumab, benralizumab, dupilumab proven; not reslizumab). Mepolizumab, dupilumab and benralizumab also treat coexisting **nasal polyposis**; mepolizumab is the only one approved for EGPA.
- ▶ Assess response at ~4 months: most have a partial response, **10–15% are non-responders** (switch biologic), a few achieve complete response (then wean OCS/ICS, watch for adrenal insufficiency).

Step 5 — Acute severe asthma / status asthmaticus

- ▶ **Recognise impending failure**: silent chest, exhaustion, altered sensorium, and a **normal or rising PaCO₂ in a distressed, tachypnoeic patient** (most present with hypocapnia — normocapnia = danger).
- ▶ **Oxygen** to keep SpO₂ >90%; **high-dose nebulised SABA** (≥3 in first hour, then frequent/continuous) + **ipratropium**; **systemic corticosteroid early** (prednisone 40–60 mg/day or methylprednisolone 1.5–2 mg/kg IV).
- ▶ **IV magnesium sulfate 2 g over 20 min** (40 mg/kg in children, max 2 g) for severe exacerbation (FEV₁ <25% predicted or non-responders).
- ▶ **NIV** in alert, cooperative patients; **heliox** and inhaled volatile anaesthetics (isoflurane/halothane) for refractory bronchospasm.
- ▶ **Mechanical ventilation** if respiratory arrest/impending arrest: **low minute ventilation** (RR 12–14, V_t 6–8 mL/kg), **high inspiratory flow**, **minimal/no PEEP**, **permissive hypercapnia** to avoid dynamic hyperinflation/barotrauma; deep sedation ± short-term paralysis. Avoid sedatives/mucolytics outside ventilation; antibiotics only for proven infection.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Asthmatic vs normal airway cross-section** — label: *epithelial denudation/shedding, basement-membrane (subepithelial collagen) thickening, smooth-muscle hypertrophy & hyperplasia, submucosal oedema, mucus plug/goblet-cell metaplasia, eosinophil/cellular infiltrate, vascular & neuronal proliferation, narrowed lumen.*
- ▶ **Type-2 inflammatory cascade with biologic targets** — label: *allergen/alarmins (TSLP, IL-33, IL-25) → epithelium → ILC2 / Th2 → IL-4, IL-5, IL-13 → IgE, eosinophils, mucus/AHR, with arrows naming omalizumab (IgE), mepolizumab/reslizumab/benralizumab (IL-5/IL-5R), dupilumab (IL-4Ra), tezepelumab (TSLP).*

Clinical / Diagnostic significance

- ▶ A structured “**confirm–exclude–phenotype–target**” pathway converts unselected “difficult” asthma into treatable subgroups and is the single highest-yield concept.

- ▶ **Biomarkers (eos, FeNO, IgE) are predictive, not merely diagnostic** — they select biologic responders and monitor type-2 activity and adherence.
- ▶ **Recognising AERD and ABPA changes management** (leukotriene modifiers/aspirin desensitisation; antifungal + steroid respectively).
- ▶ **In acute care, response to the first hour of therapy predicts need for admission better than presentation severity.**

High-yield exam pointers

- ▶ Severe asthma = GINA Step 4–5; ~5–10% of asthmatics, ~50% of cost.
- ▶ **ERS/ATS uncontrolled = any of:** ACT ≤ 19 /ACQ ≥ 1.5 ; ≥ 2 OCS bursts/yr; ≥ 1 hospitalisation-ICU-ventilation/yr; FEV₁ $< 80\%$ predicted.
- ▶ **First step is always adherence + inhaler technique** (cause in up to 50%).
- ▶ **Type-2 high** (eos ≥ 300 , FeNO ≥ 25 , $\uparrow$ IgE) responds to ICS + biologics; **type-2 low** is steroid-resistant.
- ▶ **6 biologics:** anti-IgE (omalizumab), anti-IL-5/5R (mepolizumab, reslizumab, benralizumab), anti-IL-4R α (dupilumab), anti-TSLP (tezepelumab); **tezepelumab works in biomarker-low disease.**
- ▶ **ABPA:** IgE > 1000 IU/mL + eos > 500 + central bronchiectasis $\rightarrow$ itraconazole + steroid.
- ▶ **AERD:** asthma + nasal polyps + aspirin sensitivity $\rightarrow$ leukotriene modifier / aspirin desensitisation / anti-IL-5 / dupilumab.
- ▶ **Status asthmaticus:** normalising PaCO₂ = impending failure; ventilate with permissive hypercapnia, low rate/V_T, minimal PEEP.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Asthma” (definitions of severe/difficult-to-treat asthma, pathophysiology, type-2/non-type-2 inflammation, biologics incl. tezepelumab, AERD, ABPA, acute attack/status asthmaticus management, high-risk-death features).

- ▶ **CMDT 2026** — “Pulmonary Disorders” (Asthma) (current stepwise/add-on management, IV magnesium indication, acute-exacerbation severity & antibiotic guidance).

Role of Glucocorticoids in Management of Chronic Obstructive Pulmonary Disease

Asked in: Paper III May 2019 — RGUHS MD General Medicine

Definition / Introduction — Chronic obstructive pulmonary disease (COPD) is a common, preventable, treatable disorder characterised by persistent, incompletely reversible airflow limitation arising from chronic airway and systemic inflammation driven by noxious particles/gases (chiefly cigarette smoke and biomass fuel). Because inflammation is central to its pathogenesis, **glucocorticoids** — with their broad anti-inflammatory action — are an attractive intervention. However, the inflammation of COPD is relatively *steroid-resistant*, so glucocorticoids occupy a **selective, eosinophil- and exacerbation-guided** role rather than being universal therapy. Their utility differs sharply by route (inhaled vs systemic) and by setting (stable disease vs acute exacerbation).

Rationale and why COPD is relatively steroid-resistant

- ▶ Airway and systemic inflammation are critical to COPD pathogenesis; glucocorticoids suppress transcription of pro-inflammatory cytokine genes, and **inhaled corticosteroids (ICS)** offer this benefit while minimising systemic exposure.
- ▶ Unlike asthma, COPD inflammation responds **poorly** to steroids. The molecular basis is *oxidative/nitrosative inactivation of histone deacetylase-2 (HDAC-2)* — cigarette-smoke-derived reactive oxygen species and peroxynitrite nitrate and inactivate HDAC-2, the enzyme normally recruited by the glucocorticoid receptor to switch off activated inflammatory genes.
- ▶ Consequently steroid efficacy is blunted; *low-dose theophylline* can partially **restore HDAC-2 activity and steroid responsiveness** (basis for theophylline as an add-on, though limited by its narrow therapeutic window).
- ▶ This explains the cardinal clinical rule: **ICS are never used as monotherapy in COPD** and the response is best in patients with an *eosinophilic/asthma-like* inflammatory signature.

Inhaled corticosteroids (ICS) in stable COPD

- ▶ **Main role = reduction of exacerbations**, especially in those with $FEV_1 \leq 60\%$ predicted and a frequent-exacerbator phenotype; exacerbation reduction (~20–25%) is comparable to that of a LABA or LAMA.
- ▶ Effect on lung function is **modest** — improvement in FEV_1 of only ~50–100 mL, less than achieved with bronchodilators; four large 3–5-year trials failed to show that ICS slow the long-term decline in lung function.
- ▶ **Little symptomatic benefit alone**, so ICS are always combined with a long-acting bronchodilator: ICS + LABA, or as **triple therapy** ICS + LABA + LAMA (single-inhaler triple therapy improves adherence).
- ▶ Landmark trials shaping practice:

- *TORCH* (6112 patients, 3 years; placebo vs fluticasone vs salmeterol vs combination) — fluticasone–salmeterol improved lung function, health status and exacerbations more than either agent alone; a post-hoc analysis suggested a reduced rate of FEV₁ decline.
 - *IMPACT* — triple therapy (ICS/LABA/LAMA) and ICS/LABA reduced **all-cause mortality** versus LABA/LAMA in an on-treatment analysis (strongest signal for an ICS mortality benefit, in fairly severe disease: mean FEV₁ ≈45%, CAT ≈20).
 - *FLAME* — in exacerbators, LABA/LAMA (indacaterol–glycopyrronium) was **superior** to ICS/LABA (fluticasone–salmeterol) for exacerbation reduction (0.98 vs 1.19/year), reinforcing that ICS are not first-line for all exacerbators.
- Common ICS molecules: **fluticasone (propionate/furoate)**, **budesonide**, **mometasone**, **beclomethasone**, combined with LABAs (salmeterol, formoterol, vilanterol).

Eosinophil-guided ICS use and GOLD placement

The blood eosinophil count is the key biomarker predicting ICS benefit and is built into GOLD recommendations.

Blood eosinophil count	Likelihood of ICS benefit	Practical implication
< 100 cells/μL	Low — little/no exacerbation reduction	ICS generally not favoured; consider withdrawal
100–300 cells/μL	Intermediate zone	ICS may be tried and response assessed (add if exacerbations persist on dual bronchodilators)
≥ 300 cells/μL	Greatest likelihood of benefit	ICS supported as part of initial/escalation therapy; ICS withdrawal risks more exacerbations

GOLD (2024) initial pharmacological therapy — ICS placement:

Group	Definition	Recommended start	Role of ICS
A	≤1 exacerbation (no admission); low symptoms (mMRC 0–1 / CAT <10)	A bronchodilator	No
B	≤1 exacerbation; more symptoms (mMRC ≥2 / CAT ≥10)	LABA + LAMA	No
E	≥2 moderate exacerbations or ≥1 leading to hospitalisation	LABA + LAMA	Consider adding ICS if blood eos ≥300

- ▶ On **follow-up**, ICS is **added** to dual bronchodilator therapy if exacerbations persist and eos ≥ 100 ; in stable patients without exacerbations, **ICS withdrawal** may be considered (withdrawal does not increase exacerbations overall but may cause a small fall in FEV₁; de-escalation is riskier if eos ≥ 300).
- ▶ Other favourable factors for ICS: **concomitant asthma/ACO, history of hospitalised exacerbations**.

Systemic (oral) glucocorticoids in stable COPD

- ▶ **Chronic oral glucocorticoids are NOT recommended** for stable COPD because of an unfavourable benefit/risk ratio — and chronic systemic steroid use is associated with **increased mortality**.
- ▶ Tapering patients off chronic low-dose prednisone (~10 mg/day) does **not** worsen exacerbation frequency, quality of life or lung function — supporting withdrawal.
- ▶ A rare exception: in exacerbation-prone patients requiring repeated high-dose courses, the *lowest possible* maintenance dose may occasionally reduce total annual steroid exposure, but this is discouraged.

Glucocorticoids in acute exacerbations of COPD (AECOPD)

This is the **strongest, evidence-based indication** for glucocorticoids in COPD.

- ▶ **Benefits in hospitalised exacerbations:** shorten length of stay, **hasten recovery** (faster improvement in FEV₁ and oxygenation), and **reduce the chance of relapse / subsequent exacerbation**.
- ▶ **Regimen:**
 - *Harrison 22e / GOLD:* **prednisone 40 mg orally (or equivalent) once daily for 5 days** — a short course is as effective as longer courses (REDUCE-trial principle).
 - *CMDT 2026:* **prednisone ~0.5 mg/kg/day orally for 7–10 days** in hospitalised patients, with even 5 days often adequate.
 - Oral and IV routes are equivalent in most patients; IV methylprednisolone is reserved for those unable to take oral or critically ill.
- ▶ **Key acute complication: hyperglycaemia**, most frequent in patients with pre-existing diabetes — requires glucose monitoring.
- ▶ Combined with the rest of AECOPD therapy: short-acting bronchodilators (SABA $\pm$ SAMA), **antibiotics** (for increased sputum purulence/volume + dyspnoea, typically 5–7 days), controlled **oxygen** (target SpO₂ 88–92%) and NIV for respiratory acidosis (PaCO₂ >45 mmHg, pH ≤ 7.35).

Adverse effects of glucocorticoids in COPD

Inhaled corticosteroids (ICS)	Systemic / oral glucocorticoids
Oral/oropharyngeal candidiasis (thrush)	Hyperglycaemia / glucose intolerance (commonest acute AE)
Dysphonia (hoarseness)	Osteoporosis and fractures
Pneumonia (increased incidence, esp. severe COPD)	Weight gain, fluid retention, cushingoid features
Easy bruising / skin capillary fragility	Cataracts, glaucoma
Reduced bone density, cataracts (with prolonged use)	Increased risk of infection ; myopathy; HPA-axis suppression; increased mortality with chronic use

Mitigation: spacer use, mouth rinsing/gargling after ICS, lowest effective dose, ICS withdrawal when stable, and short steroid courses for exacerbations.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **GOLD 2024 ABE initial-therapy + eosinophil decision tree (showing where glucocorticoids fit).** Labels: *Groups A / B / E; Group A → a bronchodilator; Group B → LABA + LAMA; Group E → LABA + LAMA, consider + ICS if eos ≥ 300 ; eosinophil ladder boxes — <100 (no ICS), $100-300$ (intermediate, trial ICS), ≥ 300 (ICS favoured); arrows for escalation (add ICS) and de-escalation (withdraw ICS).*
- ▶ **HDAC-2 mechanism of steroid resistance.** Labels: *cigarette smoke → oxidative/nitrosative stress (ROS, peroxynitrite) → inactivation/nitration of HDAC-2 → failure to switch off pro-inflammatory genes → relative steroid resistance; side-arrow theophylline → restores HDAC-2 activity.*

Clinical / Diagnostic significance

- ▶ **Phenotype-directed therapy:** measure the **blood eosinophil count** before committing a patient to long-term ICS — it predicts who benefits and limits unnecessary pneumonia/steroid risk.
- ▶ ICS reduce exacerbations but do **not** alter the relentless FEV₁ decline or (mostly) mortality — set patient expectations accordingly.
- ▶ **Pneumonia vigilance:** in a patient on ICS who develops recurrent pneumonia, consider ICS de-escalation, especially if eos <100 .
- ▶ For an **acute exacerbation**, give a short systemic steroid course early — it is one of the few interventions that shortens admission and prevents relapse; monitor capillary glucose.
- ▶ Avoid **chronic oral steroids** for stable COPD; if a patient is steroid-dependent, attempt a structured taper.

High-yield exam pointers

- ▶ Glucocorticoid role in COPD is **selective**, NOT universal — driven by **exacerbation risk + blood eosinophils**.
- ▶ **ICS are never used as monotherapy** — always with LABA ($\pm$ LAMA = triple therapy).
- ▶ ICS **reduce exacerbations** (~20–25%) but give only ~50–100 mL FEV₁ gain and do not slow lung-function decline.
- ▶ **Eosinophil thresholds**: <100 = **no benefit**; ≥ 300 = **favour ICS**; 100–300 = trial and assess.
- ▶ Key ICS adverse effects: **oral candidiasis, dysphonia, pneumonia**, reduced bone density, cataracts.
- ▶ **Chronic oral glucocorticoids are NOT recommended** (unfavourable risk/benefit; increased mortality).
- ▶ **AECOPD**: prednisone **40 mg/day $\times$ 5 days** (GOLD/Harrison) or **0.5 mg/kg/day $\times$ 7–10 days** (CMDT) — shortens stay, hastens recovery, cuts relapse; **hyperglycaemia** is the commonest acute complication.
- ▶ Trials to quote: **TORCH** (fluticasone–salmeterol), **IMPACT** (triple therapy $\rightarrow$ lower all-cause mortality), **FLAME** (LABA/LAMA > ICS/LABA in exacerbators).
- ▶ Mechanism of steroid resistance = **oxidative inactivation of HDAC-2**; theophylline restores it.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Chronic Obstructive Pulmonary Disease” (inhaled and oral glucocorticoids in stable disease, eosinophil-guided ICS, GOLD ABE initial therapy, systemic glucocorticoids in exacerbations — prednisone 40 mg $\times$ 5 days).
- ▶ **Murray & Nadel's Textbook of Respiratory Medicine, 7e** — “COPD: Diagnosis and Management” (ICS efficacy/FEV₁ 50–100 mL, ~20–25% exacerbation reduction, TORCH/IMPACT/FLAME, eosinophil thresholds, adverse effects, chronic systemic steroids and mortality) and “COPD: Pathogenesis and Natural History” (HDAC-2 inactivation and steroid resistance; theophylline restoring HDAC-2).
- ▶ **CMDT 2026** — “Pulmonary Disorders / COPD” (judicious ICS in severe COPD with frequent exacerbations / eos ≥ 300 / concomitant asthma; ICS withdrawal after 2 years stable; oral corticosteroids not for long-term use; hospitalised exacerbation prednisone 0.5 mg/kg/day for 7–10 days).

Sarcoidosis

Asked in: Paper III Jun 2024 · Paper III Nov 2022 (2 $\times$) — RGUHS MD General Medicine

Definition / Introduction — Sarcoidosis is a multisystem inflammatory disease of unknown aetiology characterised by the formation of **nonnecrotizing (noncaseating) epithelioid-cell granulomas** in affected organs. It involves the **lung and intrathoracic lymph nodes in >90%** of cases but can afflict almost any organ. It is presumed to result from an **exaggerated TH1 immune response to an undetermined antigen in a genetically susceptible host**. The skin lesions were first described by *Jonathan Hutchinson* (lupus pernio, Mortimer's malady) and termed "*sarkoid*" by *Caesar Boeck* (1899) because they resembled sarcoma yet were benign. Course is highly variable — spontaneous remission in just over half, chronic organ-threatening disease in the rest.

Epidemiology & Etiopathogenesis

- ▶ **Incidence/prevalence:** highest in **African Americans (~35.5/100,000)** and **Northern Europeans/Swedes (~24/100,000)**; US Black Women's Health Study noted prevalence ~2%. Female preponderance (ratio usually <2:1). **Peak age 35–45 years**, though a significant proportion present after 55.
- ▶ **Risk factors:** familial clustering, certain occupational/environmental exposures (firefighters; post-9/11 World Trade Center responders had markedly raised "sarcoid-like" disease), mould/musty environments, raised BMI. *Smoking is consistently associated with reduced odds (negative predictor)*.
- ▶ **Putative antigens:** mycobacterial proteins (*mKatG*, *ESAT-6*, *superoxide dismutase A*, *antigen 85A*, *heat-shock proteins*) and *Cutibacterium (Propionibacterium) acnes*; transmissibility supported by the historical **Kveim–Siltzbach reagent** (splenic homogenate inducing granulomas) and donor-derived sarcoid-like disease in transplant recipients.
- ▶ **Genetics:** HLA class II haplotypes determine acute vs chronic phenotype; risk/prognosis variants include **BTNL2 (butyrophilin-like 2)**, **TNF- α** and **ANXA11 (annexin A11)**.
- ▶ **Pathogenesis:** poorly degradable antigen presented by macrophages/dendritic cells via **MHC** to **CD4⁺ T cells** → **highly polarized TH1 response** (IFN- γ , IL-2, IL-12/15/18, CXCR3) → activated macrophages aggregate into tightly formed granulomas. Dysregulated **T-regulatory and TH17** responses underlie failure of resolution and progression to fibrosis.

Clinical Features & Organ Involvement

- ▶ **Constitutional:** fever, malaise, night sweats, weight loss, multifactorial fatigue (up to 80%).
- ▶ **Acute syndromes (excellent prognosis, often spontaneous remission ~80%):**
 - **Löfgren syndrome** — *fever + erythema nodosum + bilateral hilar lymphadenopathy + ankle arthritis/peri-arthralgia*; common in Northern Europeans (20–30% of Caucasians), rare in Asians/African Americans.
 - **Heerfordt (uveoparotid fever) syndrome** — *anterior uveitis + parotid enlargement + fever + facial (VII) nerve palsy*. Both are clinically diagnostic and may obviate biopsy.

Organ	Approx. frequency	Key features
Lungs/thoracic nodes	~95%	Upper-lobe predominant; perilymphatic nodules, BHL; restriction ± obstruction
Skin	~16%	Erythema nodosum (non-granulomatous); lupus pernio (chronic, poor prognosis)
Peripheral lymph nodes	~15%	Discrete, mobile, nontender
Eyes	~12%	Uveitis (commonest), optic neuropathy (vision-threatening)
Liver	~12%	Granulomas common; ↑alkaline phosphatase; usually subclinical
Spleen	~7%	Splenomegaly, usually silent
Nervous system	~5%	Cranial neuropathy (VII, optic), basal meningitis, hypothalamic-pituitary dysfunction, small-fibre neuropathy
Salivary/parotid	~4%	Heerfordt; Sjögren-like
Heart	~2% clinical	AV block, VT, cardiomyopathy, sudden death
Kidney	~1%	Interstitial nephritis; nephrocalcinosis from hypercalciuria

- ▶ **Hypercalcaemia (10–20%) / hypercalciuria (up to 50%)**: unregulated **1- α -hydroxylase** (CYP27B1) activity in macrophages converts vitamin D to **calcitriol (1,25-(OH) $_2$ D $_3$)** *despite suppressed PTH* → ↑gut absorption + bone resorption → nephrocalcinosis.
- ▶ **Cardiac sarcoidosis**: ventricular tachycardia is the commonest arrhythmia; **sudden cardiac death is the commonest cause of death** in cardiac involvement and may be the presenting event.
- ▶ **Pulmonary hypertension**: a **WHO Group 5** cause; consider when symptoms/desaturation are disproportionate to parenchymal disease or DLCO is low.

Diagnosis & Investigations

- ▶ **Three diagnostic criteria** (the diagnosis is never absolutely secure): (1) **compatible clinical/radiological picture**, (2) **histological nonnecrotizing granuloma** in ≥1 tissue, and (3) **exclusion of alternative causes** (TB/atypical mycobacteria, fungi, berylliosis, hypersensitivity pneumonitis, lymphoma, IgG4-RD, vasculitis, drug/checkpoint-inhibitor reactions).
- ▶ **Biopsy**: least-invasive accessible site (skin, conjunctiva, peripheral node). For mediastinal/hilar disease, **EBUS-guided TBNA** has high yield with low risk; **transbronchial lung biopsy** yield

~75–90%. Airway granulomas give a *cobblestone* mucosa. Surgical biopsy/mediastinoscopy reserved for nondiagnostic cases.

- ▶ **Histology:** tightly formed granuloma of epithelioid cells + **multinucleated giant cells**, rimmed by lymphocytes/fibroblasts; CD4⁺ cells central, CD8⁺/B cells peripheral. Inclusions: **asteroid bodies**, **Schaumann bodies**, **Hamazaki-Wesenberg bodies**, birefringent calcium oxalate/carbonate crystals (all non-specific).
- ▶ **BAL:** lymphocytosis with **CD4:CD8 ratio** >3.5 supports the diagnosis (specificity ~95% in some series); a normal ratio does not exclude it. Also excludes infection.
- ▶ **Baseline workup (all patients):** history/examination, PFTs, **chest imaging**, **ophthalmologic exam** (silent uveitis), ECG, serum creatinine, alkaline phosphatase, **calcium**, CBC, and 25-/1,25-vitamin D.
- ▶ **Chest radiograph — Scadding stages** (predict resolution, *not* activity):

Stage	Radiographic finding	Spontaneous resolution
0	Normal chest X-ray	—
I	Bilateral hilar lymphadenopathy alone	55–90%
II	BHL + parenchymal infiltrates	40–70%
III	Parenchymal infiltrates without BHL	10–20%
IV	Pulmonary fibrosis, volume loss, architectural distortion	~0%

- ▶ **HRCT:** perilymphatic micronodules along bronchovascular bundles and subpleural surfaces, beaded interlobular septa, mediastinal/hilar nodes; advanced → honeycombing, traction bronchiectasis, cavitation.
- ▶ **Cardiac:** ECG screening in all; **cardiac MRI with late gadolinium enhancement is the preferred test** (FDG-PET if MRI unavailable/contraindicated), largely replacing endomyocardial biopsy (low sensitivity owing to patchy involvement); perfusion shows *reverse redistribution*.
- ▶ **Serum markers:** **ACE** (from epithelioid cells) is *neither sensitive nor specific* — roughly tracks granuloma burden, not diagnostic; soluble IL-2 receptor correlates with activity/relapse. Hypercalcaemia, ↑ESR and ↑alkaline phosphatase are supportive.

Treatment

- ▶ **Principle:** there is **no cure**; aim is to suppress granulomatous inflammation, prevent irreversible fibrosis and relieve symptoms. **Treat only when indicated** — asymptomatic Stage I and mild disease are observed (high spontaneous remission). Treat for significant/progressive pulmonary impairment or dangerous extrapulmonary disease (cardiac, neuro, ocular/vision-threatening, symptomatic hypercalcaemia, disfiguring skin).

Line	Agent(s)	Dose / note
First-line	Oral corticosteroids (prednisone/prednisolone)	0.5 mg/kg/day or ~20–40 mg/day × 4 wk, taper to maintenance <10 mg/day; SARCORT (India) — 20 mg ≈ 40 mg starting dose
Second-line (steroid-sparing)	Methotrexate (most recommended)	7.5–20 mg/week + folic acid; monitor LFT/CBC; avoid in alcohol use
	Azathioprine / Leflunomide / Mycophenolate	alternatives; azathioprine has higher infection/malignancy risk
	Hydroxychloroquine	200–400 mg/day — useful for skin & hypercalcaemia, not pulmonary
Refractory / steroid-dependent	Infliximab (TNF- α mAb, best evidence) / Adalimumab	screen for TB first; avoid in heart failure
Ineffective	Etanercept	TNF-receptor antagonist — <i>not effective, do not use</i>
Topical/local	Inhaled or injected/topical steroids	mild airway cough, skin lesions

- **Refractory** = failure to respond to the equivalent of **prednisone 40 mg/day**. **Duration ~1 year** (shorter courses → higher relapse). Bisphosphonates to prevent steroid-induced osteoporosis; periodic eye exams on steroids/hydroxychloroquine. **Organ transplantation** (lung/heart/liver/kidney) for end-stage disease; granulomas may recur in the graft but rarely cause graft failure.
- **Supportive / parasarcoidosis syndromes**: fatigue, small-fibre neuropathy, pain, depression and cognitive impairment often respond poorly to immunosuppression — manage with exercise training, sleep/pain/neuropsychiatric care.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- **Immunopathogenesis schematic**: Unknown antigen → APC/macrophage with MHC → TCR on CD4⁺ T cell (activated) → TH1 response (IFN- γ , IL-2) with TH17 → noncaseating granuloma → branch to Resolution vs Fibrosis (modulated by Treg). Labels: *Unknown antigen, MHC, TCR, CD4⁺ T cell, TH1, TH17, Treg, Granuloma, Resolution, Fibrosis*.
- **Sarcoid granuloma vs comparators**: (A) Sarcoidosis — tightly formed, nonnecrotizing; (B) Tuberculosis/fungal — tight with caseous necrotic centre; (C) Hypersensitivity pneumonitis — loosely formed, non-necrotizing. Label central **epithelioid** +

multinucleated giant cells, peripheral lymphocyte rim, and inclusions (asteroid / Schaumann bodies).

Clinical / Diagnostic significance

- ▶ A diagnosis of **exclusion** — always rule out TB (critical in India) and lymphoma before labelling; necrosis on biopsy argues strongly against sarcoidosis.
- ▶ Every patient needs **baseline ophthalmology, ECG, calcium and PFTs** because silent uveitis, conduction disease and hypercalcaemia are organ/sight/life-threatening.
- ▶ **Scadding stage predicts resolution rate, not disease activity** — do not use it alone to decide treatment.
- ▶ **Pulmonary fibrosis is the leading cause of sarcoid death** (Western populations); **cardiac involvement predominates as cause of death in Japanese patients**.
- ▶ Steroid-sparing agents should be introduced early when prolonged (>1 year) therapy is anticipated to limit cumulative steroid toxicity.

High-yield exam pointers

- ▶ **Noncaseating granuloma + lung/intrathoracic nodes in >90%**; histology of **exclusion**.
- ▶ **Löfgren** = EN + BHL + ankle arthritis + fever (good prognosis); **Heerfordt** = uveoparotid fever + VII palsy.
- ▶ BAL CD4:CD8 > 3.5; EBUS-TBNA preferred for mediastinal nodes; TBLB yield 75–90%.
- ▶ **Scadding stages I–IV**: I 55–90%, II 40–70%, III 10–20%, IV ~0% resolution.
- ▶ **Hypercalcaemia** from macrophage 1- α -hydroxylase → **calcitriol with low PTH**.
- ▶ **ACE is neither sensitive nor specific** — for activity monitoring, not diagnosis.
- ▶ **Cardiac MRI (LGE)** preferred for cardiac sarcoid; VT commonest arrhythmia, **sudden death** commonest cardiac death.
- ▶ **First-line steroids**; methotrexate second-line; **infliximab** refractory; **etanercept** ineffective.
- ▶ Poor-prognosis markers: **lupus pernio, chronic uveitis, neuro/cardiac involvement, chronic hypercalcaemia/nephrocalcinosis, pulmonary hypertension, fibrotic (Stage IV) disease, African origin**.
- ▶ **Smoking is protective**; PH in sarcoidosis is **WHO Group 5**.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Sarcoidosis” (Gerke; immunopathogenesis, organ involvement frequencies, Scadding staging with resolution rates, hypercalcaemia mechanism, treatment table including doses, prognosis).

- **Murray & Nadel's Textbook of Respiratory Medicine, 7e** — “Sarcoidosis” (Scadding patterns, HRCT perilymphatic distribution, serum ACE from epithelioid cells, BAL CD4:CD8 specificity, Löfgren/Heerfordt definitions, refractory = failure of prednisone 40 mg/day, corticosteroid-sparing rationale, parasarcoidosis syndromes).
- **CMDT 2026** — “Sarcoidosis” (**Pulmonary Disorders**) (essentials, staging, transbronchial-biopsy yield, prednisone 0.5–1.0 mg/kg/day, SARCORT 20 vs 40 mg trial, cardiac MRI over PET, prognosis figures).

Screening Tools, Etiology and Treatment of Obstructive Sleep Apnea

Asked in: Paper III 15 Apr 2026 — RGUHS MD General Medicine

Definition / Introduction — Obstructive sleep apnea (OSA) is a sleep-related breathing disorder characterised by recurrent episodes of complete (apnea) or partial (hypopnea) collapse of the pharyngeal airway during sleep, producing intermittent hypoxemia, hypercapnia, large intrathoracic pressure swings and cortical arousals. Diagnosis requires either symptoms of disturbed nocturnal breathing (snoring, gasping, witnessed pauses) or unexplained daytime sleepiness **plus** ≥ 5 obstructive apneas/hypopneas per hour of sleep (the **apnea–hypopnea index, AHI**) on a sleep study; OSA may also be diagnosed *asymptotically* if $\text{AHI} \geq 15$. It is the commonest medical cause of daytime sleepiness, affects 5–15% of middle-aged and $>20\%$ of elderly adults (largely undiagnosed), and is a major driver of hypertension and cardiovascular disease.

Screening tools for OSA

Because symptoms and signs poorly predict disease severity, validated questionnaires are used to *risk-stratify* patients and decide who needs objective sleep testing (they screen, they do not diagnose).

- **STOP-BANG questionnaire** — the most widely used screen in both medical and surgical (pre-operative) populations. It combines **three symptoms** (Snoring, Tiredness, Observed apnea) with **five clinical characteristics** (high blood Pressure, BMI, Age, Neck circumference, male Gender). Each “yes” scores 1 (range 0–8). A higher score escalates probability of moderate–severe OSA (conventionally: 0–2 low risk; 3–4 intermediate; 5–8 high risk). Specificity can be improved by adding pulse oximetry, **serum bicarbonate**, or body shape (apple vs pear).

Letter	Item	Threshold
S	Snoring (loud)	Louder than talking / heard through door
T	Tiredness / daytime sleepiness	Most days

Letter	Item	Threshold
O	Observed apnea	Witnessed pauses
P	Pressure (hypertension)	Treated or untreated
B	BMI	>35 kg/m ²
A	Age	>50 years
N	Neck circumference	>40 cm
G	Gender	Male

- ▶ **Epworth Sleepiness Scale (ESS)** — quantifies *subjective daytime sleepiness* across 8 everyday situations, each rated 0–3 (total 0–24); a score >10 indicates excessive daytime sleepiness. Useful to track symptom response to therapy but does not correlate tightly with AHI.
- ▶ **Berlin Questionnaire** — three categories (snoring/witnessed apnea, daytime sleepiness/fatigue, and hypertension or obesity); patients positive in ≥2 categories are “high risk.”
- ▶ **Other instruments** — *Sleep Apnea Clinical Questionnaire*, *Pittsburgh Sleep Quality Index (PSQI)* for overall sleep quality, *Insomnia Severity Index (ISI)*, and the *Functional Outcomes of Sleep Questionnaire*. Validation in patients with coexisting pulmonary disease (e.g., COPD) is limited.
- ▶ **Confirmatory testing follows a positive screen** — overnight in-laboratory polysomnography (PSG) is the gold standard; **home sleep apnea testing (HSAT)** is a cost-effective alternative when pre-test probability is moderate–high and there is no significant cardiorespiratory comorbidity. A negative home study with high prior probability should be followed by PSG. Overnight oximetry alone is insufficient to diagnose OSA.

Etiology and risk factors

OSA arises when an **anatomically collapsible pharynx** (no bony/cartilaginous support) loses the stabilising tone of the pharyngeal dilator muscles at sleep onset; non-anatomic (“endotypic”) traits modulate this. The major risk factors are **obesity, male sex and older age**.

Category	Specific factors
Obesity (40–60% attributable)	Upper-airway fat narrowing the lumen; reduced lung volume → loss of caudal tracheal traction; reduced chest-wall compliance. <i>10% weight gain → >30% rise in AHI; ≥4-fold OSA risk vs lean</i>
Soft-tissue crowding	Macroglossia, enlarged tonsils/adenoids (chief cause in children 3–8 yr), bulky uvula, low-lying/long soft palate, increased lymphoid tissue
Craniofacial / skeletal	Mandibular retrognathia, micrognathia, mandibular retroposition, small posterior airway space, high-arched palate (most evident in non-obese patients)

Category	Specific factors
Nasal obstruction	Septal deviation, polyps, turbinate hypertrophy, allergic rhinitis ($\uparrow$ nasal resistance $\rightarrow$ mouth opening, tongue falls back)
Ventilatory-control instability (non-anatomic endotypes)	High loop gain (oversensitive CO ₂ response), low arousal threshold, poor pharyngeal muscle responsiveness
Demographic / genetic	Male sex (2 $\times$; android obesity, longer pharynx), older age, post-menopausal women, strong heritability (1st-degree relative $\rightarrow$ $\sim$ 2 $\times$ risk), East-Asian craniofacial predisposition, higher risk in African Americans
Genetic syndromes	Down syndrome, Treacher-Collins syndrome
Endocrine / metabolic	Acromegaly, hypothyroidism; associations with diabetes, PCOS
Comorbid / provocative	Hypertension, heart failure, atrial fibrillation; alcohol within 3 h of sleep, sedative-hypnotics and opiates ($\downarrow$ pharyngeal tone); supine posture and REM sleep worsen events

Diagnosis and severity grading

- ▶ **Respiratory events** — *Apnea*: ≥ 10 s cessation of airflow with persistent effort (obstructive). *Hypopnea*: $\geq 30\%$ airflow reduction for ≥ 10 s with $\geq 3\%$ desaturation **or** an arousal. *RERA*: increased inspiratory effort terminating in arousal without meeting hypopnea criteria.
- ▶ **Indices** — AHI = apneas + hypopneas per hour of sleep; RDI additionally includes RERAs.
- ▶ **Severity (AHI)** — **Mild** 5–14/h; **Moderate** 15–29/h; **Severe** ≥ 30 /h. Hypoxemic burden, event duration, sleep fragmentation and degree of sleepiness further characterise severity.
- ▶ A “non-dipping” nocturnal blood-pressure pattern, secondary erythrocytosis and a screening TSH (to exclude hypothyroidism) are typical supportive findings.

Treatment options

Management is comprehensive and individualised; therapies are *not mutually exclusive* and combination/switching is common. Objective sleep testing should precede treatment.

- ▶ **Behavioural / risk-factor modification** (foundation in all patients) — weight loss (markedly effective, including after bariatric surgery); optimise sleep duration (7–9 h) and regular schedule; **avoid supine sleep**; treat nasal allergy; increase physical activity; **eliminate alcohol within 3 h of bedtime**; minimise opiates; avoid sedative-hypnotics in moderate–severe OSA; counsel against drowsy driving.

- ▶ **Positive airway pressure (PAP)** — CPAP is the standard first-line therapy with the highest level of evidence; it acts as a pneumatic splint maintaining pharyngeal patency. **Auto-titrating CPAP (APAP, 5–20 cmH₂O)** removes the need for an in-lab titration in many patients; **BPAP** helps those who cannot exhale against pressure. Adherence is variable (~50–80%; only ~75% continue at 1 year) and is improved by a skilled team managing side effects (nasal congestion → heated humidification/saline; claustrophobia → mask change; aerophagia → antacids).
- ▶ **Oral appliances (mandibular advancement devices)** — advance the mandible and pull the tongue forward; reduce AHI by ≥50% in two-thirds of patients; best for **mild–moderate OSA or CPAP intolerance**; side effects: temporomandibular joint pain, tooth movement (need adequate dentition).
- ▶ **Positional therapy** — vibrotactile devices for **supine-predominant OSA** can cut AHI by up to 50%.
- ▶ **Upper-airway surgery** — less effective than CPAP, reserved for snorers, mild OSA, or CPAP failure. **Uvulopalatopharyngoplasty (UPPP)** is the commonest (helps ~50%, better for snoring than apnea); often combined as **multilevel surgery**; **maxillomandibular advancement** for skeletal deficiency; nasal septoplasty for anatomical deformity. **Bariatric surgery** benefits the obese. **Tracheostomy** is the definitive bypass but has major morbidity.
- ▶ **Hypoglossal nerve (upper-airway) stimulation** — implanted device for **moderate–severe OSA** (AHI 15–65, up to 100), BMI <35 (FDA <40), absence of complete concentric collapse at the velum on drug-induced sleep endoscopy, and <25% central events; for CPAP-intolerant/failed patients; durable benefit ≥5 years; also approved for children ≥13 yr and Down syndrome (AHI 10–50).
- ▶ **Pharmacotherapy** — *no agent is yet FDA-approved as primary therapy*. **GLP-1 / dual GLP-1–GIP receptor agonists** (tirzepatide ~16–17% weight loss with AHI reduction; liraglutide smaller effect) and **SGLT-2 inhibitors** are under investigation; noradrenergic–antimuscarinic combinations are in phase-3 trials. **Wake-promoting agents** (e.g., **modafinil, solriamfetol**) treat *residual* sleepiness despite adequate CPAP. **Supplemental oxygen is not routine** (may prolong apneas).
- ▶ **Treat secondary/contributory disease** — hypothyroidism, acromegaly, heart failure; optimise comorbid hypertension and atrial fibrillation.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Sagittal upper-airway diagram** (Fig 308-1): mid-sagittal pharynx showing the sites of collapse — label **Palate** (soft palate, most common), **Tongue base**, **Lateral pharyngeal walls**, **Epiglottis**, with the **nasopharynx**, **oropharynx**, **hypopharynx** and CPAP/mandibular-advancement effect arrows.

- ▶ **Polysomnography tracing of an obstructive event (Fig 308-2):** stacked channels labelled EEG, EOG, chin EMG, ECG, snore, nasal-pressure airflow, thermistor flow, chest, abdomen, SaO₂ — show **flat airflow with persistent chest–abdomen paradox** (effort against an occluded airway) terminating in an **arousal + SaO₂ desaturation**.

Clinical / Diagnostic significance

- ▶ **Cardiometabolic burden:** OSA causes/aggravates **resistant and nocturnal (non-dipping) hypertension**, coronary artery disease, heart failure (HFrEF and HFpEF), atrial and ventricular arrhythmias, stroke, insulin resistance/diabetes and a pro-thrombotic, pro-inflammatory state; CPAP lowers 24-h BP (modestly, ~2–4 mmHg, more in sleepy/resistant patients).
- ▶ **Neurobehavioural:** excessive daytime sleepiness, impaired concentration, mood disturbance, and a 2–3× increase in motor-vehicle and occupational accidents — relevant to driving fitness certification.
- ▶ **Screen high-risk groups:** resistant hypertension, type 2 diabetes, atrial fibrillation, heart failure, pre-operative patients, and professional drivers.
- ▶ Note **sex differences** — women report fatigue/insomnia rather than classic sleepiness and have REM-predominant, shorter apneas, causing under-recognition.

High-yield exam pointers

- ▶ **STOP-BANG** = Snoring, Tiredness, Observed apnea, Pressure (HTN), BMI >35, Age >50, Neck >40 cm, Gender male; score ≥3 = increased OSA risk.
- ▶ **Diagnostic AHI ≥5 with symptoms, or ≥15 without;** gold standard = **polysomnography**.
- ▶ **Severity:** Mild 5–14, Moderate 15–29, **Severe ≥30 events/h**.
- ▶ **Hypopnea** = ≥30% airflow drop ≥10 s with ≥3% desaturation or arousal.
- ▶ **Obesity accounts for 40–60% of OSA; 10% weight gain → >30% rise in AHI.**
- ▶ Commonest collapse site = **soft palate**; commonest paediatric cause = **adenotonsillar hypertrophy**.
- ▶ **CPAP = first-line / highest evidence;** oral appliance for mild–moderate or CPAP intolerance; hypoglossal nerve stimulation for CPAP-failure (AHI 15–65, BMI <35, no concentric velar collapse).
- ▶ **No FDA-approved drug;** GLP-1/GIP agonists (tirzepatide) reduce weight and AHI; modafinil/solriamfetol for residual sleepiness only.
- ▶ OSA is a recognised cause of **secondary and resistant hypertension** (a “non-dipping” BP pattern).

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Sleep Apnea” (definition, AHI/severity tables, pathophysiology, risk factors/etiology, CPAP and surgical/neurostimulation therapy, pharmacotherapy); “Disorders of Sleep” (screening, Epworth) and “Disorders of Ventilation” (STOP-Bang reference).
- ▶ **Murray & Nadel's Textbook of Respiratory Medicine, 7e** — “Sleep-Disordered Breathing: A General Approach” (STOP-Bang, Berlin, ESS, PSQI screening pathway; PSG vs HSAT), “Obstructive Sleep Apnea,” and “Sleep-Disordered Breathing: Treatment” (PAP modes, oral appliances, positional, surgical and pharmacologic options).
- ▶ **CMDT 2026** — “Pulmonary Disorders / Sleep Apnea” (clinical features, diagnostic AHI thresholds, treatment including hypoglossal nerve stimulation eligibility, UPPP, tracheostomy, GLP-1/GIP weight-loss therapy).

Coverage note: The Epworth (>10/24) and STOP-BANG numerical risk bands and item thresholds (BMI >35, age >50, neck >40 cm) are standard, universally accepted sleep-medicine values stated to complete the screening tools; the corpus confirms the eight STOP-BANG components, the Berlin/ESS/PSQI instruments and all AHI/severity, etiology and treatment specifics quoted above.

Silicosis

Asked in: Paper IV Nov 2022 · Paper IV May 2022 (2×) — RGUHS MD General Medicine

Definition / Introduction — **Silicosis** is a fibrotic interstitial lung disease (a **pneumoconiosis**) caused by inhalation of **free crystalline silica (SiO₂)**, principally as **quartz**. It is one of the oldest known occupational lung hazards and remains a major cause of disease worldwide. Pulmonary fibrosis due to silica characteristically develops in a **dose-response fashion**, usually after many years of exposure, though intense exposure can cause fulminant disease within months. The hallmark lesion is the **upper-zone silicotic nodule**, which may coalesce into **progressive massive fibrosis (PMF)**.

Etiology, sources and pathogenesis

- ▶ **Hazardous agent:** free silica (SiO₂), i.e., **crystalline quartz**. Risk relates to the *free silica content* of the inhaled dust.
- ▶ **Respirable particle size:** only particles <10 µm deposit below the larynx; **coarse-mode** (2.5–10 µm) crustal particles such as silica deposit relatively high in the tracheobronchial tree. Particles >10–15 µm are filtered in the nose/throat.
- ▶ **Major occupational exposures:** mining; stone-cutting; sand-blasting; glass and cement manufacturing; foundry work; packing of silica flour; quarrying (particularly granite).

- ▶ **Recent outbreaks / emerging high-risk work:** sand-blasting of denim jeans to make them look “used,” and the manufacture and installation of artificial (“faux granite”/engineered quartz) stone kitchen countertops — a cause of acute silicosis in young workers.
- ▶ **Pathogenesis (source-grounded):** inhaled silica is ingested by **alveolar macrophages**; silica is directly cytotoxic and causes **alveolar macrophage dysfunction**. Silica also has **immunoadjuvant properties**, driving a fibrogenic and autoimmune-prone inflammatory response that produces the characteristic nodular fibrosis. The fibrosis may be **progressive even after exposure ceases**.
- ▶ **Dose–response and cumulative dose:** the probability and severity of fibrosis rise with **intensity × duration** of respirable-silica exposure; this explains why most chronic disease follows years of work while intense confined-space exposure can cause disease within months.
- ▶ **Macrophage defence is impaired**, leaving the silicotic lung vulnerable to intracellular pathogens — a single mechanism that links silicosis to both **tuberculosis** and the autoimmune/carcinogenic complications below.

Clinical–radiological types

Type	Exposure / latency	Key features
Acute silicosis (<i>silicoproteinosis</i>)	Very heavy exposure (sand-blasting in confined spaces , tunnelling rock of 15–25% quartz , artificial-stone work) — symptoms within months	Clinical & pathological features resemble pulmonary alveolar proteinosis ; rapidly progressive; severe even after exposure stops
Accelerated silicosis	Heavy exposure over ~5–10 years (standard textbook category)	Features intermediate between acute and chronic; faster progression to PMF
Chronic simple silicosis	Long-term, less intense exposure — opacities after 15–20 years	Small rounded opacities, upper lobes ; usually without functional impairment ; “eggshell” hilar node calcification in up to 20%
Complicated silicosis / PMF	Coalescence of nodules (may progress <i>without</i> further exposure)	Non-segmental conglomerate masses >1 cm in upper zones; significant restrictive + obstructive impairment

- ▶ **Acute silicosis imaging:** chest radiograph may show **profuse miliary infiltration or consolidation**; HRCT shows a “**crazy-paving**” pattern (ground-glass with thickened intralobular/interlobular septa producing polygonal shapes).
- ▶ **Complicated silicosis:** silicotic nodules coalesce into **irregular conglomerate masses >1 cm**; when these become large the term **progressive massive fibrosis (PMF)** is applied.

Investigations and radiology

- ▶ **Chest radiograph (ILO classification):** the International Labour Organisation (ILO) International Classification of Radiographs of Pneumoconioses grades opacities; **small rounded opacities** are typical of silicosis (and coal-worker's pneumoconiosis), contrasting with the **small linear/irregular opacities** of asbestosis. Useful for epidemiology/screening but limited in the individual worker.
- ▶ **HRCT:** more sensitive than plain film for detecting **silicotic nodules** and the **crazy-paving** pattern of acute disease; nodules are often **subpleural** and **upper-zone predominant**.
- ▶ **"Eggshell" calcification** of hilar lymph nodes is a classic supportive sign (up to ~20% of cases).
- ▶ **Pulmonary function tests:** often normal in **simple** silicosis; PMF produces **mixed restrictive and obstructive** deficits with reduced diffusing capacity.
- ▶ **Occupational history** is central — quantify type, intensity and duration of exposure; combine work history with any environmental sampling data to estimate cumulative exposure.

Complications and associations

- ▶ **Tuberculosis (silicotuberculosis):** because silica causes **alveolar macrophage dysfunction**, patients are at **increased risk of active TB** and other intracellular pathogens (*Mycobacterium tuberculosis*, atypical mycobacteria, fungi). Because of this risk, **treatment of latent TB** is given for a longer duration in silicotic patients.
- ▶ **Autoimmune connective-tissue disease:** silica's **immunoadjuvant** effect predisposes to rheumatoid arthritis and scleroderma.
- ▶ **Caplan syndrome:** combination of **pneumoconiotic nodules** and **seropositive rheumatoid arthritis** — first described in coal miners but subsequently recognised in silicosis.
- ▶ **Lung cancer:** the International Agency for Research on Cancer (IARC) lists silica as a **probable lung carcinogen**.
- ▶ **COPD / chronic airflow obstruction** may accompany dust exposure.
- ▶ **Related silicate/inorganic-dust exposures** to consider: fuller's earth, kaolin, mica, diatomaceous earths, silica gel, soapstone, carbonate and cement dusts; **talc** and **vermiculite** may be contaminated with asbestos (risk of fibrosis, lung cancer, mesothelioma).

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Diagram 1 — Chest radiograph of chronic/complicated silicosis (frontal view).** Labels: *upper-zone small rounded nodules; "eggshell" calcification of hilar lymph nodes; conglomerate mass = progressive massive fibrosis (PMF); relatively spared lower zones; retracted hila.*
- ▶ **Diagram 2 — Pathogenesis flow.** Labels: *Inhaled crystalline silica (respirable, $<10\ \mu\text{m}$) → Alveolar macrophage ingestion → Macrophage cytotoxicity / dysfunction + immunoadjuvant effect → Release of inflammatory & fibrogenic mediators → Silicotic nodule formation →*

Fibrosis → coalescence → PMF; side-branches to ↑ TB risk, autoimmune disease (RA, scleroderma), probable lung carcinogen.

Clinical / Diagnostic significance

- ▶ **Diagnosis** rests on a triad of **compatible occupational exposure history**, **characteristic chest imaging** (upper-zone rounded nodules ± eggshell nodal calcification ± PMF on radiograph/HRCT), and **exclusion of mimics** (especially TB and sarcoidosis). Lung biopsy is rarely needed and is reserved for atypical presentations.
- ▶ **Differential diagnosis:** **pulmonary tuberculosis** (always exclude active disease before attributing upper-zone change to silicosis), **sarcoidosis** (bilateral hilar adenopathy, granulomas), **coal-worker's pneumoconiosis** and **chronic beryllium disease** (sarcoid-like, occupational), and for acute silicosis, **pulmonary alveolar proteinosis** (which it mimics clinically, radiologically and pathologically).
- ▶ **No specific curative therapy** exists; management is **supportive**, as for any diffuse interstitial lung disease — exposure cessation, smoking cessation, oxygen and pulmonary rehabilitation, and vaccination.
- ▶ **Whole-lung lavage** may provide **symptomatic relief and slow progression** in **acute silicosis** (mirroring its role in alveolar proteinosis).
- ▶ **Active TB surveillance** and **prolonged treatment of latent TB infection** are essential because of the markedly raised tuberculosis risk.
- ▶ **Prevention is paramount:** dust control (wet methods, enclosure, ventilation), substitution, respiratory protection, periodic chest imaging/PFT surveillance, and regulatory exposure limits — protection has improved in developed countries but risk persists in developing-country and engineered-stone settings.

High-yield exam pointers

- ▶ Causative agent = **free crystalline silica (SiO₂)/quartz**; only **respirable (<10 µm)** particles cause disease.
- ▶ **Upper-zone** small rounded nodules + “**eggshell**” **hilar nodal calcification** = classic silicosis radiology.
- ▶ **Acute silicosis** = **silicoproteinosis** — resembles **pulmonary alveolar proteinosis**, HRCT “**crazy paving**,” treat with **whole-lung lavage**; seen in **artificial-stone/quartz countertop** workers and **denim sand-blasting**.
- ▶ **Simple → complicated → PMF**: PMF = conglomerate masses >1 cm; may progress **even after exposure stops**.
- ▶ **Silicotuberculosis** — high active-TB risk; give **longer latent-TB treatment**.

- ▶ **Caplan syndrome** = pneumoconiotic nodules + **seropositive rheumatoid arthritis**.
- ▶ Silica is a **probable lung carcinogen (IARC)** and predisposes to **scleroderma & RA**.
- ▶ High-quartz tunnelling = **15–25% quartz**; tunnelling/sand-blasting in **confined spaces** → acute disease in **months**.

SOURCE & COVERAGE

Harrison's Principles of Internal Medicine, 22e — Ch 300 "Occupational and Environmental Lung Disease" (silicosis section, particle-deposition and ILO-classification sections, Table 300-1; Caplan syndrome cross-ref Ch 370). **Coverage note:** the chapter explicitly describes *acute, simple chronic* and *complicated/PMF* silicosis; the intermediate "**accelerated silicosis**" category and the generic **supportive-care/prevention** measures (smoking cessation, vaccination, dust control, surveillance) are universally accepted standard internal medicine added for completeness and are not verbatim subtypes in the provided text. Detailed molecular pathogenesis (e.g., NALP3/inflammasome) is beyond the provided chapter and is therefore not asserted.

Systemic manifestation of COPD

Asked in: Paper III Nov 2021 — RGUHS MD General Medicine

Definition / Introduction — Chronic obstructive pulmonary disease (COPD) is a disease state characterised by **persistent respiratory symptoms and airflow obstruction**, and encompasses *emphysema* (alveolar destruction with air-space enlargement), *chronic bronchitis* (chronic cough and phlegm) and *small airway disease*. Although defined by spirometric airflow limitation, COPD is now recognised as a **multi-system disorder**: a low-grade systemic inflammatory "spill-over" together with chronic hypoxaemia, physical inactivity and shared smoking-related risk drives extrapulmonary effects and **comorbidities** that independently determine symptoms, exacerbations, quality of life and mortality. Harrison explicitly directs the clinician to seek symptoms of common comorbidities — **cardiovascular disease, gastro-oesophageal reflux, osteoporosis, frailty, depression and anxiety** — in every COPD patient.

Why COPD becomes a systemic disease (mechanistic basis)

- ▶ **Systemic inflammation / cytokine spill-over** — the airway inflammatory process is mirrored by raised circulating inflammatory cytokines, notably **tumour necrosis factor- α (TNF- α)**, which mediate wasting and contribute to several extrapulmonary effects.
- ▶ **Chronic hypoxaemia** — develops as airflow obstruction worsens; drives secondary **erythrocytosis (elevated haematocrit)**, pulmonary vasoconstriction/pulmonary hypertension and cor pulmonale, and signals the need for long-term oxygen.

- ▶ **Autoimmune component** — lymphoid follicles of B and T cells, TH1/TH17 activation and autoantibodies against elastin fragments and pulmonary epithelium perpetuate chronic inflammation even after smoking cessation.
- ▶ **Deconditioning & shared exposure** — dyspnoea-limited inactivity plus the common risk factor of tobacco smoke link COPD with cardiovascular disease, lung cancer, osteoporosis and metabolic disturbance.

Systemic manifestations & comorbidities — at a glance

System	Manifestation	Mechanism / note (Harrison)
Nutritional	Cachexia, weight loss, loss of subcutaneous fat	Inadequate intake + raised cytokines (TNF- α); independent poor prognostic factor
Musculoskeletal	Skeletal-muscle dysfunction, accessory-muscle use, reduced exercise capacity	Deconditioning, hyperinflation; quantified by 6-min walk
Skeletal	Osteoporosis	Listed comorbidity; aggravated by inhaled/oral glucocorticoids
Cardiovascular	Cardiovascular disease; cor pulmonale / RV failure, pulmonary hypertension	Hypoxaemia + pulmonary vascular destruction
Haematological	Secondary polycythaemia (raised haematocrit)	Chronic hypoxaemia; <i>anemia of chronic disease may coexist</i> (see Coverage note)
Neuropsychiatric	Depression, anxiety, frailty	Common, under-recognised comorbidities
GI / Metabolic	GERD; glucose intolerance, weight gain	GERD a comorbidity; metabolic effects largely steroid-related
Neoplastic	Lung cancer	Smokers with COPD at high risk; new clubbing must prompt work-up
Thrombotic	Pulmonary embolism	Incidence increased during exacerbations

Nutritional & musculoskeletal manifestations

- ▶ **Cachexia** is a feature of advanced disease — *significant weight loss with diffuse loss of subcutaneous adipose tissue*. It is linked to both **inadequate oral intake** and **elevated inflammatory cytokines** (e.g., TNF- α).
- ▶ Such **wasting** is an **independent poor prognostic factor** in COPD — i.e., it predicts mortality over and above the degree of airflow obstruction.

- ▶ **Body mass index (BMI)** is therefore embedded in the **BODE index** (Body mass index, airflow Obstruction, Dyspnoea, Exercise capacity), a multifactorial tool that predicts mortality better than FEV₁ alone.
- ▶ **Skeletal-muscle dysfunction & deconditioning** — patients use accessory muscles (sternocleidomastoid, scalene, intercostals) and adopt the “tripod” position; exercise capacity is reduced and is quantified by the distance walked in 6 minutes.
- ▶ **Osteoporosis** is a listed comorbidity and is compounded by therapy: **inhaled corticosteroids** are associated with loss of bone density (and cataracts, oropharyngeal candidiasis, pneumonia), and **chronic oral glucocorticoids** cause osteoporosis, weight gain, cataracts, glucose intolerance and increased infection risk — hence chronic oral steroids are *not recommended*.

Cardiovascular & pulmonary-vascular manifestations

- ▶ **Cardiovascular disease** is among the most important comorbidities to screen for in the history.
- ▶ **Cor pulmonale** — signs of overt **right heart failure** (raised JVP, lower-extremity oedema). Pulmonary arterial hypertension severe enough to cause cor pulmonale and **right ventricular failure** typically occurs with FEV₁ <25 % predicted and chronic hypoxaemia (PaO₂ <55 mmHg).
- ▶ Some patients develop significant **pulmonary arterial hypertension from pulmonary vascular destruction, independent of COPD severity**.
- ▶ Cor pulmonale has become *relatively infrequent since supplemental oxygen therapy* became available, but pulmonary hypertension must be considered in any patient with persistent activity limitation or lower-extremity oedema.
- ▶ **Right ventricular hypertrophy** signs and an **elevated haematocrit** are clues to chronic hypoxaemia.

Haematological, neuropsychiatric, neoplastic & other systemic effects

- ▶ **Secondary polycythaemia / erythrocytosis** — an **elevated haematocrit** suggests chronic hypoxaemia; erythrocytosis is itself one of the qualifying signs (with pulmonary arterial hypertension or right heart failure) that lowers the oxygen-saturation threshold for long-term O₂ to ≤89 % (≤88 % otherwise).
- ▶ **Central cyanosis** — visible in the lips and nail beds, reflecting hypoxaemia.
- ▶ **Lung cancer** — smokers with COPD are at high risk; annual **low-dose chest CT** screening reduces lung-cancer mortality. **Clubbing is NOT a feature of COPD** — its appearance must trigger a search for another cause, most often **lung cancer**.
- ▶ **Depression, anxiety and frailty** — frequent neuropsychiatric/whole-patient comorbidities that should be actively elicited.
- ▶ **Gastro-oesophageal reflux disease (GERD)** — a recognised comorbidity and a contributor to exacerbations.

- ▶ **Metabolic** — glucose intolerance and weight gain occur chiefly as adverse effects of glucocorticoid therapy.
- ▶ **Venous thromboembolism** — the incidence of **pulmonary embolism** is increased during **COPD exacerbations**, and PE should be considered when an exacerbation is atypical or refractory.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **“Spokes-of-a-wheel” / systemic-effects schematic** — central hub labelled **“COPD: airflow obstruction + systemic inflammation (TNF- α) + chronic hypoxaemia”**, with labelled spokes: *Cachexia / weight loss, Skeletal-muscle dysfunction, Osteoporosis, Cardiovascular disease, Cor pulmonale / pulmonary hypertension, Secondary polycythaemia, Depression / anxiety / frailty, GERD, Lung cancer, Pulmonary embolism (exacerbations)*.
- ▶ **BODE index box** — four labelled components: **B** = Body-mass index, **O** = airflow Obstruction (FEV_1 % predicted), **D** = Dyspnoea (mMRC scale), **E** = Exercise capacity (6-minute walk distance); arrow to *“predicts mortality better than FEV_1 alone.”*

Clinical / Diagnostic significance

- ▶ **Assess every COPD patient for comorbidities** — cardiovascular disease, GERD, osteoporosis, frailty, depression and anxiety — because they drive symptoms, hospitalisation and death independent of lung function.
- ▶ **Nutritional assessment** (BMI/weight trend) and **6-minute walk distance** feed the **BODE index** for prognostication.
- ▶ **Elevated haematocrit / RV-hypertrophy signs / erythrocytosis** prompt evaluation for chronic hypoxaemia and may qualify the patient for **long-term oxygen therapy** (resting $SpO_2 \leq 88\%$, or $\leq 89\%$ with pulmonary arterial hypertension, right heart failure or erythrocytosis) — the only intervention other than smoking cessation, LVRS and transplant shown to improve survival in hypoxaemic patients.
- ▶ **New digital clubbing** → **investigate for lung cancer**; offer annual **low-dose CT** screening to eligible smokers with COPD.
- ▶ **Minimise glucocorticoid burden** (avoid chronic oral steroids; monitor bone density with ICS) to limit osteoporosis, cataracts and dysglycaemia.
- ▶ **Consider pulmonary embolism** in exacerbations that do not fit the usual pattern.

High-yield exam pointers

- ▶ **Cachexia/wasting = independent poor prognostic factor**, mediated by TNF- α — a favourite one-liner.
- ▶ **BODE index** = BMI + airflow Obstruction + Dyspnoea + Exercise capacity; better mortality predictor than FEV_1 .

- ▶ **Cor pulmonale/RV failure** appears at FEV₁ <25 % predicted and PaO₂ <55 mmHg; PAH can also be hypoxaemia-independent (vascular destruction).
- ▶ **Clubbing** is NOT due to COPD — its presence means look for **lung cancer**.
- ▶ **Raised haematocrit (erythrocytosis)** = marker of chronic hypoxaemia; one of the O₂-therapy qualifying signs (threshold ≤89 %).
- ▶ Listed comorbidities to recite: **cardiovascular disease, GERD, osteoporosis, frailty, depression, anxiety**.
- ▶ **Steroid-related systemic harms**: osteoporosis, weight gain, cataracts, glucose intolerance, infection (oral); bone-density loss, candidiasis, pneumonia (inhaled).
- ▶ **PE incidence is increased during exacerbations**.

SOURCE & COVERAGE

Harrison's Principles of Internal Medicine, 22e (2025) — Ch 303 "Chronic Obstructive Pulmonary Disease" (physical examination, laboratory findings, comorbidities, pharmacotherapy and exacerbations sections).

Coverage note: The provided chapter explicitly describes cachexia, cardiovascular disease, cor pulmonale/pulmonary hypertension, osteoporosis, secondary polycythaemia (elevated haematocrit/erythrocytosis), depression/anxiety/frailty, GERD, lung cancer and exacerbation-related PE. It does **not** describe **anaemia of chronic disease** as a COPD comorbidity (it discusses the opposite — polycythaemia); anaemia is listed here as a GOLD-recognised, universally accepted comorbidity and flagged as outside this Harrison chapter. The mMRC dyspnoea scale and standard SpO₂ figure (88 %) are referenced as universally accepted; specific BODE thresholds beyond its four components are not detailed in the chapter.

Interstitial Lung Disease Associated with Connective Tissue Disorders (CTD-ILD): Spectrum, Therapy and Complications

Asked in: Paper III May 2025 — RGUHS MD General Medicine

Definition / Introduction — Connective-tissue-disease-associated interstitial lung disease (CTD-ILD) is a heterogeneous group of diffuse parenchymal lung diseases occurring as an extra-articular/systemic manifestation of an autoimmune rheumatic disorder, in which inflammation and fibrosis remodel the alveolar–interstitial unit. ILD is a leading cause of morbidity and mortality across the connective tissue diseases (CTDs) and may **precede, accompany, or be the sole presenting feature** of the underlying CTD. It occurs most commonly in **systemic sclerosis (SSc), rheumatoid arthritis (RA), and polymyositis/dermatomyositis (PM/DM)**, and less frequently in **Sjögren syndrome (SS), systemic lupus erythematosus (SLE) and mixed connective tissue disease (MCTD)**. Compared with idiopathic

interstitial pneumonia, CTD-ILD patients are typically younger, female and non-smokers, and—stage for stage—carry a better prognosis than idiopathic pulmonary fibrosis (IPF).

Connective tissue diseases that cause ILD — prevalence and dominant pattern

CTD	Prevalence of ILD	Commonest radiologic/histologic pattern (others)	Key associations
Systemic sclerosis (SSc)	40–75% clinically significant; up to 65–70% on HRCT (~50% diffuse, ~30% limited)	NSIP (UIP)	Anti-topoisomerase-I (Scl-70) → ILD risk; anti-centromere → protective, PAH
Rheumatoid arthritis (RA)	Clinically evident ~10%; HRCT abnormalities 30–60%	UIP (NSIP, OP, LIP)	Male, smokers, high RF/anti-CCP, MUC5B variant
PM/DM (inflammatory myopathy)	ILD up to 32–45% (highest with anti-synthetase antibodies)	NSIP ± OP (UIP, DAD)	Anti-synthetase syndrome (Jo-1); anti-MDA5 → rapidly progressive
Sjögren syndrome (SS)	Clinically significant 8–27%; HRCT up to 30%	NSIP (often fibrotic) (LIP, UIP, OP)	Must exclude pulmonary lymphoma (risk ↑40–50×)
Systemic lupus (SLE)	Chronic diffuse ILD 1–15% (3–11%)	NSIP (LIP, OP, UIP)	Acute lupus pneumonitis & DAH distinct entities
MCTD	Pleuropulmonary 20–85%	NSIP (UIP)	Anti-U1-RNP defines disease

Histopathological and HRCT patterns in CTD-ILD

- ▶ **Nonspecific interstitial pneumonia (NSIP)** — the *overall most frequent* pattern: bilateral, symmetric, subpleural ground-glass opacity and reticulation with traction bronchiectasis, often peribronchovascular; relative *subpleural sparing*; honeycombing uncommon. Cellular NSIP responds better than fibrotic NSIP.
- ▶ **Usual interstitial pneumonia (UIP)** — second commonest and *the dominant pattern in RA*: subpleural, basal honeycombing, reticulation and traction bronchiectasis indistinguishable from IPF; in RA shows **fewer fibroblastic foci, more germinal centres**.
- ▶ **Organizing pneumonia (OP)** — patchy migratory subpleural consolidation (reversed-halo/atoll sign); strongly linked to PM/DM and RA; steroid-responsive.
- ▶ **Lymphocytic interstitial pneumonia (LIP)** — diffuse peribronchiolar lymphocytic infiltrate; classically Sjögren syndrome.

- ▶ **Diffuse alveolar damage (DAD)** — substrate of acute pneumonitis/acute exacerbation; seen in anti-MDA5/Jo-1 myositis, acute lupus pneumonitis.
- ▶ *Radiologic clues to an underlying CTD*: multi-compartment disease (dilated air-filled oesophagus, pleural/pericardial involvement, pulmonary artery enlargement), extensive subpleural sparing, and exuberant honeycombing being relatively rare.

Disease-specific features and serology

- ▶ **SSc** — ILD is the commonest pulmonary manifestation and a *leading cause of SSc death*. Velcro basal crackles, dry cough, exertional dyspnoea; clubbing rare. FVC may fall by up to 30%/year in the **first 3–5 years**. Risk factors: male sex, African ancestry, diffuse cutaneous disease, severe GERD/microaspiration, anti-Scl-70. **Pulmonary arterial hypertension (PAH)** may coexist or occur in isolation (commoner in limited SSc/CREST, anti-centromere) — an isolated/disproportionate fall in DLCO or rising FVC/DLCO ratio is the screening alert.
- ▶ **RA** — UIP-predominant; *male and smoker* predominance unlike articular RA. Spectrum is wide: ILD, OP, **obliterative (constrictive) bronchiolitis**, follicular bronchiolitis, bronchiectasis, rheumatoid nodules ($\pm$ **Caplan syndrome** with pneumoconiosis), pleural disease (exudate, low glucose, low pH). **Methotrexate pneumonitis** is an important mimic.
- ▶ **PM/DM** — **Anti-synthetase syndrome**: anti-tRNA-synthetase antibody (commonest **anti-Jo-1**) + myositis, ILD, arthritis, fever, Raynaud's and *mechanic's hands*. Anti-Jo-1 and especially **anti-MDA5** (often clinically amyopathic DM) predict rapidly progressive, DAD-type ILD. Low/normal CK does not exclude severe ILD. Screen for occult malignancy.
- ▶ **SLE** — ILD itself uncommon; the dangerous entities are **acute lupus pneumonitis** (DAD, >50% mortality), **diffuse alveolar haemorrhage (DAH)**, **shrinking lung syndrome** (restrictive defect with raised hemidiaphragms, diaphragmatic dysfunction), pleuritis (commonest manifestation) and PAH.
- ▶ **Sjögren** — fibrotic NSIP and LIP; xerotrachea, small-airway disease/bronchiolitis; always exclude **pulmonary lymphoma**.
- ▶ **Antibody panel**: ANA, RF and anti-CCP in all suspected cases; targeted ENA (Scl-70, anti-centromere, SSA/Ro, SSB/La, U1-RNP, Sm) and myositis antibodies (Jo-1, PL-7, PL-12, EJ, OJ, MDA-5) in selected cases; **repeat serology**, as seroconversion is common.

Diagnostic approach and severity staging

- ▶ **Multidisciplinary diagnosis** (pulmonologist, rheumatologist, radiologist, pathologist) integrating clinical features, serology, **HRCT**, and **PFTs** — no single test is diagnostic.
- ▶ **PFT**: restrictive defect — reduced TLC, FVC and DLCO with preserved/raised FEV1/FVC; **DLCO is the most sensitive early marker** and a disproportionate isolated fall suggests pulmonary vascular disease.

- ▶ **HRCT** is standard of care; surgical/transbronchial biopsy is rarely needed because histologic pattern seldom alters management or prognosis in CTD (RA-UIP is the main exception). BAL is mainly to exclude infection/haemorrhage.
- ▶ **UKRSA (Goh–Wells) staging** for SSc-ILD: **limited disease** if HRCT extent <20% (or, when indeterminate, FVC ≥70%) vs **extensive disease** if HRCT >20% (or FVC <70%) — extensive disease predicts progression and death and identifies who to treat.

Therapy

- ▶ **General principles:** Not all CTD-ILD needs treatment; *stabilisation*, not reversal, is the realistic goal in fibrotic disease. Decision to treat weighs ILD severity (extent on HRCT, FVC/DLCO), rate of progression, CTD subtype, age and comorbidity. Treat early, during the highest-risk first few years.
- ▶ **Immunosuppression (first-line for inflammatory/cellular disease):**
 - **Mycophenolate mofetil (MMF)** 1–3 g/day — now preferred first-line for SSc-ILD (Scleroderma Lung Study II: equivalent efficacy to cyclophosphamide with better tolerability).
 - **Cyclophosphamide** — oral 2 mg/kg/day or IV pulses (750–1000 mg/m² monthly) for 6–12 months; modest benefit on FVC/skin (Scleroderma Lung Study), significant toxicity (cystitis, marrow suppression, malignancy, gonadal failure) — reserve for severe/progressive disease.
 - **Azathioprine** (≤2.5 mg/kg/day, max 200 mg) and **calcineurin inhibitors** (ciclosporin, tacrolimus) as alternatives/steroid-sparing, especially in myositis-ILD.
 - **Glucocorticoids** (prednisolone) — mainstay for cellular NSIP, OP, acute pneumonitis, DAH and myositis-ILD; **use with caution/avoid high dose in SSc** (precipitates scleroderma renal crisis) and in UIP-pattern disease.
- ▶ **Biologics:** **Tocilizumab** (anti-IL-6R) slows FVC decline in early SSc-ILD (focuSSced/FaSSciate); **Rituximab** (anti-CD20) for refractory/rapidly progressive disease, most effective in myositis-ILD and anti-synthetase syndrome; abatacept used in RA-ILD.
- ▶ **Antifibrotic therapy:** **Nintedanib** (tyrosine-kinase inhibitor) 150 mg bid is approved for SSc-ILD (SENSCIS: FVC decline reduced by 41 mL/yr, ~44% relative, additive to MMF) and for **progressive pulmonary fibrosis** of any CTD (INBUILD); **pirfenidone** under study (RA-ILD/unclassifiable).
- ▶ **Adjunctive/supportive:** high-dose **proton-pump inhibitors** / **anti-reflux** measures in SSc (microaspiration drives fibrosis); pulmonary rehabilitation; supplemental **oxygen**; vaccination; *Pneumocystis* prophylaxis when heavily immunosuppressed.
- ▶ **Advanced disease:** **Autologous haematopoietic stem cell transplantation (HSCT)** for selected early, rapidly progressive SSc at risk of organ failure (ASTIS, SCOT trials — improved event-free/overall survival). **Lung transplantation** for end-stage disease unresponsive to therapy,

provided extrapulmonary activity and major oesophageal dysfunction are absent. **PAH-specific therapy** (endothelin antagonists e.g. bosentan, PDE-5 inhibitors e.g. sildenafil, riociguat, selexipag, prostacyclins) when pulmonary vascular disease is present.

Complications

- ▶ **Progressive pulmonary fibrosis** → chronic respiratory failure, the major cause of death in SSc-ILD and RA-ILD.
- ▶ **Acute exacerbation** (new DAD) — abrupt dyspnoea, fresh ground-glass on HRCT without infection; commonest/most severe in RA, very high mortality.
- ▶ **Pulmonary hypertension / cor pulmonale** — from fibrosis-hypoxia (Group 3) or pulmonary vascular disease (Group 1 PAH, esp. SSc, MCTD, SLE).
- ▶ **Diffuse alveolar haemorrhage and acute pneumonitis** — life-threatening in SLE and myositis.
- ▶ **Therapy-related:** drug-induced pneumonitis (methotrexate, anti-TNF, leflunomide), opportunistic infection, scleroderma renal crisis from steroids, malignancy from cyclophosphamide.
- ▶ **Increased risk of lung cancer** (SSc, RA) and **pulmonary lymphoma** (Sjögren).

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Diagram 1 — HRCT/histology patterns of CTD-ILD (panel):** label *UIP* (subpleural-basal honeycombing + traction bronchiectasis), *NSIP* (symmetric ground-glass + reticulation, subpleural sparing), *OP* (patchy migratory subpleural consolidation / reversed-halo sign), *LIP* (peribronchiolar cysts), and *dilated oesophagus* (SSc clue).
- ▶ **Diagram 2 — SSc-ILD screening/treatment algorithm:** boxes labelled *New SSc diagnosis* → *screening HRCT + PFT (FVC, DLCO)* → *No ILD / Limited ILD (FVC ≥70%, HRCT <20%)* / *Extensive ILD (FVC <70%, HRCT >20%)* → *Monitor PFT 3–6 monthly* → *Progression?* → *First-line MMF/cyclophosphamide* → *Add nintedanib* → *Rescue: HSCT, lung transplant, palliative care* (UKRSA staging arm shown).

Clinical / Diagnostic significance

- ▶ ILD may be the **first clue to an occult CTD** — any “idiopathic” NSIP demands a full autoimmune work-up; ~15% of apparent idiopathic interstitial pneumonia (30% of idiopathic NSIP) prove to be CTD.
- ▶ **IPAF (Interstitial Pneumonia with Autoimmune Features)** — ATS/ERS construct for ILD with autoimmune features (≥1 feature from ≥2 of clinical, serologic, morphologic domains) that does not meet full CTD criteria; a provisional, evolving entity.
- ▶ Distinguishing CTD-ILD from IPF is essential: it changes prognosis (generally better) and treatment direction (immunosuppression helps CTD but **harms IPF**). Serial **FVC and DLCO** monitoring guides therapy; FVC decline predicts mortality.

- ▶ Screen every new SSc patient for ILD and for PAH (baseline + annual echocardiography/DLCO).

High-yield exam pointers

- ▶ ILD is commonest in SSc > RA > PM/DM, less in SS, SLE, MCTD.
- ▶ NSIP is the overall commonest pattern; UIP predominates in RA (worse prognosis than NSIP).
- ▶ Anti-Scl-70 → SSc-ILD; anti-centromere → protective/PAH; anti-Jo-1 → anti-synthetase syndrome; anti-MDA5 → rapidly progressive DM-ILD.
- ▶ MMF is first-line; nintedanib (antifibrotic) for SSc-ILD & progressive fibrosis; avoid/limit steroids in SSc (renal crisis) and in UIP.
- ▶ DLCO is the most sensitive PFT abnormality; isolated low DLCO → think PAH.
- ▶ SSc-ILD: FVC can fall ~30%/year in the first 3–5 years — *treat early*.
- ▶ RA pulmonary spectrum beyond ILD: obliterative bronchiolitis, nodules, **Caplan syndrome**, pleural exudate (low glucose, low pH).
- ▶ SLE emergencies: acute lupus pneumonitis, DAH, shrinking lung syndrome; Sjögren → LIP & lymphoma risk.
- ▶ UKRSA (Goh) staging: HRCT >20% or FVC <70% = extensive disease = treat.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Interstitial Lung Disease” (ILD associated with connective tissue disease: SSc, RA, dermatomyositis/polymyositis) and “Systemic Sclerosis (Scleroderma) and Related Disorders” (pulmonary features, PAH, treatment algorithm Fig. 372-15).
- ▶ **Murray & Nadel's Textbook of Respiratory Medicine, 7e** — “Connective Tissue Diseases” (Corte & Wells): prevalence/pattern table, disease-specific sections, autoantibody and drug tables, UKRSA staging, IPAF criteria.
- ▶ **CMDT 2026** — “Pulmonary Disorders” (interstitial lung disease, differential and management) and “Rheumatologic, Immunologic & Allergic Disorders” for current drug regimens.

Spirometry — Physiological Principle, Indications and Interpretation

Asked in: Paper I 06 Apr 2026 — RGUHS MD General Medicine

Definition / Introduction — Spirometry is the most widely used pulmonary function test; it records the volume and rate (flow) of air that a subject can inhale and exhale as a function of time during standardised breathing manoeuvres. The two cardinal manoeuvres are the slow vital-capacity (VC) manoeuvre (lung-volume sub-divisions) and the forced vital-capacity (FVC) manoeuvre (dynamic

airflow), displayed as a **volume–time spirogram** and a **flow–volume loop**. It is *effort-dependent*, requiring patient cooperation and trained technique, and is the foundation for diagnosing and grading **obstructive** and **restrictive** ventilatory defects.

Physiological principle

- ▶ The lung behaves as **three coupled mechanical components** — lung (with airways), neuromuscular pump, and chest wall. Inspiratory muscles lower pleural and alveolar pressure below airway-opening pressure to drive **inflation**; expiratory muscles (and elastic recoil) raise alveolar pressure to drive **deflation**.
- ▶ During a forced expiration from **total lung capacity (TLC)** to **residual volume (RV)**, airflow becomes **flow-limited**: beyond an initial effort-dependent spike, expiratory flow at any given lung volume reaches a maximum that **cannot be increased by greater effort** (the *effort-independent* portion). This is the basis of the reproducible FVC manoeuvre.
- ▶ Flow limitation arises from **dynamic airway compression**: as gas accelerates toward the mouth, intraluminal pressure and airway transmural pressure fall (**Bernoulli effect**), collapsing the compliant bronchi. Maximal expiratory flow at any volume is set by **gas density, airway calibre/distensibility, lung elastic recoil pressure, and frictional resistance** to the flow-limiting site.
- ▶ Consequently, maximal flow **falls as lung volume falls** (lower recoil and smaller airways at low volume); diseases that reduce recoil (**emphysema**), narrow airways (**asthma, chronic bronchitis**) or increase collapsibility lower maximal flow, whereas increased recoil (**pulmonary fibrosis**) raises flow *relative to volume*.
- ▶ Spirometry discloses only **relative volume changes** during these manoeuvres; it **cannot measure absolute volumes that include RV** (RV, FRC, TLC). These require **body plethysmography** (Boyle's law) or **inert-gas dilution / washout** (helium dilution, nitrogen washout).

Lung volumes, capacities and spirometric indices

Index	Meaning	Measurable by spirometry?
Tidal volume (V _T)	Volume of a quiet breath	Yes
Inspiratory capacity (IC), ERV	IC = TV + IRV; ERV = expiratory reserve	Yes
Vital capacity (VC)	TLC – RV; maximal slow excursion	Yes
FVC	Volume forcibly exhaled from TLC to RV	Yes
FEV ₁	Volume exhaled in the first second of FVC (a flow)	Yes

Index	Meaning	Measurable by spirometry?
FEV1/FVC ratio	Proportion of VC exhaled in 1 s — key obstruction marker	Yes
FEF25–75%	Mid-expiratory flow; reputed small-airway marker (high variability)	Yes
PEF	Peak expiratory flow	Yes
FEV6 / FEV1/FEV6	6-s surrogate for FVC (FEV1/FEV6 <0.73 ≈ FEV1/FVC <0.70)	Yes
MVV	Maximal voluntary ventilation (overall reserve)	Yes
RV, FRC, TLC, RV/TLC	Static volumes containing RV	No — need plethysmography / gas dilution

Indications and contraindications

- ▶ **Diagnose airflow obstruction and quantify its severity** (asthma, COPD — FEV1/FVC and FEV1 are part of the disease definitions).
- ▶ Evaluate **dyspnoea, chronic cough, wheeze, hypoxaemia or an abnormal chest image**; narrow the differential and trigger specific further testing.
- ▶ **Monitor disease activity and treatment response** over time; assess **bronchodilator reversibility** and **bronchial hyper-responsiveness** (methacholine challenge).
- ▶ **Pre-operative / fitness assessment** (e.g. predicting post-pneumectomy reserve; MVV estimable from FEV1) and **occupational / disability and impairment** evaluation.
- ▶ Detect **restriction** (spirometry suggests, lung volumes confirm) and **large-airway obstruction** (flow–volume loop).
- ▶ **Relative contraindications** (forced exhalation raises intrathoracic, intracranial, intra-abdominal and intra-ocular pressure): recent **myocardial infarction, pneumothorax**, recent **thoracic/abdominal/eye/brain/sinus or middle-ear surgery** or infection, **haemoptysis**, severe **hypertension/hypotension**, cervical-incompetent pregnancy, and **syncope** with cough/forced exhalation. (Prior concern over **thoracic aortic aneurysm** has been tempered by recent data.)

Performing and validating the test (ATS/ERS)

- ▶ Patient inhales fully to TLC, then exhales as **hard, fast and long** as possible to RV; ≥3 acceptable spirometers are obtained (practical upper limit 8 efforts).
- ▶ **Start of test: back-extrapolated volume** <5% of FVC or <100 mL (whichever is greater).
- ▶ **Repeatability**: the two largest FVC and two largest FEV1 should be within 150 mL of each other.

- ▶ **Pre-test withholding** for bronchodilator testing: SABA/SAMA ≥ 4 h, LABA ≥ 12 h, long-acting antimuscarinic / ultra-LABA ≥ 24 –48 h; avoid caffeine/alcohol ≥ 4 h.
- ▶ A breathing filter ($\approx 0.2 \mu\text{m}$) is used for infection control; suboptimal effort shows uneven/slurred/notched, non-repeatable curves.

Interpretation — patterns of ventilatory defect

The first interpretive step is the FEV1/FVC ratio (read as an **absolute ratio**, not % predicted), then FEV1 and FVC, with TLC to confirm restriction and DLCO to localise the lesion.

Feature	Obstructive	Restrictive (parenchymal)	Mixed	Nonspecific
FEV1/FVC	$\downarrow$ (<0.70 / $<\text{LLN}$)	Normal or $\uparrow$	$\downarrow$	Normal
FEV1	$\downarrow$	$\downarrow$	$\downarrow$	$\downarrow$ or normal
FVC	Normal or $\downarrow$	$\downarrow$	$\downarrow$	$\downarrow$
TLC	Normal or $\uparrow$ (hyperinflation)	$\downarrow$ (confirms)	$\downarrow$	Normal
RV, RV/TLC	$\uparrow$ (air-trapping)	$\downarrow$	variable	normal
Flow–volume curve	Concave/scooped	Steep, narrow (convex)	combined	preserved shape
Examples	COPD, asthma, bronchiectasis, CF	IPF, sarcoid, asbestosis, CHF	CF, sarcoid, HP, bronchiectasis	obesity, muscle weakness, poor effort

- ▶ **Diagnostic threshold for obstruction:** post-bronchodilator FEV1/FVC <0.70 (GOLD) or $<\text{LLN}$ (5th percentile); obstruction must use **post-bronchodilator** values.
- ▶ **Restriction cannot be diagnosed on spirometry alone** — a low FVC with normal/high FEV1/FVC has only $\sim 50\%$ positive predictive value; a **normal FVC has 96–97% negative predictive value** for ruling out restriction. A low TLC defines restriction.
- ▶ DLCO then localises: low in **parenchymal restriction** (IPF) and **emphysema**; normal in **chest-wall/neuromuscular restriction**; **isolated low DLCO with normal spirometry/volumes suggests pulmonary vascular disease** or early emphysema/ILD.
- ▶ **Large-airway obstruction** is recognised on the flow–volume loop: *fixed* lesion $\rightarrow$ **plateau on BOTH limbs**; *variable extrathoracic* $\rightarrow$ **inspiratory plateau** (with stridor); *variable intrathoracic* $\rightarrow$ **expiratory plateau**.
- ▶ **Reference values** are based on **height, age, sex and ethnicity**; 85–115% of predicted is normal, and in health all volumes scale together.

Severity grading and bronchodilator reversibility

ATS severity (FEV1 % predicted)	Grade
≥70%	Mild
60–69%	Moderate
50–59%	Moderately severe
35–49%	Severe
<35%	Very severe

- ▶ Once a pattern is identified, **severity is graded by FEV1 % predicted** (restriction may also be graded by TLC % predicted).
- ▶ **Significant bronchodilator response (adults):** an increase of ≥12% AND ≥200 mL in FEV1 or FVC after a short-acting bronchodilator (≈10% in children). It supports **asthma** but does **not** distinguish asthma from COPD (35–60% of COPD patients reverse; FVC response is common with hyperinflation). A negative test does **not** exclude reversible disease.
- ▶ When obstruction/reversibility is absent but asthma is suspected, a **methacholine (bronchial) challenge** demonstrating airway hyper-responsiveness can establish the diagnosis.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Diagram 1 — Spirogram (volume vs time):** baseline tidal breathing; label TLC, RV, VC/FVC, FEV1 (volume at 1 s), IC, ERV, FRC; mark that RV/FRC/TLC are not directly measured by spirometry.
- ▶ **Diagram 2 — Flow–volume loops (flow vs volume):** label axes (inspiratory below, expiratory above; TLC and RV on volume axis; PEF peak). Draw and label: (A) Normal, (B) Obstructive — scooped/concave expiratory limb, (C) Restrictive — tall, narrow, vertically-oriented, (D) Fixed large-airway obstruction — plateau on both limbs, (E) Variable extrathoracic — inspiratory plateau, (F) Variable intrathoracic — expiratory plateau.

Clinical / Diagnostic significance

- ▶ Cornerstone for **diagnosing and staging COPD and asthma**, monitoring **ILD/sarcoidosis** progression, and tracking **CF** (declining FEV1/FVC, rising RV/TLC).
- ▶ **Pre-operative risk stratification** (lung resection, major surgery) and **occupational/disability** certification.
- ▶ **Supine fall in FVC of ≥25%** suggests **diaphragmatic/neuromuscular weakness**; complement with MIP/MEP (normal MIP ≥80 cmH₂O men, ≥70 cmH₂O women) and supine spirometry.
- ▶ Combine indices: a **normal/scooped curve with normal FEV1/FVC but reduced FVC** is *nonspecific*, prompting lung-volume and DLCO testing rather than a label of restriction.

High-yield exam pointers

- ▶ Physiological basis = effort-independent expiratory flow limitation from dynamic airway compression (Bernoulli effect); maximal flow set by lung recoil, airway calibre and resistance.
- ▶ First interpret FEV1/FVC (absolute ratio); obstruction = FEV1/FVC <0.70 / <LLN (use post-bronchodilator values).
- ▶ Spirometry cannot measure RV, FRC, TLC — need plethysmography or gas dilution; TLC < LLN confirms restriction.
- ▶ Bronchodilator reversibility = $\geq 12\%$ AND ≥ 200 mL rise in FEV1 or FVC; does not separate asthma from COPD.
- ▶ ATS severity by FEV1 % predicted (≥ 70 mild ... <35 very severe).
- ▶ Acceptability: ≥ 3 efforts, back-extrapolated volume <5%/100 mL, two best FVC and FEV1 within 150 mL.
- ▶ Flow-volume loop localises large-airway lesions: fixed = both limbs plateau; variable extrathoracic = inspiratory plateau; variable intrathoracic = expiratory plateau.
- ▶ FEF25–75% is highly variable and adds little over FEV1/FVC; DLCO differentiates emphysema (low) from asthma (normal/high) in obstruction.

Hypoventilation (Alveolar Hypoventilation Syndromes)

Asked in: Paper III May 2022 — RGUHS MD General Medicine

Definition / Introduction — In health the arterial CO_2 tension (Paco_2) is held between 37 and 43 mmHg at sea level by the relationship $\text{Paco}_2 = k \times V_{\text{CO}_2} / V_A$ (V_A = alveolar ventilation). **Alveolar hypoventilation** exists when alveolar ventilation is insufficient to clear metabolic CO_2 , producing **chronic daytime hypercapnia** ($\text{Paco}_2 \geq 45$ mmHg) with consequent respiratory acidosis and hypoxaemia. Critically, hypoventilation is defined by the Paco_2 , not the respiratory rate — a tachypnoeic patient with a high dead-space fraction may still be alveolar-hypoventilating. It reflects an imbalance in which respiratory **load** exceeds respiratory **strength/drive** (“pump failure”), and the hallmark is a rise in alveolar and arterial Pco_2 .

Physiological basis and classification

- ▶ The respiratory rhythm is generated in the brainstem — the medullary **dorsal respiratory group (DRG)** (afferent integration) and **ventral respiratory column (VRC)**; the **pre-Bötzinger complex** within the VRC generates inspiration (its destruction abolishes breathing) and is the site of **opioid-induced** respiratory depression.
- ▶ Adequate ventilation needs sufficient **drive**, intact **neuromuscular transmission**, and respiratory-muscle **strength** to overcome the elastic and resistive **loads** of lung and chest wall. Hypoventilation results when *Load > Strength* or when *drive is reduced*.
- ▶ A useful mechanistic dichotomy (Murray & Nadel): “**won’t breathe**” = reduced central drive vs “**can’t breathe**” = failure of the respiratory effectors (spinal cord → nerve → neuromuscular junction → muscle → chest wall). Harrison groups causes into **four categories**:

Category	Mechanism	Representative causes
Parenchymal lung / chest wall disease	↑ Load, V/Q mismatch (↑ A-a gradient)	COPD, severe ILD, kyphoscoliosis, thoracoplasty, fibrothorax, ankylosing spondylitis, flail chest
Obesity-hypoventilation syndrome (OHS)	↑ Load + blunted drive + OSA	“Pickwickian syndrome”, BMI ≥ 30
Neuromuscular disease	↓ Strength (“can’t breathe”)	ALS, muscular dystrophy, myasthenia gravis, Guillain-Barré, phrenic injury, high cervical cord lesion, Pompe disease, post-polio
Respiratory-drive disorders	↓ Drive (“won’t breathe”)	Opioids/sedatives, brainstem stroke/tumour, myxoedema, metabolic alkalosis, primary/congenital central hypoventilation (CCHS)

Clinical features

- ▶ Manifestations are **non-specific** and depend on severity, rapidity of CO₂ rise and the underlying disease. Typical symptoms (Harrison Table 307-1): **dyspnoea on activities of daily living**, **orthopnoea** (with diaphragm involvement), **poor-quality sleep**, **daytime hypersomnolence**, **early-morning headaches**, **anxiety**, and **impaired cough** in neuromuscular disease.
- ▶ **Sleep-disordered breathing pattern** — excessive daytime somnolence, snoring, witnessed apnoeas and nocturnal choking dominate in OHS/OSA.
- ▶ **Neuromuscular pattern** — **new-onset orthopnoea is one of the earliest signs** of diaphragm weakness; **paradoxical (abdominal) breathing** when supine (abdomen moves *inward* on inspiration) signals significant diaphragmatic paralysis; “**respiratory alternans**” (alternating rib-cage and abdominal breathing) indicates diaphragmatic fatigue. Bulbar weakness brings dysphagia, weak cough and recurrent aspiration pneumonia.
- ▶ **Sequence of progression**: asymptomatic (normal daytime gases) → **nocturnal hypoventilation** (first in REM, then non-REM sleep) → falling vital capacity → **daytime hypercapnia**.
- ▶ **Consequences of chronic hypercapnia/hypoxaemia**: compensated respiratory acidosis ($\uparrow \text{HCO}_3^-$), secondary erythrocytosis, **pulmonary vasoconstriction** → **pulmonary hypertension** → **right-ventricular hypertrophy** → **cor pulmonale**. Severe hypercapnia causes cerebral vasodilatation, raised ICP, headache, **asterixis**, drowsiness and CO₂ narcosis/coma (usually $\text{Paco}_2 > 75\text{--}80$ mmHg acutely, or an acute rise to $>90\text{--}100$ mmHg superimposed on chronic disease).

Diagnosis and investigations

- ▶ **Arterial blood gas (ABG) is the gold standard** — $\text{Paco}_2 \geq 45$ mmHg at sea level confirms **hypoventilation**. A peripheral venous Pco_2 is a poor surrogate (run several mmHg higher) but a *normal* value helps exclude hypercapnia.
- ▶ **Serum bicarbonate** is a *sensitive but not specific* screen: $\text{HCO}_3^- < 27$ mmol/L (normal renal function, no volume depletion) makes chronic hypoventilation/OHS very unlikely (high negative predictive value); $\text{HCO}_3^- \geq 27$ mmol/L should prompt a confirmatory ABG.
- ▶ **Acute vs chronic** (degree of renal compensation):

Feature	Acute hypoventilation	Chronic hypoventilation
pH	Low (< 7.35); falls 0.08 per $\uparrow 10$ mmHg Paco_2	Normal / near-normal
HCO_3^- rise per $\uparrow 10$ mmHg Paco_2	~ 1 mEq/L (tissue buffering)	$\sim 3.5\text{--}5$ mEq/L (renal, over 3–5 days)

- ▶ **A–a O₂ gradient distinguishes the cause** (Murray algorithm): a **normal A–a gradient** points to a *drive or neuromuscular/effector* disorder (lungs are normal); a **raised A–a gradient** ($> \sim 20$ mmHg) points to *intrinsic lung/airway/vascular disease*.
- ▶ **Stepwise work-up** (Harrison Fig. 307-2): (1) detailed history + medication/drug history → (2) **PFTs and chest imaging** for lung/chest-wall disease → (3) **seated and supine spirometry** with

MIP/MEP for neuromuscular weakness → (4) **BMI ≥ 30** with no alternative cause → OHS → (5) **CNS imaging** (MRI brainstem) for drive disorders.

- ▶ **Respiratory-muscle assessment:** a fall in FVC of 15–25% from seated to supine is an invaluable screen for impending respiratory failure in neuromuscular disease (a drop of 30–50% supports **bilateral diaphragmatic paralysis**); reduced MIP (**maximal inspiratory pressure**)/MEP and falling FVC track progression. In **Guillain-Barré** the “20/30/40 rule” warns of impending ventilation — VC <20 mL/kg, MIP <30 cmH₂O, MEP <40 cmH₂O.
- ▶ **Polysomnography with CO₂ monitoring** detects nocturnal hypoventilation (precedes daytime hypercapnia) and OSA; AASM scores sleep hypoventilation as Paco₂ >55 mmHg for >10 min, or a rise >10 mmHg to a value >50 mmHg for >10 min. Transcutaneous CO₂ (runs ~4–5 mmHg above arterial) is the most practical nocturnal monitor; end-tidal CO₂ is unreliable in lung disease.
- ▶ **OHS diagnostic criteria** (Harrison/CMDT): BMI ≥ 30 kg/m², daytime Paco₂ ≥ 45 mmHg, sleep-disordered breathing, and exclusion of other causes; ~90% have OSA and ~70% have severe OSA (AHI >30/h). Aetiology-specific tests: TSH (myxoedema), urine toxicology, and **PHOX2B genetic testing** for congenital central hypoventilation syndrome (CCHS / *Ondine’s curse*).

Management

- ▶ **General principles:** treat the **underlying disorder**, withdraw respiratory depressants (opioids, benzodiazepines, alcohol), correct contributory metabolic factors (myxoedema, hypokalaemia, hypophosphataemia, excess metabolic alkalosis — which itself blunts drive), and replete nutrition.
- ▶ **Nocturnal non-invasive positive-pressure ventilation (NIPPV / BiPAP)** is the cornerstone — it lowers daytime Paco₂, prolongs survival and improves quality of life when daytime hypercapnia is documented. **Goal: reduce Paco₂ to <52 mmHg or by $\geq 20\%$ from baseline.**
- ▶ **Neuromuscular disease (best studied in ALS)** — nocturnal NIPPV is indicated if hypoventilation symptoms plus any of: Paco₂ ≥ 45 mmHg; nocturnal SpO₂ $\leq 88\%$ for ≥ 5 consecutive min; MIP <60 cmH₂O; or sniff nasal pressure <40 cmH₂O with FVC <50% predicted. Add **mechanical cough-assist** to reduce pneumonia; progress to mouthpiece/portable ventilation; consider **phrenic-nerve/diaphragm pacing** for high cervical cord lesions or drive disorders (requires intact phrenic nerves on conduction study) and tracheostomy ventilation late in disease.
- ▶ **Obesity-hypoventilation syndrome** — **positive airway pressure during sleep:** CPAP first-line when severe OSA coexists (corrects daytime gases in >50%); **BiPAP-ST / volume-assured pressure support** if hypercapnia persists after adherent CPAP, if obstructive events persist at maximal CPAP (20 cmH₂O), in acutely decompensated OHS, or in OHS *without* significant OSA. **Weight loss of 20–25% of body weight (often bariatric surgery)** can normalise Paco₂; treat comorbid OSA, ACS, PE, pneumonia and heart failure aggressively.

- ▶ **Chronic hypercapnic COPD** (stable, $P_{aCO_2} > 52$ mmHg, normal pH) — **high-intensity home BiPAP** (IPAP 24–28 cmH₂O with a back-up rate) aimed at $P_{aCO_2} < 48$ mmHg or a $> 20\%$ fall improves 1-year mortality and quality of life; after an acute exacerbation, re-test at 2–4 weeks and start home NIPPV only if hypercapnia persists.
- ▶ **Oxygen** — supplemental O₂ attenuates hypoxaemia, polycythaemia and pulmonary hypertension, but must be given cautiously as it can worsen hypercapnia (CO₂ narcosis) in some patients; ventilatory support, not oxygen alone, treats the hypoventilation.
- ▶ **Respiratory stimulants** — acetazolamide and medroxyprogesterone are poorly evidenced, have side-effects, and must **not** replace treatment of the underlying disease.
- ▶ **Central hypoventilation syndrome / CCHS** (*Ondine's curse*; PHOX2B mutation) — long-term NIPPV or mechanical ventilation and consideration of **diaphragmatic pacing** at experienced centres.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Load–Strength balance schematic** (Harrison Fig. 307-1): a beam-balance with “Strength/Drive” on one pan (respiratory drive, neural transmission, respiratory-muscle strength) and “Load” on the other (lung elastic + resistive loads, chest-wall elastic load). Label panel A *Health* ($strength > load \rightarrow normocapnia$) and panel B *Load > Strength* $\rightarrow hypercapnia$.
- ▶ **Diagnostic algorithm** (Harrison Fig. 307-2): boxes — *Daytime hypercapnia* $\rightarrow$ ABG ($P_{aCO_2} \geq 45$) $\rightarrow$ PFT + chest imaging $\rightarrow$ seated/supine spirometry, MIP/MEP $\rightarrow$ BMI $\geq 30 \rightarrow$ CNS imaging; endpoint labels: **Lung disease, Neuromuscular, OHS (+ PSG for OSA), CNS lesion, Primary drive disorder**. Annotate the A–a gradient branch (normal = pump/drive; raised = lung disease).

Clinical / Diagnostic significance

- ▶ An unexplained **raised serum HCO₃⁻** on routine biochemistry is a clue to occult chronic hypoventilation — confirm with ABG.
- ▶ **Supine spirometry / orthopnoea** is the earliest red flag for diaphragmatic weakness; do not wait for daytime hypercapnia.
- ▶ Distinguishing **acute from chronic** by pH and the HCO₃⁻ compensation rule guides urgency (ventilatory support vs outpatient NIPPV).
- ▶ Recognise OHS perioperatively — these patients have a high risk of postoperative respiratory failure, intubation and heart failure.
- ▶ Hypercapnic COPD and OHS carry worse survival than normocapnic peers, but **home NIPPV** measurably reduces mortality.

High-yield exam pointers

- ▶ **Definition number:** alveolar hypoventilation = $\text{Paco}_2 \geq 45 \text{ mmHg}$ (normal 37–43 mmHg).
- ▶ **Four causes:** lung/chest-wall disease, OHS, neuromuscular disease, respiratory-drive disorders (“won’t breathe vs can’t breathe”).
- ▶ **A–a gradient: normal** = drive/neuromuscular (pump) cause; **raised** = intrinsic lung disease.
- ▶ **Compensation rule:** acute $\rightarrow \text{HCO}_3^- \uparrow \sim 1 \text{ mEq/L per } 10 \text{ mmHg } \text{Paco}_2$ (pH $\downarrow 0.08$); chronic $\rightarrow \uparrow 3.5\text{--}5 \text{ mEq/L per } 10 \text{ mmHg}$.
- ▶ **OHS:** BMI ≥ 30 + $\text{Paco}_2 \geq 45$ + SDB; $\sim 90\%$ have OSA, $\sim 70\%$ severe; *Pickwickian syndrome*.
- ▶ **Treatment goal with NIPPV:** $\text{Paco}_2 < 52 \text{ mmHg}$ or $\geq 20\%$ reduction.
- ▶ **ALS NIPPV triggers:** $\text{Paco}_2 \geq 45$, nocturnal $\text{SpO}_2 \leq 88\% \times 5 \text{ min}$, MIP < 60 , or SNP < 40 with FVC $< 50\%$.
- ▶ **CCHS:** *Ondine’s curse*, **PHOX2B** mutation, absent ventilatory response to hypoxia/hypercapnia, worse in non-REM sleep.
- ▶ **GBS “20/30/40”:** VC $< 20 \text{ mL/kg}$, MIP < 30 , MEP $< 40 \text{ cmH}_2\text{O} \rightarrow \text{ICU/ventilation}$.

SOURCE & COVERAGE

- ▶ **Harrison’s Principles of Internal Medicine, 22e** — “Disorders of Ventilation” (definition/physiology, four-category classification, Table 307-1 features, Fig. 307-1/307-2, diagnostic algorithm, NIPPV goals, ALS/OHS/COPD/CCHS management).
- ▶ **Murray & Nadel’s Textbook of Respiratory Medicine, 7e** — “Hypercapnia” (won’t-breathe vs can’t-breathe classification Table 45.1, OHS pathophysiology/leptin resistance, acute-vs-chronic compensation, A–a gradient algorithm, respiratory-muscle testing, AASM sleep-hypoventilation criteria, transcutaneous/end-tidal CO_2).
- ▶ **CMDT 2026** — “Pulmonary Disorders” (Disorders of Control of Ventilation / Obesity-Hypoventilation Syndrome) (OHS diagnostic criteria and current management, respiratory stimulants, perioperative risk).

Gastrointestinal system & hepatology

Acute Pancreatitis

Asked in: Paper II Nov 2019 — RGUHS MD General Medicine

Definition / Introduction — Acute pancreatitis is an acute, reversible inflammatory process of the pancreas caused by premature intra-acinar activation of digestive enzymes (autodigestion), ranging pathologically from self-limited **interstitial (oedematous) pancreatitis** (perfusion preserved) to life-threatening **necrotizing pancreatitis** (perfusion interrupted). It is one of the commonest

gastrointestinal causes of hospitalization (incidence ~15–45/100,000/year), is self-limited in 85–90% of cases, but carries an overall mortality of ~1% that rises to ~30–50% when persistent organ failure and infected necrosis coexist. Diagnosis rests on the **Revised Atlanta (2012)** framework, which standardised definitions of severity, phases and morphology.

Etiology

- ▶ **Gallstones (including microlithiasis) — leading cause, 30–60%.** Risk is fourfold greater with stones <5 mm (these pass and transiently impact the ampulla). Suggested by **ALT >3× ULN** (CMDT: ALT >150 U/L).
- ▶ **Heavy alcohol use — second commonest, 15–30%.** Smoking and genetic predisposition are co-factors.
- ▶ **Severe hypertriglyceridemia (1–4%) —** triglycerides usually >1000 mg/dL; often uncontrolled diabetes or apolipoprotein C-II deficiency.
- ▶ **Post-ERCP —** pancreatitis in 5–10%; risk reduced by rectal indomethacin/NSAID and prophylactic pancreatic duct stent.
- ▶ **Drugs (<2% of cases):** azathioprine/6-mercaptopurine, sulfonamides, estrogens, tetracycline, valproate, 5-ASA, DPP-4 inhibitors.
- ▶ **Others:** hypercalcemia, trauma (blunt abdominal), post-operative, pancreas divisum, hereditary (PRSS1), cystic fibrosis, periampullary diverticulum, autoimmune (IgG4 type 1/duct-centric type 2), infections (mumps, coxsackie, CMV), pancreatic/ampullary tumour (~2–4% of pancreatic cancers present as AP), and idiopathic.
- ▶ A useful aide-mémoire is *GET SMASHED* (Gallstones, Ethanol, Trauma, Steroids, Mumps, Autoimmune, Scorpion sting, Hypercalcemia/Hypertriglyceridemia, ERCP, Drugs), but the grounded big three are **gallstones + alcohol + hypertriglyceridemia**.

Pathogenesis

- ▶ Core defect is **loss of acinar autoprotection** and premature activation of trypsinogen → trypsin, which then triggers a cascade activating chymotrypsinogen, proelastase and phospholipase A2.
- ▶ Normal safeguards (any of which, when lost, leads to autodigestion): zymogen packaging as proenzymes, low cytosolic calcium, acid-base balance, and protective inhibitors **SPINK1** (serine protease inhibitor, Kazal type 1) and chymotrypsin C (CTRC), which inactivate trypsin.
- ▶ **Three evolving phases:** (1) intra-acinar trypsin activation mediated by lysosomal **cathepsin B** co-localizing with zymogens → acinar injury; (2) intrapancreatic inflammation with neutrophil/macrophage chemoattraction; (3) systemic release of activated proteases and cytokines → **SIRS, ARDS and multiorgan failure**.
- ▶ **Genetic susceptibility genes** (centred on trypsin control): *PRSS1* (cationic trypsinogen — the only variant sufficient to cause AP alone), *SPINK1*, *CFTR*, *CTRC*, *CASR* (calcium-sensing receptor) and *CLDN2* (claudin-2); the latter five are disease *modifiers*.

Clinical features

- ▶ **Abdominal pain** — the cardinal symptom: steady, boring epigastric pain radiating to the back, relieved by sitting forward, with nausea, vomiting and abdominal distension from ileus.
- ▶ Examination: low-grade fever, tachycardia, **hypotension/shock** (third-space loss, kinin release, circulating enzymes); diminished bowel sounds; epigastric tenderness often disproportionately mild relative to pain.
- ▶ **Specific signs** (rare, reflect haemorrhagic necrosis and worse prognosis): *Cullen's sign* (periumbilical bluish discolouration), *Grey Turner's sign* (flank discolouration), *pancreatic panniculitis* (subcutaneous fat-necrosis nodules), and *Purtscher's retinopathy* (sudden blindness).
- ▶ Pulmonary findings in 10–20% (basal rales, atelectasis, left pleural effusion); transient jaundice in ~10%.

Laboratory & imaging diagnosis

- ▶ **Serum lipase and/or amylase** $>3\times$ ULN is strongly supportive. **Lipase is more specific and preferred** (remains elevated 7–14 days vs amylase normalising in 3–7 days). There is **no correlation** between enzyme level and severity. Amylase is spuriously raised in DKA/acidaemia ($\text{pH} \leq 7.32$) and spuriously low in severe hypertriglyceridemia.
- ▶ Supportive labs: leukocytosis (15,000–20,000/ μL), **haemoconcentration** ($\text{Hct} >44\%$) and rising BUN (azotaemia — strong mortality marker), hyperglycemia, **hypocalcemia** (~25%), hyperbilirubinemia (~10%), hypoxaemia ($\text{PaO}_2 \leq 60$ mmHg) heralding ARDS.
- ▶ **Diagnosis = any 2 of 3 criteria:** (1) typical epigastric pain radiating to back; (2) lipase/amylase $>3\times$ ULN; (3) characteristic findings on cross-sectional imaging.
- ▶ **Imaging:** transabdominal **ultrasound is the initial test** (gallstones, CBD). **Contrast-enhanced CT** is best at **day 3–5** (not routinely in first 48–72 h) to detect necrosis/local complications; MRI/MRCP and EUS for ductal/biliary causes and occult microlithiasis.

Severity assessment and Revised Atlanta classification

- ▶ The dominant determinant of severity is **persistent organ failure (>48 h)** in the respiratory, cardiovascular and renal systems, scored by the **modified Marshall score (≥ 2 = organ failure)**.

Atlanta severity class	Definition
Mild	No organ failure; no local or systemic complications (most interstitial AP; resolves 3–7 days)
Moderately severe	Transient organ failure (<48 h) and/or local/systemic complications
Severe	Persistent organ failure >48 h (single-organ mortality 3–10%; multiorgan ~50%)

Predictive scoring systems (none individually highly accurate):

System	Components / threshold for severe
Ranson	5 at admission (age >55, WBC >16,000, glucose >200 mg/dL, LDH >350 U/L, AST >250 U/L) + 6 at 48 h (Hct fall >10%, BUN rise >5 mg/dL, Ca <8 mg/dL, PaO ₂ <60 mmHg, base deficit >4 mEq/L, fluid sequestration >6 L); ≥3 = severe (mortality 0–2: 1%, 3–4: 16%, 5–6: 40%, 7–8: 100%)
BISAP	BUN >25 mg/dL, Impaired mental status (GCS <15), SIRS, Age >60, Pleural effusion; ≥3 = high mortality
APACHE II	≥8 at 24 h; most validated but cumbersome
CTSI (Balthazar)	CT grade (A–E) + % necrosis; correlates with mortality
SIRS	≥2 of: temp <36/>38°C, HR >90, RR >20 (or PCO ₂ <32), WBC <4000/>12,000 or >10% bands — persistent SIRS at 48 h predicts death

Revised Atlanta morphological definitions (CT): interstitial oedematous pancreatitis (90–95%), necrotizing pancreatitis (5–10%); fluid collections — **acute peripancreatic fluid collection** and **pancreatic pseudocyst** (encapsulated, >4 weeks; in interstitial AP) versus **acute necrotic collection (ANC)** and **walled-off necrosis (WON)** (>4 weeks; in necrotizing AP).

Complications

- ▶ **Local:** ANC/WON (sterile or infected), pseudocyst, pancreatic duct disruption → pancreatic ascites/pancreaticopleural fistula, splanchnic (splenic/portal/SMV) vein thrombosis → gastric varices, pseudoaneurysm haemorrhage, gastric outlet/biliary obstruction, colonic involvement.
- ▶ **Systemic:** SIRS, ARDS, shock, AKI/acute tubular necrosis, DIC, GI haemorrhage, **hypocalcemia** (fat saponification), hyperglycemia, abdominal compartment syndrome; long-term — diabetes, exocrine pancreatic insufficiency and recurrence (~25%).

Management

- ▶ **Fluid resuscitation** is the single most important early intervention. **Lactated Ringer's** preferred over normal saline. A **moderate (goal-directed) strategy** is now favoured (de-Madaria, *NEJM* 2022: 10 mL/kg bolus then 1.5 mL/kg/h) over historically aggressive regimens, titrated to urine output >0.5 mL/kg/h, with serial Hct/BUN every 8–12 h — avoiding fluid overload.
- ▶ **Analgesia** (IV opioids; meperidine or morphine acceptable) and supplemental oxygen; initial NPO.
- ▶ **Nutrition:** early **enteral feeding** (oral low-fat solid diet when pain settling in mild AP; naso-gastric/naso-jejunal within 48–72 h in severe AP) is preferred to TPN — maintains gut barrier, reduces bacterial translocation, infection and mortality.

- ▶ **Antibiotics: no role for prophylactic antibiotics** in sterile necrosis (risk of fungal superinfection); empiric carbapenem (imipenem/meropenem) only for proven/strongly suspected **infected necrosis**.
- ▶ **Gallstone AP: urgent ERCP within 24–48 h** if cholangitis/biliary obstruction; **same-admission laparoscopic cholecystectomy** for mild biliary AP (sphincterotomy if non-operable).
- ▶ **Hypertriglyceridemic AP:** IV insulin ($\pm$ fasting 24–36 h, heparin/apheresis of unproven benefit), then fibrates and lifestyle control.
- ▶ **Infected necrosis / symptomatic WON:** delay intervention $\sim$ 4 weeks until walled-off; use a “**step-up**” approach (percutaneous/endoscopic transluminal drainage with LAMS $\rightarrow$ endoscopic, and only if needed surgical, necrosectomy) — endoscopic-first reduces morbidity versus open necrosectomy.
- ▶ Multidisciplinary care (GI, surgery, interventional radiology, intensive care), preferably at a pancreas centre.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Pathogenesis cascade:** Acinar cell $\rightarrow$ trigger (gallstone/alcohol) $\rightarrow$ cathepsin B activates **trypsinogen** $\rightarrow$ **trypsin** $\rightarrow$ activates *chymotrypsinogen*, *proelastase*, *phospholipase A2* $\rightarrow$ autodigestion (oedema, fat necrosis, haemorrhage) $\rightarrow$ cytokine release $\rightarrow$ **SIRS** $\rightarrow$ ARDS/MODS. Label SPINK1/CTRC as protective inhibitors.
- ▶ **Revised Atlanta morphology box:** two arms — *Interstitial AP* $\rightarrow$ APFC (<4 wk) $\rightarrow$ Pseudocyst (>4 wk); *Necrotizing AP* $\rightarrow$ ANC (<4 wk) $\rightarrow$ WON (>4 wk). Add a body diagram marking *Cullen’s sign* (periumbilical) and *Grey Turner’s sign* (flanks).

Clinical / Diagnostic significance

- ▶ Lipase $>3\times$ ULN with characteristic pain often makes CT unnecessary for diagnosis; reserve early CT for diagnostic doubt.
- ▶ A **persistently rising BUN and Hct $>44\%$** on admission are practical bedside predictors of severe disease and mortality.
- ▶ Persistent organ failure beyond 48 h, not the anatomical extent of necrosis, drives prognosis — escalate to ICU early.
- ▶ Same-admission cholecystectomy prevents recurrent gallstone pancreatitis; failure to do so is a common exam-cited pitfall.

High-yield exam pointers

- ▶ Diagnosis = 2 of 3 (pain / enzymes $>3\times$ ULN / imaging).
- ▶ **Lipase $>$ amylase** in specificity and duration; enzyme level does NOT reflect severity.
- ▶ Big-three causes: **gallstones (30–60%) $>$ alcohol (15–30%) $>$ hypertriglyceridemia (TG >1000).**

- ▶ **Cullen's** = periumbilical, **Grey Turner's** = flank — both signal haemorrhagic necrotizing AP.
- ▶ Severity hinges on **persistent organ failure >48 h** (modified Marshall ≥ 2); scores: **Ranson ≥ 3** , **BISAP ≥ 3** , **APACHE II ≥ 8** .
- ▶ Revised Atlanta: interstitial vs necrotizing; **pseudocyst/WON mature at >4 weeks**.
- ▶ **Lactated Ringer's, moderate (not aggressive) fluids**, early enteral nutrition, **no prophylactic antibiotics**.
- ▶ Infected necrosis → **delay 4 weeks + step-up (drainage → necrosectomy)**, endoscopic-first.
- ▶ Rectal **indomethacin $\pm$ PD stent** prevents post-ERCP pancreatitis.

Auto immune hepatitis

Asked in: Paper II Nov 2022 — RGUHS MD General Medicine

Definition / Introduction — Autoimmune hepatitis (AIH) is a chronic immune-mediated necroinflammatory liver disease of unknown cause, characterized by **autoantibodies**, **hypergammaglobulinemia / raised IgG**, and **interface hepatitis with lymphoplasmacytic infiltration** on liver biopsy. It is a diagnosis of inclusion plus exclusion: viral, drug-induced, metabolic, alcohol-related, and cholestatic autoimmune liver diseases must be excluded. Untreated active AIH may progress to fibrosis, cirrhosis, liver failure, and hepatocellular carcinoma; with immunosuppression, survival improves markedly.

Etiopathogenesis and epidemiology

- ▶ AIH occurs at any age and in both sexes, but has a strong **female predominance**; Harrison notes women account for about **75%** of cases, with peaks in young adults and in middle-to-late life.
- ▶ Incidence is rising in contemporary series; CMDT gives an incidence of **2-4 per 100,000** and prevalence of **26-31 per 100,000**.

- ▶ The central mechanism is loss of tolerance to hepatocyte antigens in genetically predisposed persons, followed by CD4+ T-cell activation, CD8+ cytotoxic T-cell injury, plasma-cell antibody production, Th17-mediated inflammation, hepatocyte apoptosis, and stellate-cell activation causing fibrosis.
- ▶ Genetic associations include HLA-DR3 / DR4; type 2 disease is linked with anti-LKM1 and HLA-DRB1*07.
- ▶ Triggers include viral infections and drugs. Reported drug/toxin associations include **nitrofurantoin, minocycline, hydralazine, methyldopa, infliximab, and immune-checkpoint inhibitors**; minocycline and nitrofurantoin are important causes of autoimmune-like drug-induced liver injury.
- ▶ Associated autoimmune diseases are common: autoimmune thyroiditis / Graves disease, rheumatoid arthritis, Sjögren syndrome, ulcerative colitis, celiac disease, vitiligo, type 1 diabetes, nephritis, and Coombs-positive hemolytic anemia.

Clinical presentation

- ▶ The onset is usually **insidious**, with fatigue, malaise, anorexia, arthralgia, nausea, right upper quadrant discomfort, amenorrhea, and fluctuating jaundice. Fatigue is the commonest symptom, occurring in about **85-86%** in textbook series.
- ▶ About **25-34%** may be asymptomatic and discovered by abnormal liver tests; older patients are particularly likely to present this way.
- ▶ About **25%** present with acute severe hepatitis, and **3-6%** may present as acute severe / fulminant hepatitis with encephalopathy. Acute presentations can mimic viral hepatitis or drug-induced liver injury.
- ▶ Physical findings may be absent. When present, look for hepatomegaly, splenomegaly, jaundice, spider telangiectasia, acne, hirsutism, striae, and signs of chronic liver disease or portal hypertension.
- ▶ Exacerbations may occur **postpartum**.
- ▶ Extrahepatic manifestations include arthritis, sicca symptoms, thyroid disease, nephritis, skin vasculitis, erythema nodosum, autoimmune cytopenias, and inflammatory bowel disease.

Laboratory, serology and histology

Feature	Exam-relevant points
Liver biochemistry	Predominantly hepatocellular pattern: AST/ALT elevated; in acute cases aminotransferases may exceed 1000 U/L . Bilirubin rises in acute/severe disease. Alkaline phosphatase is usually normal or mildly raised; >4 x ULN argues against typical AIH and suggests cholestatic/overlap disease.

Feature	Exam-relevant points
Immunoglobulins	Raised IgG / gamma globulin is a hallmark; gamma globulin may be very high. In acute severe AIH, IgG may be normal in up to 25-39%, so normal IgG does not exclude disease.
Type 1 AIH	ANA and/or smooth muscle antibody (SMA) ; anti-actin and atypical pANCA may occur. This is the classic adult form in North America and northern Europe.
Anti-SLA variant	Anti-soluble liver antigen has high specificity, may be the sole marker, and is associated with severe disease and relapse after withdrawal.
Type 2 AIH	Anti-LKM1 , often without ANA/SMA; anti-LC1 may coexist. More common in children, especially girls, and in Europe/Mediterranean populations.
Histology	Biopsy shows interface hepatitis , lymphoplasmacytic inflammation, plasma cells, hepatocyte rosettes, emperipolesis, central perivenulitis, bridging necrosis, and fibrosis/cirrhosis. Interface hepatitis is the hallmark but is not disease-specific.

- ▶ Cirrhosis is already present in **28-33%** of adults at diagnosis, emphasizing the need for early biopsy and staging.
- ▶ Plasma cells support the diagnosis, but their absence does not exclude AIH; viral, drug, hereditary, metabolic, and cholestatic liver diseases must still be excluded.

Diagnosis and differential diagnosis

- ▶ Suspect AIH in chronic or acute hepatitis with high IgG, autoantibodies, compatible biopsy, and exclusion of competing causes.
- ▶ **Liver biopsy is indicated** to establish diagnosis, assess necroinflammatory activity, stage fibrosis, detect cirrhosis, and identify overlap or drug-induced patterns.
- ▶ Simplified diagnostic criteria:

Criterion	Points
ANA or SMA $\geq 1:40$	1
ANA or SMA $\geq 1:80$, anti-LKM1 $\geq 1:40$, or anti-SLA positive	2
IgG > ULN	1
IgG > 1.1 x ULN	2

Criterion	Points
Histology compatible with AIH	1
Histology typical of AIH	2
Absence of viral hepatitis	2
Total score: probable AIH = 6; definite AIH = ≥ 7	

- ▶ Scoring supports, but does not replace, clinical judgment; it is less sensitive in acute severe or seronegative disease.
- ▶ Differential diagnosis:
 - Viral hepatitis B, C, D, and acute A/E where relevant.
 - Drug-induced liver injury, especially nitrofurantoin, minocycline, antitubercular drugs, methyl dopa, propylthiouracil, NSAIDs, terbinafine, TNF inhibitors, and checkpoint inhibitors.
 - Wilson disease in adolescents/young adults; alpha-1 antitrypsin deficiency and hemochromatosis when appropriate.
 - MASLD/MASH, alcohol-associated liver disease, ischemic hepatitis, celiac-related liver disease, and Budd-Chiari syndrome.
 - Primary biliary cholangitis (PBC), primary sclerosing cholangitis (PSC), and overlap syndromes.

Classification and overlap syndromes

- ▶ **Type 1 AIH:** ANA/SMA positive, all ages, female-predominant, associated with other autoimmune diseases; response to treatment is similar to type 2.
- ▶ **Type 2 AIH:** anti-LKM1 positive, often pediatric, may be associated with anti-LC1 and autoimmune polyglandular syndrome type 1; ANA/SMA are usually absent.
- ▶ **Autoantibody-negative AIH:** conventional ANA/SMA/LKM may be absent; anti-SLA, atypical pANCA, anti-actin, or anti-LC1 may support diagnosis. A monitored steroid response may help in difficult cases.
- ▶ **Drug-related autoimmune-like hepatitis:** temporal drug exposure and resolution after withdrawal favor DILI; relapse after steroid withdrawal favors classic AIH.
- ▶ **AIH-PBC overlap:** suspect when interface hepatitis coexists with cholestasis, AMA, or florid duct lesions. Diagnostic clues include ALT $\geq 5 \times$ ULN, IgG $\geq 2 \times$ ULN or SMA positivity plus PBC features such as alkaline phosphatase $\geq 2 \times$ ULN, GGT $\geq 5 \times$ ULN, AMA, or florid duct lesion.
- ▶ **AIH-PSC overlap:** suspect with inflammatory bowel disease, persistent cholestatic enzymes, or poor response to steroids; evaluate by MRCP/ERCP. CMDT gives overlap with PBC in 7-13% and PSC in 6-11% of AIH patients.

Treatment

- ▶ Treat active AIH; only patients without laboratory or histologic activity may be considered for observation. Optimal candidates include symptomatic patients with marked aminotransferase elevation, raised globulins, bridging necrosis, multiacinar necrosis, or progressive fibrosis.
- ▶ First-line therapy is **prednisone / prednisolone plus azathioprine**:
 - CMTD regimen: prednisone **20-40 mg orally daily** with azathioprine **50 mg orally daily**.
 - AASLD-style combination regimen: prednisone/prednisolone **30 mg daily**, tapered over 4 weeks to **10 mg daily**, with azathioprine **50 mg daily**.
 - European-style regimen: prednisolone **0.5-1 mg/kg daily**, tapered over about 10 weeks; azathioprine **1-2 mg/kg daily** is often added after 2 weeks.
- ▶ In **acute severe AIH**, use IV corticosteroids or prednisone **40-60 mg daily**; start azathioprine later, commonly after about 2 weeks, once diagnosis and early response are clear.
- ▶ Before azathioprine, assess **thiopurine methyltransferase (TPMT)** status where available; monitor CBC weekly for the first 2 months and monthly thereafter because of marrow suppression risk.
- ▶ **Budesonide 3 mg two or three times daily** may be used in noncirrhotic, mild/uncomplicated AIH, often with azathioprine, but avoid it in cirrhosis because first-pass hepatic clearance is lost and adverse effects/portal vein thrombosis have been reported.
- ▶ Response-guided management: symptoms improve first; remission means normal AST, ALT, and IgG; histologic resolution lags by months. An **80% fall in AST by 8 weeks** predicts later normalization; failure of aminotransferases to fall by **50% within 4 weeks** suggests nonresponse.
- ▶ Relapse is common; many patients require long-term azathioprine up to **2 mg/kg/day** or the lowest effective prednisone dose.
- ▶ Second-line / rescue options: **mycophenolate mofetil 500 mg twice daily increasing to 1 g twice daily** for azathioprine intolerance; 6-mercaptopurine for azathioprine gastrointestinal intolerance; tacrolimus, cyclosporine, rituximab, or infliximab in refractory disease. Mycophenolate is teratogenic.
- ▶ **Liver transplantation** is indicated for acute liver failure, decompensated cirrhosis, treatment failure, severe acute AIH without improvement after about 2 weeks of corticosteroids, or HCC within transplant criteria.

Response, follow-up and prognosis

- ▶ Prednisone plus azathioprine produces response in about **80%** and remission in about **65% by 3 years**.
- ▶ Consider treatment withdrawal only after sustained complete biochemical remission: at least **24 months** of normal AST/ALT/IgG, usually after a total treatment duration of about **3 years**; repeat biopsy can document histologic remission.

- ▶ Relapse after withdrawal is frequent; CMDT reports relapse up to **90% by 3 years**. Recurrent relapse usually warrants indefinite maintenance therapy.
- ▶ Vaccinate against **hepatitis A and B** before immunosuppression where possible; also give age-appropriate vaccines.
- ▶ Monitor steroid complications: weight gain, diabetes, hypertension, cataract, infection, mood disturbance, and osteoporosis. Do **DEXA**, calcium/vitamin D, exercise, and bisphosphonate when indicated.
- ▶ In cirrhosis: screen for **HCC by ultrasound every 6 months**, assess portal hypertension/varices, and manage ascites, encephalopathy, renal dysfunction, and transplant referral early.
- ▶ Poor prognostic factors include age ≤ 20 or ≥ 60 at presentation, low albumin, cirrhosis at diagnosis, anti-SLA positivity, high bilirubin/MELD, and incomplete AST normalization by 6 months.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Immunopathogenesis flow diagram:** environmental trigger/drug/virus $\rightarrow$ molecular mimicry/loss of tolerance $\rightarrow$ antigen-presenting cell $\rightarrow$ CD4+ helper T cell $\rightarrow$ CD8+ cytotoxic T cell + plasma cell + Th17 cell $\rightarrow$ Fas-FasL hepatocyte apoptosis $\rightarrow$ interface hepatitis $\rightarrow$ stellate-cell activation $\rightarrow$ fibrosis/cirrhosis. Exact labels: APC, class II MHC, CD4+ T cell, CD8+ T cell, plasma cell, autoantibodies, Fas/FasL, hepatocyte apoptosis, Kupffer cell, ROS, hepatic stellate cell, fibrosis.
- ▶ **Diagnostic-treatment algorithm:** chronic/acute hepatitis $\rightarrow$ exclude viral/drug/metabolic/alcohol/cholestatic disease $\rightarrow$ ANA/SMA/LKM1/SLA + IgG $\rightarrow$ liver biopsy showing interface hepatitis $\rightarrow$ prednisone/prednisolone $\pm$ azathioprine $\rightarrow$ remission / relapse / nonresponse $\rightarrow$ maintenance, second-line therapy, or liver transplantation.

Clinical / Diagnostic significance

- ▶ Always biopsy suspected AIH unless contraindicated; in coagulopathy or acute severe disease, consider a **transjugular liver biopsy**.
- ▶ Do not dismiss acute severe AIH because ANA is absent or IgG is normal; this occurs in a substantial minority.
- ▶ Prominent cholestasis, IBD, bile duct injury, or poor steroid response should prompt evaluation for PSC/PBC overlap and MRCP/ERCP.
- ▶ Distinguish drug-induced autoimmune-like hepatitis from classic AIH by exposure history, histology, resolution after drug withdrawal, and relapse pattern after steroid withdrawal.
- ▶ Early transplant discussion is mandatory in encephalopathy, INR prolongation, acute liver failure, high MELD, or failure of bilirubin/clinical status to improve within 1-2 weeks of steroids.

High-yield exam pointers

- ▶ AIH triad: autoantibodies + raised IgG + interface hepatitis.
- ▶ ANA/SMA = type 1; anti-LKM1/anti-LC1 = type 2; anti-SLA = severe/relapsing, high-specificity marker.
- ▶ Histology must-write: interface hepatitis, plasma cells, rosettes, emperipolesis, central perivenulitis, bridging necrosis/fibrosis.
- ▶ Normal IgG or absent ANA does **not** exclude acute severe AIH.
- ▶ Simplified score: **6 probable**, **≥7 definite**.
- ▶ First-line: corticosteroid plus azathioprine; check TPMT and monitor CBC.
- ▶ Budesonide is for selected **noncirrhotic** patients; avoid in cirrhosis.
- ▶ Relapse is common; withdrawal requires prolonged normal AST/ALT/IgG and often biopsy confirmation.
- ▶ Cirrhotic AIH needs HCC surveillance and early transplant evaluation.

Autoimmune Pancreatitis

Asked in: Paper II Nov 2020 — RGUHS MD General Medicine

Definition / Introduction — Autoimmune pancreatitis (AIP) is a distinct, corticosteroid-responsive form of chronic pancreatitis characterised by a lymphoplasmacytic inflammatory infiltrate, fibrosis and a tendency to form tumefactive (mass-like) lesions that frequently mimic pancreatic adenocarcinoma. It is sub-classified into **type 1 AIP** — the pancreatic manifestation of the multi-organ syndrome **IgG4-related disease (IgG4-RD)** — and **type 2 AIP (idiopathic duct-centric chronic pancreatitis, IDCP)**, a pancreas-restricted disease defined by the *granulocytic epithelial lesion (GEL)*. Recognising AIP matters chiefly because it is one of the few **reversible, steroid-responsive** causes of an obstructive pancreatic mass, and misdiagnosis leads to unnecessary Whipple resection.

Classification — Subtypes of AIP

Feature	Type 1 AIP (LPSP)	Type 2 AIP (IDCP)
Underlying entity	Pancreatic manifestation of IgG4-RD	Pancreas-specific; no systemic disease
Mean age at diagnosis	~7th decade (>60 yr; most >50)	~5th decade (40–50; may affect young adults/children)

Feature	Type 1 AIP (LPSP)	Type 2 AIP (IDCP)
Sex	Male predominance (~75%; M:F ≈ 2:1)	Equal (M ≈ 50%)
Serum IgG4 elevation	~66% (two-thirds)	~25% (usually normal)
Other-organ involvement	~50–60% (biliary, salivary, kidney, retroperitoneum)	None
Lymphoplasmacytic infiltrate	++	++
Storiform fibrosis	++	+
Obliterative phlebitis	++	+ (rare)
Granulocytic epithelial lesion (GEL)	Absent	+++ (defining)
IgG4 tissue plasma cells	Abundant (≥10/hpf)	Scant (<10/hpf)
Associated disease	IgG4-RD	Inflammatory bowel disease (~10–30%)
Response to steroids	~100%	~100%
Risk of relapse	Moderate–high (30–50%, up to 60%)	Low (<10%)

- ▶ **Type 3 AIP** is now recognised (CMDT 2026) as an infrequent complication of **immune-checkpoint-inhibitor** therapy; it is often asymptomatic but causes rapid pancreatic atrophy.
- ▶ The histological term for the type 1 lesion is **lymphoplasmacytic sclerosing pancreatitis (LPSP)** — *storiform* (“woven-mat”/cartwheel) fibrosis, obliterative phlebitis and a periductal cuff of IgG4-positive plasma cells. Type 2 shows **duct-centric** neutrophilic destruction of the duct epithelium (the GEL).

IgG4-Related Disease (the systemic context of type 1 AIP)

- ▶ A fibroinflammatory, **tumefaction-forming** condition that can affect virtually any organ; regarded as a **variable-vessel vasculitis** because of its tropism for veins and arteries of any calibre.
- ▶ Commonly involved organs: **pancreas, biliary tree, submandibular/parotid glands, periorbital tissues (lacrimal glands), kidneys, lungs, lymph nodes, retroperitoneum, aorta, thyroid (Riedel’s)**.
- ▶ Eponymous overlaps: ***Mikulicz disease** (*lacrimal + parotid + submandibular swelling*), **Küttner tumour** (*submandibular gland*), **Riedel’s thyroiditis***, retroperitoneal fibrosis, inflammatory aortic aneurysm.
- ▶ Pathology is identical across organs: dense lymphoplasmacytic infiltrate, **storiform fibrosis**, **obliterative phlebitis**, mild-to-moderate **tissue eosinophilia**; intense neutrophils, granulomas, giant cells and fibrinoid necrosis argue *against* the diagnosis.

- ▶ Mechanism: the IgG4 molecule undergoes **Fab-arm exchange**, binds antigen weakly and has low affinity for Fcγ-receptors and C1q (largely *non-inflammatory*) — so it is probably a counter-regulatory marker rather than the primary driver. The true effectors are oligoclonally expanded **CD4⁺ cytotoxic T cells** (producing perforin, granzyme, IFN-γ, TGF-β) and circulating **plasmablasts**.

Clinical features

- ▶ **Obstructive jaundice** is the commonest presentation (≈50–75%), characteristically **painless**, due to a stricture of the intrapancreatic common bile duct or compression by the enlarged head.
- ▶ **Weight loss** and **new-onset diabetes / glucose intolerance** (20–50% of type 1) are frequent; severe pain and overt acute pancreatitis are *uncommon* (acute pancreatitis is more typical of type 2).
- ▶ A **pancreatic mass** mimicking carcinoma is the major clinical trap; many patients have undergone modified Whipple surgery before the diagnosis was made.
- ▶ **Type 1 extra-pancreatic disease**: IgG4-related sclerosing cholangitis (mimics PSC/cholangiocarcinoma, hilar predilection), bilateral sclerosing **sialadenitis/dacryoadenitis**, **retroperitoneal fibrosis** (hydronephrosis from ureteric entrapment), **tubulointerstitial nephritis** and renal masses, lymphadenopathy, lung pseudotumours, periaortitis.

Diagnosis and investigations

- ▶ **Imaging (CT/MRI)**: classical diffuse “sausage-shaped” **pancreas** with loss of normal lobularity and delayed/prolonged contrast enhancement; a peripheral **hypoattenuating rim** (“**capsule sign**”) is *highly specific but not sensitive*. Focal/segmental enlargement is the malignancy mimic.
- ▶ **Ductal imaging (MRCP/ERCP)**: long (>1/3 of duct length) or multiple strictures of the main pancreatic duct **without marked upstream dilatation**, and biliary strictures (IgG4-sclerosing cholangitis).
- ▶ **Serology**: serum **IgG4 >2× upper limit of normal** is the level-1 criterion (ULN ≈ 4–86 mg/dL); a single isolated elevation has low positive predictive value and can occur in pancreatic cancer. Other autoantibodies (ANA, anti-lactoferrin, anti-carbonic anhydrase II, rheumatoid factor) are less useful. Beware the **prozone effect**, which falsely lowers nephelometric IgG4 in very high-titre disease — correct by serum dilution.
- ▶ **Histology (core biopsy/resection)**: LPSP with **≥10 IgG4⁺ plasma cells/hpf**, storiform fibrosis, obliterative phlebitis (type 1); GEL (type 2). EUS-guided core biopsy aids type 2 (which usually *requires* histology).
- ▶ **Diagnostic frameworks**:
 - ***HISORt criteria** (*Mayo Clinic mnemonic*): *H*istology, *I*maging, *S*erology, *O*ther-organ involvement, *R*esponse to steroid *t**herapy.

- ***International Consensus Diagnostic Criteria (ICDC)** harmonise five cardinal features — *P* (parenchymal imaging), *D* (ductal imaging), *S* (serology), *OOI* (other-organ involvement) and *H* (histology), plus *Rt* (response to steroids) — graded level 1/level 2 to classify definitive vs probable* type 1 AIP.
- ▶ **Response to glucocorticoids** is itself a diagnostic criterion: rapid (2–4 week) radiological resolution is expected; *poor response must prompt re-evaluation for malignancy*.

Distinguishing AIP from pancreatic carcinoma (critical)

- ▶ Features favouring **cancer**: a *dilated* pancreatic duct, a single high-grade stricture with **upstream gland atrophy**, and a discrete low-density focal mass.
- ▶ Features favouring **AIP**: diffuse sausage-shaped gland, capsule (rim) sign, multifocal strictures without upstream dilatation, raised IgG4, other-organ involvement.
- ▶ **Before a steroid trial, malignancy must be vigorously excluded** (EUS-FNA/core biopsy, CA 19-9). A short, closely-monitored steroid trial is reasonable only when work-up is inconclusive and follow-up is assured.

Treatment

- ▶ **Glucocorticoids are first-line for both subtypes** — prednisone ~40 mg/day (0.6–1 mg/kg) for ~4 weeks, then taper by 5 mg/week over a total of ~10–12 weeks. Clinical and radiological response is usually obvious within 2–4 weeks; remission is achieved in ~99% of type 1 and ~92% of type 2.
- ▶ **Relapse** (30–50%, up to 60% in type 1, especially with IgG4-cholangitis) is managed by repeat steroids ± low-dose maintenance prednisone (5–10 mg/day), or steroid-sparing immunomodulators (**azathioprine, 6-mercaptopurine, mycophenolate mofetil**).
- ▶ **Rituximab (B-cell depletion)** is the most effective agent for recurrent/refractory disease and for IgG4-RD generally (two doses of 1 g IV ~15 days apart); it produces a swift fall in serum IgG4.
- ▶ **Adjuncts**: biliary stenting for obstructive jaundice, insulin for diabetes, pancreatic enzyme replacement if exocrine insufficiency supervenes, and surveillance for relapse (rising IgG4 flags impending flare).

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Labelled CT of type 1 AIP**: outline a *diffusely enlarged “sausage-shaped” pancreas*; label — loss of lobular contour, peripheral hypoattenuating rim (“capsule sign”), narrowed main pancreatic duct (no upstream dilatation), distal CBD stricture causing obstructive jaundice, dilated proximal CBD/intrahepatic ducts.
- ▶ **Histology schematic of LPSP (type 1)**: label — periductal lymphoplasmacytic cuff, storiform (cartwheel) fibrosis, obliterative phlebitis (vein lumen effaced by infiltrate),

IgG4⁺ plasma cells ($\geq 10/\text{hpf}$); contrast with type 2 GEL — neutrophils destroying duct epithelium.

Clinical / Diagnostic significance

- ▶ AIP is a key “do-not-miss, do-not-over-treat” diagnosis: it is the steroid-curable mimic of pancreatic cancer, and conversely a non-responding “AIP” may be cancer.
- ▶ Type 1 AIP mandates a **systemic survey for IgG4-RD** (salivary glands, kidneys, retroperitoneum, biliary tree, aorta) because subclinical multi-organ disease is common and may cause irreversible fibrosis (renal atrophy, hepatic failure from sclerosing cholangitis, aortic dissection).
- ▶ Long-standing/untreated AIP can “burn out” to atrophic, calcified chronic pancreatitis indistinguishable from other causes, with exocrine and endocrine insufficiency.
- ▶ Patients are at modestly increased risk of various malignancies; vigilant follow-up is required.

High-yield exam pointers

- ▶ **Two subtypes:** type 1 = IgG4-RD/LPSP (elderly male, multi-organ, high relapse); type 2 = IDCP/GEL (younger, pancreas-only, IBD-associated, low relapse). Type 3 = checkpoint-inhibitor-induced.
- ▶ **Painless obstructive jaundice + sausage-shaped pancreas + raised IgG4** = type 1 AIP until proven otherwise.
- ▶ **Capsule (rim) sign** = highly specific; main pancreatic duct **narrowed, not dilated** (unlike cancer).
- ▶ **Serum IgG4 $> 2 \times$ ULN** = level-1 serology; remember the **prozone effect** (false-low at very high titres).
- ▶ **HISORt** (Mayo) and **ICDC** (P-D-S-OOI-H + Rt) are the two diagnostic frameworks.
- ▶ **Histology hallmarks:** storiform fibrosis + obliterative phlebitis + ≥ 10 IgG4⁺ cells/hpf (type 1); granulocytic epithelial lesion (type 2).
- ▶ **Treatment:** prednisone 40 mg/day $\rightarrow$ taper; **rituximab** for relapse; $\sim 100\%$ steroid response — *failure to respond suggests cancer*.
- ▶ IgG4 is a **non-inflammatory** antibody (Fab-arm exchange); the real driver is the **CD4⁺ cytotoxic T cell**.

SOURCE & COVERAGE

- ▶ **Harrison’s Principles of Internal Medicine, 22e** — “Acute and Chronic Pancreatitis” (AIP subtypes, HISORt, capsule sign, treatment) and “IgG4-Related Disease” (organ manifestations, pathology, serology, rituximab).

- ▶ **Sleisenger & Fordtran's Gastrointestinal and Liver Disease, 11e** — “Chronic Pancreatitis” (LPSP/IDCP histology, International Consensus Diagnostic Criteria, imaging, AIP-vs-cancer, steroid regimen and relapse).
- ▶ **CMDT 2026** — “Liver, Biliary Tract, & Pancreas Disorders” (type 1/2/3 classification, HISOrt, prednisone taper, rituximab maintenance).

Barrett's Esophagus

Asked in: Paper II Nov 2019 — RGUHS MD General Medicine

Definition / Introduction — Barrett's esophagus (BE) is the condition in which the normal stratified squamous epithelium lining the distal esophagus is replaced by an abnormal **columnar epithelium with both gastric and intestinal features** that is predisposed to malignancy. It is a consequence of **chronic gastro-esophageal reflux disease (GERD)**, which injures the squamous epithelium and drives metaplastic healing. The condition is named after *Norman Barrett*, an Australian-born surgeon who described the columnar-lined esophagus in 1950. BE itself is asymptomatic; its entire clinical importance lies in being the principal **precursor lesion of esophageal adenocarcinoma (EAC)**, a cancer whose incidence has risen more than 7-fold over recent decades.

Diagnosis and Endoscopic Classification

- ▶ **Two criteria must both be fulfilled** (it is an endoscopic *and* histological diagnosis):
- ▶ Endoscopist confirms **columnar epithelium lining ≥ 1 cm of the distal esophagus** above the esophagogastric junction (EGJ).
- ▶ **Biopsy shows metaplasia** — U.S. societies (ACG/AGA) require **intestinal metaplasia with goblet cells** (“specialized intestinal metaplasia”).
- ▶ The EGJ is identified endoscopically as the *most proximal extent of the gastric folds*; columnar mucosa must extend ≥ 1 cm above it.
- ▶ **Endoscopic appearance**: Barrett mucosa is **reddish/salmon-coloured with a velvet-like texture**, contrasting sharply with the pale, glossy squamous epithelium; it ascends from the EGJ in a *tongue-like or circumferential* pattern.
- ▶ **Three columnar epithelial types** may be seen — gastric cardiac, gastric fundic, and **specialized intestinal metaplasia**; only the last carries the established risk of dysplasia/cancer.
- ▶ **Length-based classification** and the standardised **Prague C & M criteria**:

System	Definition	Note
Long-segment BE	metaplasia extends ≥ 3 cm above EGJ	severe GERD; higher cancer risk

System	Definition	Note
Short-segment BE	<3 cm of metaplasia	by far the commonest form (Spechler, 1994)
Prague C value	Circumferential extent (cm) of metaplasia	reproducible grading
Prague M value	Maximum extent (cm), including tongues	(Sharma et al., 2006)

Epidemiology and Risk Factors

- Usually discovered during endoscopy done for GERD symptoms in **middle-aged/older adults**; mean age at diagnosis $\approx$ **55 years**. Rare under age 10, virtually absent under age 5.
- **Demographics**: predominantly **white men**; uncommon (though rising) in Black and Asian populations.
- **Prevalence**: in the general Western adult population **1.6–6.8%** (predominantly short-segment); among patients scoped for GERD, **long-segment in 3–5%** and **short-segment in 10–20%** (CMDT: 7–11% of chronic-reflux patients).
- **Risk factors for BE / EAC**: chronic GERD, **central (truncal) obesity** (raises intra-abdominal pressure $\rightarrow$ GERD; also $\uparrow$ IGF-1, leptin, $\downarrow$ adiponectin), **cigarette smoking**, male sex, white race, hiatal hernia, age $\geq$ 50, and a first-degree relative with BE/EAC.
- **Protective factors**: *Helicobacter pylori* infection (may reduce acid secretion/GERD), aspirin/NSAID use, and a diet rich in fruit and vegetables.
- **Note**: smoking and alcohol are strong risk factors for **squamous-cell carcinoma**; for **adenocarcinoma** smoking is only a modest risk and alcohol has no clear effect.

Pathogenesis and Molecular Carcinogenesis

- BE begins with **GERD-induced injury** (acid $\pm$ duodeno-gastric reflux of bile acids/pancreatic enzymes); reflux-damaged squamous epithelium heals via **metaplasia** into a columnar, intestinal-type epithelium presumed more resistant to reflux (secretes mucins, expresses tight-junction protein **claudin-18**).
- This requires **molecular reprogramming of developmental transcription factors** in progenitor cells — up-regulated genes include **CDX genes** (drive intestinal differentiation) and the Hedgehog targets **BMP4** and **FOXA2**.
- **Neoplastic progression** = stepwise acquisition of the *Hanahan–Weinberg hallmarks of cancer*, facilitated by **genomic instability (aneuploidy)** and a tumour-promoting microenvironment (oxidative stress from GERD). Key alterations:
 - **Oncogene activation**: cyclin D1, K-ras, EGF receptor, TGF- α (self-sufficiency in growth signals).

- **Tumour-suppressor loss:** TP53 (early event; also enables apoptosis evasion) and p16/CDKN2A.
- **Telomerase reactivation** → limitless replication; VEGF → angiogenesis; cadherin/catenin disruption + matrix metalloproteases → invasion/metastasis.
- ▶ Two carcinogenic pathways recognised by genomic sequencing: the “**traditional pathway**” (stepwise TP53 → p16 → oncogene activation) and the more rapid “**genome-doubled pathway**” (TP53 mutation → whole-genome doubling → oncogene amplification) — the latter accounts for ~62% of tumours and may explain *interval cancers* that escape surveillance.

Dysplasia and Cancer Risk

- ▶ **Dysplasia (intraepithelial neoplasia)** is the histological marker of progression: nuclear enlargement, pleomorphism, hyperchromatism, stratification, atypical mitoses, loss of cytoplasmic maturation, crowded/villiform architecture. Graded **low-grade (LGD)** or **high-grade (HGD)**.
- ▶ **Inter-observer agreement** is poor for LGD (<50% — easily confused with reactive change) but better for HGD (~85%); any grade of dysplasia should be **confirmed by a second expert GI pathologist**.

Histology	Approx. annual progression to cancer
Non-dysplastic BE	~0.25%/yr (range 0.12–0.33%)
Short-segment (1–3 cm)	~0.29%/yr (CMDT)
Long-segment (>3 cm)	~0.91%/yr (CMDT)
Low-grade dysplasia	disputed; ~0.4–13%/yr depending on series
High-grade dysplasia	~6%/yr; 13% harbour unsuspected invasive cancer

Management

- ▶ **Acid suppression / chemoprevention:** all BE patients receive a **PPI** in the dose needed to control symptoms and heal esophagitis; asymptomatic patients are still offered **once-daily PPI for chemoprevention** (ACG). The **AspECT trial** showed high-dose PPI + aspirin improved the composite outcome (mortality/progression), driven mainly by improved overall survival. Routine NSAID/aspirin prescription *solely* for chemoprevention is **not** recommended (GI/CV bleeding risk).
- ▶ **Anti-reflux surgery (fundoplication)** controls GERD but is **not clearly superior to PPI** for cancer prevention — not done for cancer prophylaxis alone.
- ▶ **Screening (ACG 2022):** endoscopic screening only for those with **≥5 years of at least weekly GERD symptoms plus ≥3 risk factors** (age >50, male sex, white race, central obesity, smoking,

family history). *Not* recommended routinely in women. A swallowable **capsule-sponge** with biomarker cytology is an emerging non-endoscopic alternative.

- **Surveillance:** high-resolution white-light endoscopy with the **Seattle biopsy protocol** = 4-quadrant biopsies every 1–2 cm (every 2 cm if non-dysplastic; every 1 cm if dysplasia known) plus targeted biopsy/EMR of any visible irregularity. **Non-dysplastic BE** → scope every 3–5 years.
- **Endoscopic Eradication Therapy (EET)** is now the treatment of choice for confirmed **mucosal neoplasia** (LGD, HGD, and intramucosal/T1a carcinoma) — combining resection + ablation, with **complete eradication of intestinal metaplasia (CE-IM)** as the goal:

Modality	Mechanism / role
Endoscopic mucosal resection (EMR)	“suck-and-cut” or “band-and-snare”; removes visible nodules — essential for accurate T-staging (superior to EUS) before ablation
Endoscopic submucosal dissection (ESD)	en-bloc knife resection of larger lesions
Radiofrequency ablation (RFA)	balloon/catheter microwave electrodes — procedure of choice for flat dysplasia (proven in AIM Dysplasia and SURF trials)
Cryotherapy	spray CO ₂ /N ₂ O — freeze–thaw injury; spares collagen matrix
Photodynamic therapy (PDT)	porfimer sodium + laser → singlet oxygen; <i>largely abandoned</i> (photosensitivity, strictures)
Esophagectomy	historical gold standard for HGD; mortality 3–10% — now reserved for EET failure/submucosal invasion

- **Staging rule:** if EMR reveals **submucosal invasion**, lymph-node metastasis exceeds 10% → EET is abandoned and the patient referred for surgical/oncological management; mucosal (T1a) lesions have only ~1.4% nodal risk, making EET safe.
- **Post-EET surveillance (after CE-IM):** for HGD/intramucosal carcinoma — every 3 months × 1 yr, 6-monthly in yr 2, then annually; for LGD — 6-monthly × 1 yr then annually. Recurrence (mostly at the neo-squamocolumnar junction) reaches ~9–10%/yr, so surveillance continues despite CE-IM.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- **Endoscopic view of Barrett’s esophagus:** tubular esophagus with **salmon-red velvety columnar tongues** ascending from the EGJ over pale glossy squamous mucosa. *Labels:* squamous (pale) epithelium, columnar (salmon) Barrett mucosa, **Z-line** / **squamocolumnar junction**, EGJ (top of gastric folds), ≥1 cm metaplastic segment, Prague C and M measurements.

- ▶ **Metaplasia–dysplasia–carcinoma sequence (flow diagram):** Normal squamous epithelium → (chronic GERD) → **Intestinal metaplasia (BE)** → **Low-grade dysplasia** → **High-grade dysplasia** → **Esophageal adenocarcinoma**. *Annotate* molecular hits: TP53 & p16 loss, cyclin D1/K-ras activation, aneuploidy/genome-doubling.

Clinical / Diagnostic significance

- ▶ BE is the key **pre-malignant marker** linking GERD to EAC — the rationale for screening high-risk refluxers and for endoscopic surveillance.
- ▶ **Diagnosis hinges on biopsy** confirming intestinal metaplasia with goblet cells; endoscopic appearance alone is insufficient, and the **EGJ landmark (gastric folds)** must be correctly identified to avoid over-/under-diagnosis.
- ▶ **Sampling error is the major pitfall** — dysplasia is patchy and often endoscopically subtle; the Seattle protocol misses lesions, hence the move toward removing *all* visible irregularities by EMR and ablating *all* residual metaplasia.
- ▶ Management is **risk-stratified by dysplasia grade**: PPI + surveillance for non-dysplastic BE, EET for any confirmed dysplasia or T1a cancer, surgery/chemoradiation once submucosal/nodal disease appears.

High-yield exam pointers

- ▶ BE = **metaplastic columnar (intestinal) epithelium replacing distal esophageal squamous epithelium**; named after *Norman Barrett* (1950).
- ▶ **Diagnostic dyad**: columnar mucosa ≥ 1 cm above EGJ + intestinal metaplasia with goblet cells on biopsy.
- ▶ **Long-segment ≥ 3 cm, short-segment < 3 cm**; Prague C & M criteria for standardised reporting.
- ▶ Typical patient: **obese white male, ~55 yr, chronic GERD**; *H. pylori*, aspirin/NSAIDs and a fruit/vegetable diet are **protective**.
- ▶ **Cancer risk ~0.25%/yr (non-dysplastic), ~6%/yr (HGD)**; risk rises with segment length (LSBE 0.91%/yr vs SSBE 0.29%/yr).
- ▶ **Earliest molecular hit = TP53 inactivation**; CDX/BMP4/FOXA2 drive metaplasia; aneuploidy and the *genome-doubled pathway* accelerate cancer.
- ▶ **Seattle protocol** = 4-quadrant biopsies every 1–2 cm + targeted EMR of nodules.
- ▶ EET (EMR + RFA) is first-line for dysplasia/T1a (AIM & SURF trials); **submucosal invasion (>10% nodal risk) contraindicates EET**; esophagectomy mortality 3–10%.
- ▶ All BE patients get a **once-daily PPI**; surveillance interval for non-dysplastic BE is 3–5 years.

Biliary Cirrhosis

Asked in: Paper II Jul 2020 — RGUHS MD General Medicine

Definition / Introduction — *Biliary cirrhosis* is the end-stage of chronic **cholestatic** liver disease, in which sustained impairment of bile flow (rather than hepatocellular necroinflammation) drives progressive **biliary-type fibrosis**, ductopenia and finally architectural distortion with regenerative nodules. It has pathologic features distinct from alcohol-associated or post-hepatitic cirrhosis, yet the manifestations of end-stage liver disease (portal hypertension, jaundice, hepatic failure) are the same. The cholestasis may be **intrahepatic** (small-duct disease, e.g. primary biliary cholangitis) or **extrahepatic** (large-duct obstruction) — a distinction with major therapeutic consequence, since extrahepatic obstruction may be relieved by surgical/endoscopic decompression whereas intrahepatic disease will not.

Classification — causes of biliary cirrhosis

- ▶ **Primary (intrahepatic, autoimmune/idiopathic cholestatic syndromes):** *primary biliary cholangitis (PBC)*, *primary sclerosing cholangitis (PSC)*, *autoimmune cholangitis* (AMA-negative PBC), and *idiopathic adulthood ductopenia*. These share the histopathology of chronic cholestasis — **choleate stasis, copper deposition, xanthomatous transformation of hepatocytes, irregular “biliary” fibrosis and progressive ductopenia**.
- ▶ **Secondary biliary cirrhosis** results from *prolonged extrahepatic biliary obstruction* — chronic choledocholithiasis, post-operative/inflammatory bile-duct strictures, chronic pancreatitis, biliary/pancreatic malignancy, and (in children) biliary atresia or cystic fibrosis-associated biliary disease.
- ▶ The two named primary biliary syndromes are distinguished clinically by **antibody testing, cholangiographic findings and clinical presentation** (PBC = small ducts, AMA, female; PSC = whole biliary tree, MRCP beading, IBD).

Primary biliary cholangitis — epidemiology & pathogenesis

- ▶ Prevalence ~100–200 per million, strong female preponderance (~9:1), median age at diagnosis ~50 years (40–60). The term *cholangitis* replaced *cirrhosis* in 2015 because most patients are now diagnosed pre-cirrhotic.
- ▶ An **immune-mediated** disease arising in genetically susceptible individuals; there is **chronic non-suppurative destructive cholangitis** of small and medium intrahepatic bile ducts mediated by CD4+/CD8+ T-cell cytotoxicity against biliary epithelium, with loss of tolerance to mitochondrial autoantigens.
- ▶ **Antimitochondrial antibodies (AMA)** are present in ~90–95% and are the immunologic hallmark. They target the **E2 component of the pyruvate dehydrogenase complex (PDC-E2)** plus the branched-chain 2-oxoacid (BCOADC-E2) and 2-oxoglutarate (OGDC-E2) dehydrogenase complexes on the **inner mitochondrial membrane**, recognising the bound *lipoic acid*. AMA are **diagnostic markers but are not themselves pathogenic** (titre does not track severity; they persist after transplant).
- ▶ **Genetic/environmental contributors:** association with HLA **DRB1\08** (*DQB1*); *concordance* ~60% in monozygotic twins; *triggers proposed include* molecular mimicry (e.g. *E. coli*, *Novosphingobium aromaticivorans*), *recurrent UTIs*, *smoking** (associated with advanced fibrosis) and xenobiotics (2-octynoic acid in cosmetics/hair dye).

Clinical features & associated diseases

- ▶ Up to 50–60% are **asymptomatic** at diagnosis (incidental cholestatic enzyme elevation). The two cardinal symptoms are **fatigue** (most disabling, out of proportion to disease) and **pruritus** (~50%, worse at night; pruritus *before* jaundice signals severe disease/poor prognosis).
- ▶ Signs reflecting chronic cholestasis: **hyperpigmentation** (melanin deposition), **xanthelasma** and **xanthomata**, hepatosplenomegaly, and — late — jaundice, ascites, variceal bleeding and encephalopathy. **Metabolic bone disease** (osteopenia/osteoporosis) and **fat-soluble vitamin (A, D, E, K) deficiency** complicate advanced disease.
- ▶ **Associated autoimmune conditions** are characteristic and should be screened:

Associated disease	Approx. frequency
Sjögren syndrome (sicca complex)	72–100%
Renal tubular acidosis	50–60%
Arthritis / arthropathy	4–42%
Gallstones	~33%
Autoimmune thyroiditis	15–20%
Systemic sclerosis / CREST variants	15–19%
Coeliac disease	1–7%

Associated disease	Approx. frequency
Hepatocellular carcinoma (with cirrhosis)	1–3% (~19-fold ↑ risk)

Histological staging (Ludwig / Scheuer — four stages)

Stage	Key feature
Stage 1	<i>Chronic non-suppurative destructive cholangitis</i> — portal inflammation centred on small bile ducts; the florid duct lesion (lymphocytic destruction ± non-caseating epithelioid granuloma) is near-diagnostic
Stage 2	Inflammation extends beyond portal tract into parenchyma (interface hepatitis / piecemeal necrosis); bile-duct destruction with ductular proliferation
Stage 3	Bridging fibrosis (septal fibrosis without regenerative nodules); progressive ductopenia
Stage 4	Cirrhosis (micronodular or macronodular) with fibrous septa and regenerative nodules

- ▶ The only consistently diagnostic histologic clue is **ductopenia** — absence of interlobular bile ducts in >50% of portal tracts.

Diagnosis & investigations

- ▶ **Biochemistry** — **cholestatic pattern**: elevated **alkaline phosphatase (ALP)** and **γ-glutamyl transpeptidase (GGT)**; ALT/AST only mildly raised (usually <3× ULN; >5× ULN suggests **PBC–autoimmune hepatitis overlap**). **IgM** characteristically elevated; **hypercholesterolaemia**; bilirubin rises late and is a poor-prognosis marker.
- ▶ **Diagnosis requires 2 of 3 criteria**: (1) chronic cholestasis with **ALP ≥1.5× ULN**, (2) **AMA titre ≥1:40**, (3) **compatible liver biopsy**. Biopsy is *not* needed in most AMA-positive patients.
- ▶ **AMA-negative PBC (~5–10%)**: confirm with PBC-specific antinuclear antibodies — **anti-sp100** (multiple-nuclear-dots) and **anti-gp210** (rim-like/membranous nuclear-envelope pattern, highly specific, poor prognosis). Here **liver biopsy and MRCP are mandatory** to exclude small-duct **PSC**, **IgG4 cholangiopathy**, **sarcoidosis**.
- ▶ **Imaging**: ultrasound/CT/MRI to exclude extrahepatic obstruction; periportal “**halo**” sign on MRI; **transient/MR elastography** for non-invasive fibrosis staging and prognosis.
- ▶ **Prognostic scores**: **Mayo risk score**, **GLOBE score** and **UK-PBC score** (incorporate age, bilirubin, albumin, ALP, platelets, transaminases); **Paris-II criteria** define low-risk biochemical response after 1 year of UDCA (ALP and AST <1.5× ULN, bilirubin ≤1 mg/dL).

Treatment of PBC

- ▶ **Ursodeoxycholic acid (UDCA) 13–15 mg/kg/day** is the first-line, disease-modifying drug — it improves liver biochemistry and histology, reduces varices/ascites/HCC risk, delays cirrhosis and improves transplant-free survival; responders have survival approaching that of healthy controls. ~20–40% are inadequate responders (more common in men and younger-onset disease).
- ▶ **Second-line agents for UDCA non-responders/intolerance** (avoid all in decompensated cirrhosis / portal hypertension):

Agent	Class / mechanism	Note
Obeticholic acid	Farnesoid-X-receptor (FXR) agonist	Start 5 mg/day; pruritus common; Child B/C → max 5 mg/week
Seladelpar (10 mg/day)	PPAR- δ agonist	Recently approved; ↓ALP, ↓pruritus
Elafibranor (80 mg/day)	PPAR- α/δ agonist	Recently approved
Bezafibrate / fenofibrate	Fibrate / PPAR agonist	Second-line; improve ALP even in non-responders

- ▶ **Symptomatic / complication management:** *Pruritus* — **cholestyramine** (4 g, dosed around breakfast), then **rifampin** 150–300 mg BD, **naltrexone**, **sertraline**, ondansetron; refractory cases → plasmapheresis. *Fatigue* — no proven drug; modafinil tried. *Bone disease* — **DEXA** at diagnosis, oral **calcium + vitamin D**, **bisphosphonates**. *Fat-soluble vitamin (A, D, E, K) screening/replacement* if bilirubin >2 mg/dL.
- ▶ **Liver transplantation** is the treatment of choice for end-stage PBC (also for intractable pruritus); consider at MELD ≥ 15 , bilirubin ≥ 6 mg/dL, or Mayo score ≥ 7.8 . One-year survival ~85–90%; PBC recurs in the graft in ~20% by 3 years (lower with UDCA prophylaxis and cyclosporine-based immunosuppression).

Primary sclerosing cholangitis (contrast)

- ▶ Chronic fibrosing inflammation of the **entire intra- and extrahepatic biliary tree** → multifocal strictures, biliary cirrhosis, portal hypertension.
- ▶ **65% pANCA-positive; 60–80% have inflammatory bowel disease (predominantly ulcerative colitis)** — colonoscopy advised at diagnosis.
- ▶ Diagnosis is **cholangiographic**: **MRCP (first-line)** shows multifocal strictures and beading (“beaded appearance”) with intervening normal/dilated segments.
- ▶ **No proven medical therapy** (high-dose UDCA 28–30 mg/kg/day is *harmful*); manage dominant strictures endoscopically; treat cholangitis with antibiotics; **liver transplantation** is definitive. Dreaded complication: **cholangiocarcinoma**.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Ludwig staging of PBC (4-panel):** draw a portal tract with central bile ductule and label — *Stage 1: florid duct lesion (lymphocytes + granuloma around bile duct, portal inflammation); Stage 2: interface hepatitis + ductular proliferation; Stage 3: bridging fibrous septa + ductopenia; Stage 4: cirrhosis with regenerative nodules.*
- ▶ **MRCP in PSC:** sketch intra- and extrahepatic ducts with labels — *multifocal strictures, intervening dilated segments (“beading”), dominant stricture, pruned-tree intrahepatic ducts.*

Clinical / Diagnostic significance

- ▶ A persistently isolated raised ALP/GGT in a middle-aged woman should prompt AMA testing — early PBC is treatable and UDCA started early prevents progression.
- ▶ Differentiating intrahepatic vs extrahepatic cholestasis (AMA + MRCP) is critical: extrahepatic obstruction needs decompression, intrahepatic does not.
- ▶ Marked transaminase elevation ($>5\times$ ULN) or high IgG flags PBC–AIH overlap, which may need adjunctive immunosuppression.
- ▶ Surveillance obligations: HCC screening once cirrhotic, endoscopy for varices, DEXA for bone disease, and screening for associated autoimmune disease (thyroid, coeliac, Sjögren).

High-yield exam pointers

- ▶ Biliary cirrhosis = chronic cholestasis → biliary fibrosis/ductopenia; subtypes **primary** (PBC, PSC, autoimmune cholangitis) and **secondary** (chronic extrahepatic obstruction).
- ▶ **PBC:** middle-aged woman, AMA (anti-PDC-E2) ~90–95%, raised ALP + IgM, pruritus + fatigue; diagnose by 2 of 3 (cholestatic ALP $\geq 1.5\times$ ULN, AMA $\geq 1:40$, biopsy).
- ▶ **Ludwig four stages:** 1 florid duct lesion → 2 interface hepatitis → 3 fibrosis → 4 cirrhosis; **ductopenia $>50\%$ portal tracts** is the diagnostic hallmark.
- ▶ UDCA 13–15 mg/kg/day is first-line and improves survival; non-responders → **obeticholic acid (FXR)**, **seladelpar/elafibranor (PPAR)**, **fibrates** — *avoid in decompensation.*
- ▶ **AMA-negative PBC** → look for **anti-sp100 / anti-gp210**; biopsy + MRCP mandatory.
- ▶ **Pruritus ladder:** cholestyramine → rifampin → naltrexone → sertraline.
- ▶ **PSC:** whole biliary tree, **pANCA**, **UC association**, **MRCP beading**, risk of **cholangiocarcinoma**, no effective drug, transplant definitive.
- ▶ Indications/markers for **transplant** in PBC: Mayo ≥ 7.8 , MELD ≥ 15 , bilirubin ≥ 6 ; recurs in ~20% of grafts.

SOURCE & COVERAGE

Celiac Disease

Asked in: Paper II Nov 2019 — RGUHS MD General Medicine

Definition / Introduction — Celiac disease (celiac sprue, gluten-sensitive enteropathy) is a chronic, immune-mediated enteropathy of the small intestine precipitated by dietary **gluten** in genetically predisposed (HLA-DQ2 / DQ8) individuals. It is characterised by **villus atrophy, crypt hyperplasia and intraepithelial lymphocytosis** of the proximal small bowel, the presence of **anti-tissue transglutaminase (tTG-2) autoantibodies**, and clinical plus histological recovery on a strict **gluten-free diet (GFD)** with relapse on gluten re-exposure. Global seroprevalence is ~1.4% (biopsy-confirmed ~0.7%), making it one of the commonest lifelong food-related disorders.

Etiopathogenesis (the gluten–genes–immunity triad)

- ▶ **The antigen (gluten):** the water-insoluble storage proteins of wheat, rye and barley. Gluten = **prolamins + glutenins**; the toxic prolamins are *gliadin* (wheat), *secalin* (rye) and *hordein* (barley). These are rich in **glutamine (~30%) and proline (~15%)**, rendering them resistant to luminal digestion. *Avenin* (oats) has intermediate content, so most patients tolerate **uncontaminated oats**; rice, corn, sorghum and millet are non-toxic.
- ▶ **Genetic predisposition:** HLA-DQ2 is present in >90% of patients and HLA-DQ8 in almost all the remainder; one haplotype is *necessary but not sufficient*. As they occur in 25–35% of the general population, a positive test is non-diagnostic, but a **negative HLA-DQ2/DQ8 has a negative predictive value >99%** (used to *exclude* disease). First-degree relative prevalence is 10–15%; monozygotic-twin concordance reaches 49–83%.
- ▶ **Immune mechanism:** tissue **transglutaminase-2 (tTG-2)** *deamidates* glutamine residues of gliadin to negatively charged glutamic acid, which binds avidly to the antigen-binding groove of DQ2/DQ8 on antigen-presenting cells. This activates **gliadin-specific CD4⁺ T-cells** in the lamina propria, releasing IFN- γ , TNF- α , IL-2, IL-6 (adaptive response). The enterocyte/macrophage

cytokine IL-15 drives the innate arm, expands CD8⁺ and γ/δ intraepithelial lymphocytes (IELs) and bridges the two — γ/δ IELs may rise from <10% to ~35% (a *hallmark*). The net result is enterocyte injury, crypt hyperplasia and villus atrophy. tTG-2 within the endomysium is the target autoantigen, explaining the diagnostic serology.

Clinical spectrum

Presentation is protean and has shifted from the “classical” malabsorptive child to the **non-classical / silent adult** (5th decade most common age at diagnosis).

- ▶ **Classical (GI):** chronic/episodic diarrhoea, steatorrhoea, abdominal bloating, flatulence, weight loss; in infants — failure to thrive, irritability, hypotonia, muscle wasting, abdominal distension after weaning.
- ▶ **Non-classical / extraintestinal:** unexplained **iron-deficiency anaemia** (commonest; consider in IDA without GI blood loss), fatigue, **osteopenia/osteoporosis** (>70% have low bone density), **dermatitis herpetiformis**, aphthous stomatitis, dental enamel defects, raised aminotransferases (~27–40%), **gluten ataxia** and peripheral neuropathy, **infertility/recurrent miscarriage**, short stature, delayed puberty, amenorrhoea.
- ▶ **Silent / potential:** asymptomatic seropositive individuals detected on screening (relatives, T1DM, Down syndrome). Up to ~40% of seropositive patients have no symptoms.
- ▶ **Celiac crisis:** rare, life-threatening profuse diarrhoea with dehydration, electrolyte derangement, metabolic acidosis, hypocalcaemia and hypoproteinaemia — needs IV fluids $\pm$ glucocorticoids.
- ▶ **Dermatitis herpetiformis (DH):** intensely pruritic, symmetrical papulovesicles over extensor surfaces, buttocks, trunk and scalp — the “*celiac disease of the skin*.” Granular **IgA deposits at the dermal papillae**; autoantigen is **epidermal (type 3) transglutaminase**. ~80% have enteropathy. Responds to **dapsone** (1–2 mg/kg/day) for skin plus a GFD for the gut.

Diagnosis

Diagnosis (in an adult on a **gluten-containing diet**) rests on **serology + duodenal biopsy**.

Test	Role / remark
IgA anti-tTG-2	Screening test of choice — sensitivity ~98%, specificity ~98%
Total serum IgA	Co-test to detect selective IgA deficiency (in 2–3% of celiacs $\rightarrow$ false-negative tTG)
IgG tTG / IgG-DGP	Used when IgA deficient
IgA endomysial antibody (EMA)	Very high specificity (~100%); labour-intensive, confirmatory
Anti-deamidated gliadin peptide (DGP)	Useful adjunct, IgG class in IgA deficiency

Test	Role / remark
Native anti-gliadin antibody (AGA)	Not recommended — low specificity
HLA-DQ2 / DQ8	High NPV; used to rule out disease, esp. in self-treated patients

- ▶ **Small-intestinal biopsy** (gold standard): take 4–6 biopsies from the 2nd/3rd part of the duodenum plus the bulb (lesions are patchy and proximal). Histology: **villus atrophy**, **crypt hyperplasia**, **increased IELs** (≥ 25 per 100 enterocytes) and lamina propria plasmacytosis.
- ▶ **Marsh classification** of severity (see table).
- ▶ **Endoscopic clues** (insensitive): scalloping/loss of duodenal folds, mosaic/nodular pattern, fissuring — a normal-looking duodenum does **not** exclude disease.
- ▶ **Pediatric biopsy-free pathway** (ESPGHAN): symptoms + IgA-tTG $\geq 10 \times$ ULN + positive EMA on a separate sample + compatible HLA — may avoid biopsy (not universally adopted in adults/US).
- ▶ **Gluten challenge** (for patients already on a GFD with uncertain diagnosis): ~2–4 g gluten/day (1–2 slices of bread); biopsy may be diagnostic by 2 weeks, serology rise by ~4 weeks.

Marsh stage	Histology
0 (pre-infiltrative)	Normal mucosa
1 (infiltrative)	Normal villi, increased IELs
2 (hyperplastic)	Increased IELs + crypt hyperplasia
3 (destructive)	Villus atrophy — 3a partial, 3b subtotal, 3c total
4 (hypoplastic/atrophic)	Total villus atrophy with crypt hypoplasia

Treatment and monitoring

- ▶ **Lifelong strict gluten-free diet** is the cornerstone — eliminate **wheat, rye, barley** (and contaminated oats); beware *hidden gluten* in processed foods, medications and cross-contamination. **Dietitian** referral and patient education are essential. Most improve within 2–6 months; serology normalises over 1–2 years.
- ▶ **Nutritional repletion**: iron, folate, vitamin B12, calcium, vitamin D, zinc, and fat-soluble vitamins (A, E, K) as required; ensure ~1500 mg calcium/day. Treat coexistent **lactose intolerance** (transient secondary lactase deficiency) until mucosa heals.
- ▶ **Bone health**: DEXA scan within 1 year of diagnosis; calcium + vitamin D, and **bisphosphonates** for established osteoporosis.
- ▶ **Glucocorticoids / budesonide**: *not* for routine disease — reserved for **celiac crisis** and **refractory disease**.

- ▶ **Monitoring:** clinic review at 3–6 monthly intervals in year 1 with serial IgA-tTG (falls confirm adherence; half-life ~6–8 weeks). Persistently positive serology = ongoing gluten exposure. Follow-up duodenal biopsy at ~2 years to confirm mucosal healing, especially if symptoms persist.

Complications and associated disorders

- ▶ **Non-responsive celiac disease (NRCD)** (~10%): persistent symptoms despite ≥6–12 months GFD — commonest cause is **continued (often inadvertent) gluten ingestion**; also lactose/fructose intolerance, SIBO, pancreatic insufficiency, microscopic colitis, IBS.
- ▶ **Refractory celiac disease (RCD)** (~0.3–1.5%): villus atrophy persisting despite ≥12 months strict GFD with negative serology.
 - **Type I** — normal *polyclonal* IEL phenotype; responds to budesonide/steroids ± azathioprine.
 - **Type II** — *aberrant clonal* IELs with **loss of surface CD3/CD8** and **monoclonal TCR-γ rearrangement**; steroid-resistant, treated with cladribine/autologous stem-cell transplant; ~50% progress to lymphoma at 5 years (poor prognosis).
- ▶ **Enteropathy-associated T-cell lymphoma (EATL), ulcerative jejunoileitis, and small-bowel adenocarcinoma** — suspect when a previously controlled patient develops new weight loss, pain, obstruction or bleeding.
- ▶ **Hyposplenism** (up to 50% of adults) — thrombocytosis, **Howell-Jolly bodies**, risk of pneumococcal sepsis → pneumococcal vaccination.
- ▶ **Associations:** **type 1 diabetes mellitus** (~5–6%), autoimmune thyroid disease, **selective IgA deficiency**, autoimmune hepatitis, **Down and Turner syndromes**, Sjögren syndrome, IgA nephropathy, microscopic colitis.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Small-intestinal villus histology — normal vs celiac:** draw two adjacent panels. *Normal* — tall finger-like villi (villus:crypt ≈ 3–5:1), columnar enterocytes, few IELs. *Celiac* — **flat mucosa / villus atrophy, elongated hyperplastic crypts, increased intraepithelial lymphocytes, dense lamina propria plasma-cell infiltrate**. Label: *villus atrophy, crypt hyperplasia, intraepithelial lymphocytes, lamina propria infiltrate*.
- ▶ **Pathogenesis flow diagram:** Dietary gliadin → ↑intestinal permeability → tTG-2 deamidation of gliadin → binding to HLA-DQ2/DQ8 on APC → CD4⁺ T-cell activation (IFN-γ, TNF-α) + IL-15-driven CD8⁺/γδ IELs → villus atrophy + anti-tTG antibodies. Label each labelled box.

Clinical / Diagnostic significance

- ▶ Test for celiac disease in **unexplained iron-deficiency anaemia, osteoporosis, transaminitis, infertility, IBS-D phenotype, and gluten ataxia** — it is frequently underdiagnosed in adults.

- ▶ Always check serology and biopsy **BEFORE** starting a GFD; pre-treatment gluten avoidance causes false-negative results.
- ▶ Screen **high-risk groups**: first-degree relatives, T1DM, autoimmune thyroid disease, Down/Turner syndrome.
- ▶ A **rising or non-falling tTG** on treatment signals ongoing gluten exposure; **new alarm symptoms** in a stable patient mandate evaluation for RCD/EATL.

High-yield exam pointers

- ▶ Triad: **gluten + HLA-DQ2/DQ8 + tTG-2 autoimmunity**; toxic prolamins = gliadin/secalin/hordein; oats (avenin) usually safe.
- ▶ **IgA anti-tTG = screening test of choice** (sens/spec ~98%); always co-test **total IgA**.
- ▶ HLA-DQ2/DQ8 used to **exclude** disease (NPV >99%), not to confirm.
- ▶ **Marsh staging** (0 → 4); diagnosis needs villus atrophy + crypt hyperplasia + raised IELs, not IELs alone.
- ▶ Biopsy **proximal duodenum + bulb**, 4–6 samples; lesion is patchy and proximal.
- ▶ **Dermatitis herpetiformis** = granular IgA at dermal papillae, **epidermal tTG**, treat with **dapsone + GFD**.
- ▶ Complications: RCD type I vs II, EATL, **ulcerative jejunoileitis**, **small-bowel adenocarcinoma**, **hyposplenism** (Howell-Jolly bodies), **osteoporosis**.
- ▶ **Lifelong strict GFD** is the only definitive therapy; steroids only for celiac crisis/RCD.
- ▶ *Eponyms*: first described by **Areataeus of Cappadocia**; **Samuel Gee** (1888); **Dicke** linked wheat during the Dutch famine.

Approach to Chronic Diarrhea

Asked in: Paper III Nov 2022 — RGUHS MD General Medicine

Definition / Introduction — Diarrhea is the passage of abnormally liquid or unformed stools at increased frequency; on a typical Western diet a **stool weight >200 g/day** is generally considered diarrheal. By duration it is **acute (<2 weeks)**, **persistent (2–4 weeks)**, and **chronic (>4 weeks)**. Diarrhea lasting **>4 weeks warrants evaluation to exclude serious underlying pathology**, and unlike acute diarrhea (mostly infective), **most causes of chronic diarrhea are non-infectious**. Classifying chronic diarrhea by its **predominant pathophysiologic mechanism** allows a rational, cost-effective approach, though many diseases produce diarrhea by more than one mechanism.

Relevant physiology & conditions to exclude first

- ▶ About **9 L of fluid enter the GI tract daily**, ~1 L reaches the colon, and only **~0.2 L is excreted in stool**; the colon has large absorptive reserve (can recover up to ~4× the usual 0.8 L/d), so diarrhea reflects altered fluid/electrolyte handling, motility, or both.
- ▶ Distinguish true diarrhea from mimics (different algorithms): **pseudodiarrhea** (frequent small-volume stools with urgency/tenesmus, <200 g/d — seen in IBS, proctitis); **fecal incontinence** (involuntary discharge from neuromuscular or anorectal structural disease); and **overflow diarrhea** from **fecal impaction** in elderly/nursing-home patients (detectable on rectal exam).
- ▶ First step in any chronic diarrhea: **exclude an iatrogenic cause — medications and prior surgery**.

Pathophysiologic classification (Harrison Table 49-3)

Mechanism	Key stool features	Representative causes
Secretory	Watery, large-volume, painless, persists with fasting, no osmotic gap	Stimulant laxatives (senna, bisacodyl, castor oil), chronic ethanol, drugs/toxins (arsenic, olmesartan), bile acid diarrhea (BAD) , bowel resection/disease/fistula, partial obstruction/impaction, hormonal tumors (carcinoid, VIPoma, gastrinoma, medullary thyroid carcinoma, mastocytosis, villous adenoma), Addison's disease, congenital ion-transport defects
Osmotic	Watery, ceases with fasting, osmotic gap >50 , low fecal pH (carbohydrate)	Osmotic laxatives (Mg^{2+} , PO_4^{3-} , SO_4^{2-}), lactase/disaccharidase deficiency , non-absorbable carbohydrates (sorbitol, fructose, lactulose, PEG), wheat and FODMAP intolerance

Mechanism	Key stool features	Representative causes
Steatorrheal (fat malabsorption)	Greasy, foul-smelling, difficult-to-flush, weight loss, nutrient deficiencies	Intraluminal maldigestion (pancreatic exocrine insufficiency, bacterial overgrowth, bariatric surgery, liver disease); mucosal malabsorption (celiac, Whipple's, abetalipoproteinemia, ischemia, drug-induced); post-mucosal lymphatic obstruction , amyloidosis
Inflammatory	Pain, fever, blood , fecal leukocytes/calprotectin	IBD (Crohn's, ulcerative colitis), microscopic (lymphocytic/collagenous) colitis , immunodeficiency, eosinophilic gastroenteritis , radiation injury, GI malignancy
Dysmotile	Often secretory-like; may have mild steatorrhea (≤ 14 g/d)	IBS (incl. post-infectious), visceral neuromyopathy, hyperthyroidism, prokinetic drugs, post-vagotomy, diabetic diarrhea
Factitial / Iatrogenic	Variable; hypokalemia, hypotension	Laxative abuse, Munchausen, eating disorders; cholecystectomy, ileal resection, bariatric surgery, vagotomy/fundoplication

Mechanistic high-yield points

- ▶ Stool osmotic gap = $290 - 2 \times ([\text{stool Na}^+] + [\text{stool K}^+])$. Gap >50 mosmol/L = osmotic; <50 = secretory. (Fecal osmolality measured directly can be falsely elevated by bacterial carbohydrate metabolism.)
- ▶ **Bile acid diarrhea (BAD)**: dihydroxy bile acids escaping absorption (e.g., Crohn's ileitis or resection of <100 cm terminal ileum) cause **cholerheic diarrhea**; idiopathic BAD reflects reduced FGF-19 feedback and may explain **~40% of unexplained chronic diarrhea** (~1% of the population). Diagnosed by elevated fasting **serum 7 α C4** or fecal bile acids.
- ▶ **Lactase deficiency** is one of the commonest causes of chronic diarrhea in adults (osmotic, low fecal pH).
- ▶ **Pancreatic exocrine insufficiency** manifests when **$>90\%$ of secretory function is lost**; fecal fat is normally <7 g/d, rises to **14 g/d** with rapid transit, **15–25 g** in small-intestinal disease, and **>32 g** with pancreatic insufficiency.

- ▶ **Hormonal secretory diarrheas:** carcinoid (serotonin, flushing, wheezing, right-heart valvular disease); **VIPoma** = pancreatic cholera / **WDHA syndrome** (Watery Diarrhea, Hypokalemia, Achlorhydria), stool can exceed 3 L/d (up to 20 L); gastrinoma (diarrhea in up to one-third); medullary thyroid carcinoma (calcitonin/prostaglandins); systemic mastocytosis (urticaria pigmentosa); colorectal villous adenoma.
- ▶ **Congenital electrolyte defects:** congenital chloridorrhea (**DRA gene**, $\text{Cl}^-/\text{HCO}_3^-$ exchange, alkalosis) and congenital sodium diarrhea (**NHE3 gene**, acidosis).

Clinical approach: history and examination

- ▶ **History:** onset/duration/pattern; aggravating (especially diet) and relieving factors; **stool character** (volume, nocturnal episodes, undigested food/fat, blood, consistency by **Bristol Stool Form Scale**); weight loss, fever, pain; exposures (travel, antibiotics, contacts); medications and surgery; family history of IBD or celiac disease; extraintestinal features (skin, arthralgia, oral aphthae).
- ▶ **Examination (Table 49-4):** look for signs of **malabsorption/IBD** (anemia, **dermatitis herpetiformis**, clubbing, edema, arthritis); features of **autonomic neuropathy or collagen-vascular disease** (pupils, orthostasis, skin); abdominal mass/tenderness; **rectal/anal sphincter** abnormalities; mucocutaneous clues — **flushing** (carcinoid), **erythema nodosum/pyoderma gangrenosum** (IBD), **thyroid mass**, wheeze, heart murmurs, lymphadenopathy, perianal fistula.

Diagnostic workup (rational triage)

- ▶ **Routine/limited organic screen:** CBC, chemistries, CRP, ESR, iron, folate, B12, TTG-IgA (on gluten) for celiac, serum 7aC4 (C4), stool fat, fecal calprotectin. Leukocytosis/raised CRP-ESR → inflammation; eosinophilia → parasites, allergy, eosinophilic gastroenteritis.
- ▶ **Quantitative stool studies** when weight >200 g/d: electrolytes (osmotic gap), pH, occult blood, leukocytes/calprotectin, fat and bile-acid quantitation, and laxative screen.
- ▶ **Secretory pattern:** reconsider drugs/surreptitious laxatives; stool **multiplex PCR/cultures** (incl. *Aeromonas*, *Plesiomonas*), ova & parasites, **Giardia antigen** (most sensitive for giardiasis); **breath tests** (glucose/lactulose H_2/CH_4) for bacterial overgrowth; **peptide hormone screen** when indicated — gastrin, VIP, calcitonin, thyroid hormone/TSH, **urinary 5-HIAA**, histamine.
- ▶ **Osmotic pattern:** test for **lactose/fructose intolerance**, fecal magnesium and laxative levels; **low fecal pH** indicates carbohydrate malabsorption.
- ▶ **Fatty (steatorrheal):** **endoscopy with small-bowel biopsy** ± aspirate for quantitative culture; small-bowel imaging (CT enterography, MR enteroclysis); confirm **pancreatic exocrine insufficiency** with secretin-CCK stimulation or indirect tests (**fecal elastase/chymotrypsin**, **bentiromide** — low sensitivity/specificity).

- ▶ **Inflammatory:** blood/leukocytes in stool → stool pathogens, **colonoscopy with biopsies** (random biopsies of normal-appearing colon needed to diagnose **microscopic colitis**), and small-bowel imaging as indicated. **BAD** confirmed by radiolabeled bile-acid retention test (SeHCAT), serum 7αC4/FGF-19, fecal bile acids, or therapeutic trial of a sequestrant.
- ▶ A **therapeutic trial** is appropriate, definitive and cost-effective when a specific diagnosis is suggested early (e.g., lactose-free diet for lactose intolerance; metronidazole for suspected giardiasis after backpacking; **cholestyramine/colestipol/colesevelam** for post-ileal-resection bile-acid diarrhea).

Treatment (curative, suppressive, or empirical)

- ▶ **Curative** when the cause is eradicable: resect colorectal cancer, antibiotics for Whipple's disease or tropical sprue, stop offending drug.
- ▶ **Suppressive (mechanism-directed):** lactose restriction (lactase deficiency); gluten exclusion (celiac); anti-inflammatory agents (IBD); **bile-acid sequestrants** (BAD); **PPIs** for gastrinoma acid hypersecretion; **octreotide** for malignant carcinoid; **indomethacin** for medullary thyroid carcinoma; **pancreatic enzyme replacement** for pancreatic insufficiency; budesonide/bismuth/loperamide for microscopic colitis.
- ▶ **Empirical / symptomatic:** opioid antimotility agents — **loperamide or diphenoxylate** for mild-moderate watery diarrhea, **codeine or tincture of opium** for severe (avoid in severe IBD — risk of toxic megacolon); **clonidine** (α_2 -agonist) for **diabetic diarrhea**; **5-HT₃ antagonists** (**alosetron, ondansetron**), **rifaximin**, and **eluxadoline** for IBS-diarrhea; **crofelemer** for AIDS-associated diarrhea. For all patients: **fluid/electrolyte repletion** and **fat-soluble vitamin replacement** in chronic steatorrhea.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Stepwise algorithm** (Harrison Fig. 49-4) — “Approach to chronic diarrhea”: Box 1
Chronic diarrhea → *Exclude iatrogenic (medication, surgery)* → branch by presentation into
Blood p.r. → colonoscopy + biopsy; **Fatty diarrhea** → small-bowel imaging, biopsy, aspirate; **Pain relieved by BM/incomplete evacuation** → suspect IBS; no
blood/malabsorption features → functional diarrhea / dietary exclusion (lactose, sorbitol). Central box: Limited organic screen — hematology, chemistry, CRP, ESR, Fe, folate, B12, TTG-IgA, C4, stool fat, calprotectin → then stool-fat thresholds (>20 g/d = pancreatic; 14–20 g/d = small-bowel cause; <14 g/d = normal) and 48 h stool bile acid → BA sequestrant.
- ▶ **Stool osmotic gap bar/flow label:** $Gap = 290 - 2 \times (Na + K)$; >50 = osmotic; <50 = secretory.

Clinical / Diagnostic significance

- ▶ The **fasting test** is a key bedside discriminator: secretory diarrhea persists with fasting; osmotic diarrhea stops.
- ▶ **Red flags mandating prompt structural evaluation (colonoscopy)**: blood/hematochezia, weight loss, anemia, nocturnal diarrhea, older age, or any middle-aged/older patient with inflammatory-type diarrhea — to exclude **colorectal carcinoma** and IBD.
- ▶ **Microscopic colitis** is clinically indistinguishable from IBS-D/functional diarrhea and needs **biopsy of normal-appearing colon**; associated with NSAIDs, statins, PPIs, SSRIs and middle-aged women.
- ▶ **Factitial diarrhea** accounts for up to 15% of unexplained diarrheas at tertiary centers (laxative abuse, Munchausen); suspect with hypokalemia, hypotension, very high/low stool osmolarity (water/urine added).
- ▶ In **two-thirds of cases the cause is unclear after the first encounter**, justifying staged, triage-guided testing rather than indiscriminate investigation.

High-yield exam pointers

- ▶ Chronic diarrhea = **>4 weeks**; **>200 g/d**; most causes **non-infectious**.
- ▶ **Osmotic gap >50 = osmotic**; **<50 = secretory**. Secretory = high-volume, painless, **persists on fasting**.
- ▶ **BAD** $\approx$ **40% of unexplained chronic diarrhea**; ileal resection **<100 cm** $\rightarrow$ choleraic; treat with **cholestyramine/colesevelam**; diagnose by **serum 7 α C4 / SeHCAT**.
- ▶ **Fecal fat**: normal **<7 g/d**; **>32 g** suggests pancreatic insufficiency (**>90% function lost**).
- ▶ **VIPoma** = **WDHA / pancreatic cholera**; carcinoid $\rightarrow$ urinary **5-HIAA**; gastrinoma $\rightarrow$ **PPI**; medullary thyroid Ca $\rightarrow$ **indomethacin**.
- ▶ **Lactase deficiency** = commonest osmotic cause in adults; **low fecal pH**.
- ▶ First-line empirical antidiarrheal = **loperamide/diphenoxylate**; avoid antimotility agents in severe IBD (**toxic megacolon**).
- ▶ Limited organic screen mnemonic: **CBC, CRP/ESR, Fe/folate/B12, TTG-IgA, C4, stool fat, calprotectin**.
- ▶ Always exclude **pseudodiarrhea, fecal incontinence, overflow (impaction)**, and **iatrogenic** causes first.

SOURCE & COVERAGE

Harrison's Principles of Internal Medicine, 22e — Ch 49 "Diarrhea and Constipation" (definitions, Table 49-3 classification, Table 49-4 examination, Fig. 49-4 algorithm, evaluation and treatment of chronic diarrhea). Drug doses are not specified in the chapter and have been

omitted as the source gives agents qualitatively; SeHCAT/WDHA expansions and the Bristol scale are standard textbook internal medicine consistent with the chapter. No coverage gap.

Criteria for Diagnosis and Management of Irritable Bowel Syndrome

Asked in: Paper II May 2025 — RGUHS MD General Medicine

Definition / Introduction — Irritable bowel syndrome (IBS) is a chronic **functional bowel disorder** (a disorder of *gut–brain interaction*) characterised by **recurrent abdominal pain associated with altered bowel habit** in the absence of any detectable structural, biochemical or organic abnormality. No pathognomonic marker exists, so the diagnosis is **positive and clinical**, resting on the symptom-based **Rome IV criteria** plus the *exclusion of alarm features*. It affects ~10% of adults worldwide, presents before age 45 in most, and is 2–3 times commoner in women (who form ~80% of severe cases).

Symptom-based diagnostic criteria (evolution)

- ▶ Diagnosis has progressively moved from physician-led exclusion scores to **positive symptom criteria**: *Manning (1978) → Kruis (1984) → Rome I → II → III → Rome IV (2016)*.
- ▶ **Manning criteria** (≥3 of 6 favour IBS): pain eased by defecation; looser stools at onset of pain; more frequent stools at onset of pain; abdominal distension; mucus per rectum; sensation of incomplete evacuation.
- ▶ **Kruis criteria** combine a patient symptom score with *physician exclusion items* (abnormal examination, ESR >20 mm/2 h, anaemia, leucocytosis >10,000, blood in stool) that argue against IBS.
- ▶ **Rome IV** is the current standard — more stringent than Rome III: pain must occur ≥1 day/week, and the word “discomfort” has been *deleted*. Painless diarrhoea or constipation does **not** qualify as IBS.

Rome IV diagnostic criteria & subtyping

Element	Rome IV requirement
Core	Recurrent abdominal pain, on average ≥1 day per week in the last 3 months
Associated with ≥2 of	(1) Related to defecation ; (2) Associated with a change in frequency of stool; (3) Associated with a change in form/appearance of stool
Time rule	Criteria met for the last 3 months , with symptom onset ≥6 months before diagnosis

- ▶ **Subtyping** uses the **Bristol Stool Form Scale (BSFS)** on days with abnormal bowel habit (threshold = >25% of bowel movements):
 - IBS-C (constipation): >25% stools **Bristol 1–2** (hard/lumpy) and <25% Bristol 6–7.
 - IBS-D (diarrhoea): >25% stools **Bristol 6–7** (loose/watery) and <25% Bristol 1–2.
 - IBS-M (mixed): >25% hard **and** >25% loose stools.
 - IBS-U (unsubtyped): abnormality insufficient to fit the above.
- ▶ Subtypes are **unstable** — ~75% of patients change subtype over a year, and ~29% switch between IBS-C and IBS-D, so the bowel pattern is recorded as predominant on *symptomatic days*.
- ▶ **Supportive (non-diagnostic) symptoms**: straining, urgency, incomplete evacuation, passage of mucus, bloating and visible distension (distension worsens through the day; bloating affects ≥60%). Frequent overlap occurs with **dyspepsia, GERD, fibromyalgia, chronic fatigue, headache, backache and genitourinary symptoms**.

Pathophysiology (multifactorial — the “biopsychosocial” model)

- ▶ **Altered GI motility** — exaggerated, prolonged post-prandial and distension-evoked colonic contractions; rapid transit in IBS-D, slow transit/pelvic-floor dyssynergia in IBS-C.
- ▶ **Visceral hypersensitivity** — lowered pain threshold to rectal balloon distension; selective for visceral (not somatic) afferents; *TRPV1* up-regulation on sensory neurons.
- ▶ **Brain–gut axis dysregulation** — abnormal central processing (functional MRI: heightened mid-cingulate and prefrontal activation), HPA-axis and autonomic dysfunction; psychiatric comorbidity (anxiety, depression, somatisation) in up to 80%.
- ▶ **Post-infectious IBS** — >10% of patients develop IBS after infectious enteritis (4-fold risk); commoner in young women, severe/bacterial-parasitic infection, antibiotic use and psychological comorbidity.
- ▶ **Low-grade mucosal immune activation** — mast cells adjacent to nerves, raised IL-6/IL-1 β /TNF, increased permeability (“leaky gut”, chiefly IBS-D/post-infectious).
- ▶ **Gut dysbiosis** — reduced diversity; ↓ *Bifidobacterium* and *Faecalibacterium*, ↑ Enterobacteriaceae; SIBO over-represented.
- ▶ **Abnormal serotonin signalling** (↑ enterochromaffin cells, *TPH1* polymorphism, down-regulated *SERT*); **bile-acid malabsorption** in up to ~25–30% of IBS-D; genetic contributions (*SERT* polymorphism; rare *SCN5A*/ $\text{Na}_v1.5$ mutation in IBS-C).

Approach to diagnosis & limited investigation

- ▶ Diagnosis is **clinical**: a positive history fulfilling Rome IV + a normal/near-normal examination + **absence of alarm features**, then confirm the subtype with the BSFS.
- ▶ **Alarm (“red flag”) features mandating organic work-up**: rectal bleeding/melaena, unexplained weight loss, iron-deficiency anaemia, **nocturnal** pain/diarrhoea, **fever**, progressive dysphagia,

recurrent vomiting, short symptom history, **new onset after age 50**, family history of colorectal cancer/IBD/coeliac disease, abdominal/rectal mass, or signs of malabsorption.

- ▶ **Examination** is usually normal; mild colonic tenderness may occur. *Carnett test* distinguishes abdominal-wall from visceral pain; a digital rectal examination screens for **pelvic-floor dyssynergia**, and pelvic examination excludes ovarian malignancy in older women with new symptoms.
- ▶ **Limited, targeted tests** (avoid over-investigation): **CBC, CRP, faecal calprotectin** (or lactoferrin) to exclude IBD — IBD risk is <1% if CRP ≤ 0.5 mg/dL or calprotectin ≤ 40 μ g/g (CMDT flags >50 μ g/g for endoscopy); **coeliac serology (anti-tTG IgA)** especially in IBS-D; stool ova/parasite or *Giardia* PCR where parasitic infection is likely/endemic.
- ▶ **Colonoscopy** is reserved for alarm features, persistent IBS-D, or first presentation at/after age 45–50 (to exclude malignancy), with **random biopsies for microscopic colitis**. Reserve hydrogen breath tests (lactose/SIBO) and **anorectal manometry + balloon-expulsion** (dyssynergia) for selected patients; routine SIBO testing is *not* recommended.
- ▶ **Differential diagnosis**: IBD, colorectal cancer, microscopic colitis, coeliac disease, lactase deficiency, bile-acid diarrhoea, SIBO, giardiasis, thyroid disease, drug-induced bowel change, and (with painful constipation) porphyria and lead poisoning.

Management

Principles — stepwise and severity-based (Harrison: ~70% mild, ~25% moderate, ~5% severe/refractory). Foundation for all is **reassurance, education and a strong therapeutic relationship**; drugs are *adjunctive* and targeted at the dominant symptom.

- ▶ **General & dietary measures (first line, all patients)**: explain the gut–brain mechanism and chronic relapsing course; identify and avoid food/stress triggers; encourage moderate exercise.
 - **Soluble fibre** (psyllium 20–30 g/day total, titrated slowly) helps global symptoms/constipation; **avoid insoluble fibre/bran** (worsens gas/bloating).
 - **Low-FODMAP diet** — relieves symptoms (especially pain and bloating) in 50–80%; delivered as a **3-step protocol**: 2–6-week *restriction* of all FODMAP groups → structured *reintroduction* to find triggers → long-term *personalisation*. Avoid in those with eating disorders.
- ▶ **Antispasmodics (pain/cramps)**: anticholinergics **dicyclomine** or **hyoscyamine** given ~30 min before meals to blunt the gastrocolic reflex; **enteric-coated peppermint oil** improves global symptoms and pain (main side-effect heartburn).
- ▶ **IBS-D pharmacotherapy**:
 - **Loperamide** 2–4 mg as needed (max 12 mg/day) — improves stool frequency/urgency but not pain.

- **Bile-acid sequestrants** — cholestyramine or colesevelam (for the ~25–30% with bile-acid malabsorption).
- **Eluxadoline** 75–100 mg bid — mixed μ -/ κ -opioid agonist + δ -opioid antagonist; *contraindicated* after cholecystectomy, in significant alcohol use or prior pancreatitis (risk of pancreatitis / sphincter-of-Oddi spasm).
- **Alosetron** 0.5–1 mg bid — selective 5-HT₃ antagonist, restricted to women with severe IBS-D under a risk-management programme (ischaemic-colitis risk).
- **Rifaximin** 550 mg tid × 14 days — non-absorbed antibiotic for IBS-D/bloating; re-treatment effective on relapse.
- ▶ **IBS-C pharmacotherapy:**
 - **Osmotic laxative** — polyethylene glycol (PEG 3350) 17 g/day; improves frequency/consistency but not pain. *Avoid lactulose/sorbitol* (gas, distension).
 - **Secretagogues** — **lubiprostone** 8 μ g bid (type-2 chloride-channel/ClC-2 activator), **linaclotide** 290 μ g od and **plecanatide** 3 mg od (guanylate cyclase-C agonists), **tenapanor** 50 mg bid (intestinal NHE3 inhibitor) — all FDA-approved for IBS-C.
 - **Tegaserod** (5-HT₄ agonist) — re-approved for women <65 years with ≤ 1 cardiovascular risk factor and no ischaemic CVD.
- ▶ **Central neuromodulators (pain-predominant / moderate–severe): tricyclic antidepressants** (imipramine, nortriptyline, desipramine) started low (10–25 mg at night) — analgesic/visceral effects independent of mood, and useful in IBS-D (anticholinergic, slows transit); **SSRIs** (e.g. sertraline, citalopram, paroxetine, fluoxetine) may help IBS-C and comorbid mood disorder.
- ▶ **Psychological therapies (severe/refractory):** cognitive-behavioural therapy, gut-directed hypnotherapy and relaxation/yoga; refer disabling cases to specialist/pain services.
- ▶ **Probiotics:** evidence weak — **not recommended** by current AGA/ACG guidelines.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Diagram 1 — Bristol Stool Form Scale with IBS subtyping grid.** Draw the 7 stool types in a column (Type 1 *separate hard lumps* → Type 7 *entirely watery*) and an axis grid with labels: % BM hard/lumpy (Bristol 1–2) vs % BM loose/watery (Bristol 6–7), the 25% threshold lines, and the four quadrants labelled IBS-C, IBS-D, IBS-M, IBS-U.
- ▶ **Diagram 2 — Pathophysiology / brain–gut axis schematic.** Central box “IBS” with radiating labelled arrows: *Motility abnormalities*, *Visceral hypersensitivity (TRPV1)*, *Brain–gut interaction (HPA axis, autonomic dysfunction)*, *“Leaky gut”/altered permeability + mast-cell activation*, *Gut dysbiosis*, *Bile-acid malabsorption*, *Serotonin/SERT*, *Genetic factors (SERT, SCN5A)*, *Psychological (anxiety/depression/somatisation)*.

Clinical / Diagnostic significance

- ▶ IBS is a **positive diagnosis** — confident application of Rome IV plus absence of alarm features avoids costly, anxiety-reinforcing over-investigation.
- ▶ **Faecal calprotectin/CRP** are the key non-invasive screens to separate IBS from IBD; **coeliac serology** is essential in IBS-D as coeliac disease mimics it.
- ▶ Recognise mimics that change management: **microscopic colitis** (random colonic biopsies), **bile-acid diarrhoea** (empirical sequestrant trial), **pelvic-floor dyssynergia** (biofeedback, not laxatives), and **ovarian cancer** in older women.
- ▶ Treatment is **symptom-targeted and stepwise**; an empirical therapeutic trial that succeeds confirms the diagnosis and obviates further testing.

High-yield exam pointers

- ▶ **Rome IV core**: recurrent abdominal pain ≥ 1 day/week $\times$ 3 months + ≥ 2 of (defecation-related / change in stool frequency / change in stool form); onset ≥ 6 months prior.
- ▶ Rome IV vs III: pain frequency raised to ≥ 1 /week and term “**discomfort**” removed.
- ▶ Subtypes by **Bristol scale**, **25% rule**: IBS-C, IBS-D, IBS-M, IBS-U — *highly unstable* over time.
- ▶ Older criteria: **Manning** (≥ 3 of 6) and **Kruis** (with exclusion items).
- ▶ **Alarm features**: bleeding, weight loss, anaemia, nocturnal symptoms, fever, age of onset >50 , FH of CRC/IBD/coeliac $\rightarrow$ investigate (colonoscopy).
- ▶ First-line therapy = **education + soluble fibre/psyllium + low-FODMAP (3-step)**; drugs are symptom-directed adjuncts.
- ▶ IBS-D: loperamide, bile-acid binders, **eluxadoline**, **alosetron** (women), **rifaximin**. IBS-C: PEG, **secretagogues** (lubiprostone/linaclotide/plecanatide/tenapanor).
- ▶ **TCAs/SSRIs** as neuromodulators for moderate–severe/pain-predominant disease; **CBT/hypnotherapy** for refractory cases; **probiotics not recommended**.
- ▶ **Eluxadoline contraindicated** post-cholecystectomy/alcohol; **alosetron** carries ischaemic-colitis risk; **tegaserod** restricted to women <65 with low CV risk.

SOURCE & COVERAGE

CROHN'S DISEASE

Asked in: Paper II Dec 2023 — RGUHS MD General Medicine

Definition / Introduction — Crohn disease is a chronic, relapsing, idiopathic inflammatory bowel disease characterized by **transmural**, **segmental** inflammation that may affect any part of the gastrointestinal tract from mouth to anus. It most often involves the terminal ileum and proximal colon, produces skip lesions, fissuring ulcers, strictures, fistulas, abscesses, and perianal disease, and is not cured by surgery. Pathogenesis reflects an inappropriate mucosal immune response to intestinal microbiota in a genetically susceptible host, modified by environmental factors such as smoking, diet, antibiotics, and prior enteric infection.

Etiopathogenesis and risk factors

- ▶ **Genetic susceptibility:** familial aggregation is important; NOD2/CARD15 variants are linked particularly with younger onset, ileal disease and stricturing tendency; ATG16L1/autophagy and IL-12/IL-23 pathways explain biologic targets.
- ▶ **Microbiota and barrier defect:** dysbiosis, reduced microbial diversity, increased mucosa-associated bacteria, defective Paneth cell defensins, epithelial permeability and impaired mucosal tolerance lead to sustained inflammation.
- ▶ **Immune cascade:** activated dendritic cells/macrophages and T cells produce TNF, IL-1, IL-6, IL-12, IL-23 and other mediators; Th1/Th17 pathways, alpha4beta7 lymphocyte trafficking and JAK/STAT signalling are clinically important because they are drug targets.
- ▶ **Environmental factors:** **cigarette smoking** strongly increases Crohn risk, resistance to medical therapy and early relapse. Diets rich in animal fat, refined sugars and processed foods, low fibre intake, oral contraceptives, early-life infections and infectious gastroenteritis are associated risks.
- ▶ **Epidemiology:** onset is common in adolescence and young adulthood, but disease may occur at any age; newly industrialized countries, including Asian populations, show rising incidence.

Pathology and classification

- ▶ **Gross pathology:** discontinuous disease with **skip areas**, aphthous ulcers in early disease, deep linear/serpiginous ulcers, **cobblestoning**, thickened bowel wall, luminal narrowing, mesenteric lymphadenopathy and **creeping fat**.
- ▶ **Microscopy:** focal crypt inflammation, focal crypt abscesses, transmural lymphoid aggregates, fissures, sinus tracts and fistulas. **Noncaseating granulomas** are highly suggestive but absent in many mucosal biopsies; exclude tuberculosis when granulomas are seen.
- ▶ **Distribution:** about one-third have small-bowel disease alone, around one-half have ileocolonic disease, and about one-fifth have colitis alone; terminal ileum is the commonest site. Perianal disease occurs in about one-third.

Montreal axis	Categories	Exam implication
Age	A1 ≤16 yr; A2 17-40 yr; A3 >40 yr	Early onset often predicts aggressive course
Location	L1 ileal; L2 colonic; L3 ileocolonic; L4 upper GI modifier	Determines symptoms, nutrition and imaging
Behaviour	B1 inflammatory; B2 stricturing; B3 penetrating	Guides medical, endoscopic and surgical strategy
Modifier	p = perianal disease	Must be actively looked for and imaged

Clinical features

- ▶ **Luminal inflammatory disease:** insidious malaise, low-grade fever, anorexia, weight loss, chronic or intermittent diarrhoea and crampy abdominal pain. Ileocolitis classically causes recurrent **right lower quadrant pain**, diarrhoea and sometimes an appendicitis-like presentation with fever, mass and leukocytosis.
- ▶ **Stricturing disease:** postprandial colicky pain, bloating, borborygmi, vomiting, decreasing diarrhoea and recurrent subacute obstruction; obstruction may be inflammatory/edematous early or fixed fibrotic late.
- ▶ **Penetrating disease:** phlegmon, intra-abdominal abscess, enteroenteric, enterovesical, enterocutaneous or rectovaginal fistulas. Enterovesical fistula causes recurrent UTI, pneumaturia or fecaluria; rectovaginal fistula causes foul vaginal discharge and dyspareunia.
- ▶ **Colonic Crohn disease:** fever, malaise, diarrhoea, crampy pain and sometimes hematochezia; massive bleeding is uncommon compared with ulcerative colitis.
- ▶ **Perianal disease:** painful skin tags, eccentric fissures, anal ulcers/stenosis, abscesses and complex fistulas; it may precede intestinal symptoms by years.
- ▶ **Upper GI and jejunoileal disease:** dyspepsia, nausea, vomiting, gastric outlet obstruction, malabsorption, steatorrhea, anemia, hypoalbuminemia, B12/folate/iron and fat-soluble vitamin deficiencies.

Investigations and diagnosis

- ▶ **Principle:** no single symptom, sign or test diagnoses Crohn disease; diagnosis requires compatible clinical features plus endoscopic, histologic and radiologic evidence.
- ▶ **Baseline tests:** CBC, ESR/CRP, albumin, electrolytes, liver tests, iron studies, B12/folate, vitamin D and nutritional screen. CRP may be normal in a minority despite active disease.
- ▶ **Stool tests before steroids/biologics:** culture or multiplex PCR for pathogens, ova/parasites when relevant, and *C. difficile* testing; consider CMV biopsy testing in steroid-refractory colitis.

- ▶ **Fecal markers:** fecal calprotectin and lactoferrin help distinguish active inflammation from IBS-like symptoms, assess relapse and monitor treatment response; calprotectin is less sensitive for isolated ileal disease.
- ▶ **Ileocolonoscopy with biopsies:** first-line investigation; inspect colon and terminal ileum, biopsy involved and normal-looking segments separately. Findings: rectal sparing, aphthae, stellate/linear ulcers, cobblestoning, strictures, fistula openings and skip lesions.
- ▶ **Cross-sectional imaging:** MR enterography or CT enterography defines small-bowel extent, wall thickening, enhancement, comb sign, strictures, fistulas, abscess and phlegmon; MRI is preferred for young patients and repeated follow-up when available.
- ▶ **Capsule endoscopy:** useful for suspected small-bowel Crohn disease when ileocolonoscopy and imaging are nondiagnostic, but avoid if stricture is possible; use patency capsule/radiology first. Pelvic MRI is the best noninvasive test for perianal fistula/abscess.

Complications and differentials

- ▶ **Local complications:** obstruction, strictures, intra-abdominal or pelvic abscess, fistulas, severe perianal disease, malabsorption, short bowel syndrome after resections, hemorrhage and rare free perforation.
- ▶ **Cancer:** chronic Crohn colitis carries colorectal cancer risk related to extent and duration, broadly similar to ulcerative colitis with comparable colitis burden; begin surveillance colonoscopy about 8 years after Crohn colitis diagnosis.
- ▶ **Extraintestinal manifestations:** oral aphthae, erythema nodosum, pyoderma gangrenosum, peripheral arthritis, sacroiliitis/ankylosing spondylitis, episcleritis, uveitis, fatty liver, gallstones after ileal disease/resection, PSC, nephrolithiasis, osteoporosis, thromboembolism and reactive amyloidosis.
- ▶ **Differential diagnosis:** ulcerative colitis, intestinal tuberculosis, Yersinia, Salmonella/Shigella/Campylobacter, C. difficile, amoebiasis, CMV, Behcet disease, NSAID enteropathy, ischemic colitis, diverticulitis, lymphoma, celiac disease and IBS. In India, **intestinal TB** is a key mimic: caseating granulomas, AFB/culture/PCR positivity, necrotic nodes and typical ulcers favour TB.

Management

- ▶ **General measures:** assess disease location, behaviour, severity and risk. Stop smoking; avoid NSAIDs; optimize nutrition; correct iron, B12, folate, vitamin D/calcium and fat-soluble vitamin deficiencies; vaccinate before immunosuppression; screen for TB and hepatitis B before biologics/JAK inhibitors.
- ▶ **Treatment target:** steroid-free clinical remission plus objective healing: absence of ulcers on endoscopy, falling CRP/fecal calprotectin, radiologic improvement in transmural disease, fistula healing and restored quality of life.

- ▶ **Mild low-risk ileocecal disease:** controlled-release budesonide 9 mg once daily for 8 weeks, then taper in 3 mg steps over 2-4 weeks if remission occurs. Limited colonic mild disease may respond to sulfasalazine; mesalamine has limited and inconsistent value in Crohn disease.
- ▶ **Moderate to severe or high-risk disease:** use corticosteroids only for induction or bridging: prednisone/prednisolone 40 mg daily for 1-2 weeks, taper by 5-10 mg/week over 4-8 weeks; hospitalized severe disease may need methylprednisolone 40-60 mg/day IV after excluding abscess.
- ▶ **Maintenance and disease modification:** biologic therapy is preferred early in high-risk disease. Options include anti-TNF agents (infliximab 5 mg/kg IV at 0, 2, 6 weeks then every 8 weeks; adalimumab 160 mg day 0, 80 mg day 14, then 40 mg every 2 weeks), vedolizumab 300 mg IV at 0, 2, 6 weeks then every 8 weeks, ustekinumab weight-based IV induction then 90 mg SC every 8 weeks, risankizumab 600 mg IV every 4 weeks for 3 doses then 180/360 mg SC every 8 weeks, and upadacitinib 45 mg daily for 12 weeks then 15/30 mg daily after biologic failure or when appropriate.
- ▶ **Immunomodulators:** azathioprine 2-3 mg/kg/day, 6-mercaptopurine 1-1.5 mg/kg/day, and methotrexate 15-25 mg weekly IM/SC may maintain steroid-free remission or reduce anti-drug antibodies; check TPMT where available and monitor CBC/LFTs.
- ▶ **Perianal/fistulizing disease:** combine gastroenterology and colorectal surgery. Drain abscesses, place setons when needed, give metronidazole 250 mg TID or ciprofloxacin 500 mg BID for symptom relief, and use anti-TNF therapy for fistula closure; pelvic MRI guides anatomy and follow-up.
- ▶ **Abscess/obstruction/surgery:** abscess requires antibiotics plus percutaneous or surgical drainage if large; corticosteroids are unsafe until abscess is excluded. Obstruction from inflammatory edema may respond to bowel rest, NG suction and steroids; fixed short strictures need endoscopic dilation, resection or stricturoplasty. Surgery is indicated for medical intractability, obstruction, abscess, massive bleeding, refractory fistulas or suspected cancer; resect the least bowel possible and check postoperative recurrence endoscopically within 3-6 months.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Segmental Crohn ileocolitis diagram:** terminal ileum + caecum/ascending colon, skip normal areas, aphthous ulcers, deep linear ulcers, cobblestoning, stricture, creeping fat, mesenteric nodes.
- ▶ **Perianal Crohn fistula diagram:** anal canal, internal opening, intersphincteric/transsphincteric tract, external opening, abscess cavity, seton, rectovaginal extension label if present.

Clinical / Diagnostic significance

- ▶ Crohn disease is an exam favourite because it integrates **chronic diarrhoea, malabsorption, obstruction, fistula, abscess, perianal disease and EIMs** in one diagnosis.
- ▶ Distinguish it from UC by transmural inflammation, skip lesions, ileal involvement, rectal sparing, perianal disease, fistulas/strictures and granulomas; distinguish it from intestinal TB before starting anti-TNF therapy.
- ▶ Always exclude **C. difficile, CMV and abscess** when a patient flares or fails steroids; giving corticosteroids into an occult abscess can be dangerous.
- ▶ Deep ulcers, early steroid need, young onset, perianal disease, stricturing/penetrating behaviour, upper GI disease, low albumin/hemoglobin and high CRP/calprotectin indicate aggressive disease and justify early biologic therapy.
- ▶ Therapeutic drug monitoring helps anti-TNF failures: low trough/no antibody means increase dose or shorten interval; high antibody/low trough means switch anti-TNF; active inflammation with therapeutic trough means switch drug class.

High-yield exam pointers

- ▶ Write first: **Crohn = transmural, skip, mouth-to-anus, terminal ileum, noncaseating granuloma, fistula/stricture/perianal disease.**
- ▶ Montreal classification: **A1/A2/A3; L1/L2/L3 with L4 modifier; B1/B2/B3 with p modifier.**
- ▶ Most common presentation: chronic right lower quadrant pain + diarrhoea + weight loss; appendicitis mimic is classic.
- ▶ Perianal disease affects about one-third; pelvic MRI and colorectal surgery involvement are essential.
- ▶ Fecal calprotectin/lactoferrin are practical inflammatory markers; symptoms alone do not prove active disease.
- ▶ Capsule endoscopy is sensitive for small bowel disease but contraindicated until stricture is excluded.
- ▶ Steroids induce remission but are **not maintenance therapy**; aim for steroid-free mucosal healing.
- ▶ Anti-TNF agents are preferred for severe, perianal or fistulizing disease; screen for TB/hepatitis B and update vaccines.
- ▶ Surgery treats complications but is not curative; preserve bowel length and prevent/monitor postoperative recurrence.

Describe various recommendations for treatment of chronic Hepatitis “B”

Asked in: Paper II May 2022 — RGUHS MD General Medicine

Definition / Introduction — Chronic hepatitis B (CHB) is HBV infection with persistence of HBsAg and ongoing necroinflammatory liver disease for ≥ 6 months. The **level of HBV replication** (serum HBV DNA) is the **single most important determinant** of progression to cirrhosis and hepatocellular carcinoma (HCC), in both HBeAg-reactive and HBeAg-negative disease. Treatment decisions integrate three variables — HBeAg status, HBV DNA level, and necroinflammatory activity (ALT and/or biopsy) — plus the presence of cirrhosis. Eight drugs exist; modern practice rests on **three first-line agents** (PEG IFN- α , entecavir, tenofovir) guided by AASLD and EASL recommendations.

Goals and endpoints of therapy

- ▶ **Suppress HBV DNA** to undetectable levels (most important virologic endpoint).
- ▶ **Normalize ALT** (biochemical remission) and achieve **histologic improvement** (improved in 50–90% of orally treated patients).
- ▶ **HBeAg loss / seroconversion to anti-HBe** in HBeAg-positive disease — the therapeutic milestone that permits stopping in non-cirrhotics.
- ▶ **HBsAg loss (“functional cure”)** — the ultimate but uncommon goal; in HBeAg-negative disease it is the only event that justifies stopping therapy.
- ▶ These short-term gains translate into **reduced cirrhosis, hepatic decompensation, HCC, need for transplantation, and death**; long-term suppression can produce **regression of fibrosis/cirrhosis and of esophageal varices**.

Whom to treat — recommendations by disease phase (AASLD; EASL footnoted)

HBeAg status	Clinical setting	HBV DNA (IU/mL)	ALT	Recommendation
HBeAg-positive	Chronic hepatitis	$>2 \times 10^4$	$>2 \times \text{ULN}$	Treat (oral agent or PEG IFN)
	“Immune-tolerant”/high DNA, normal ALT	$>2 \times 10^4$	$\leq 2 \times \text{ULN}$	No treatment; monitor HBV DNA + ALT q6 months*
HBeAg-negative	Inactive carrier	$\leq 2 \times 10^3$	$\leq \text{ULN}$	Treatment not necessary; monitor
	Chronic hepatitis	$>2 \times 10^3$	$>2 \times \text{ULN}$	Treat

HBeAg status	Clinical setting	HBV DNA (IU/mL)	ALT	Recommendation
	"Gray zone"	$>2 \times 10^3$	1 to $>2 \times$ ULN	Treatment suggested; individualise*
Either	Compensated cirrhosis	Detectable (treat if $>2 \times 10^3$)	Any	Treat with oral agents, not PEG IFN
Either	Decompensated cirrhosis	Detectable	Any	Treat (oral agents) + refer for liver transplant
Either	Decompensated cirrhosis	Undetectable	Any	Observe; refer for transplant

- ▶ EASL threshold is lower: treat HBeAg-positive disease at HBV DNA $>2 \times 10^3$ IU/mL with ALT $>$ ULN. For older patients and advanced fibrosis, lower the HBV DNA treatment threshold to $>2 \times 10^3$ IU/mL*.
- ▶ Treatment is also considered in "gray-zone"/normal-ALT patients who are >40 years, have a family history of cirrhosis/HCC, extrahepatic manifestations, prior treatment, or biopsy/non-invasive evidence of moderate-severe inflammation or fibrosis*.
- ▶ No treatment for inactive "non-replicative" carriers (HBeAg-negative, normal ALT, HBV DNA $\leq 10^3$ IU/mL documented serially).
- ▶ Compensated cirrhosis with detectable HBV DNA is a universal treatment indication, regardless of HBeAg/ALT, because antiviral therapy retards progression and stopping risks decompensation.

First-line antiviral agents (route, dose, resistance)

Agent	Route / dose	Status	Resistance
PEG IFN- α ($\alpha 2a$)	SC injection, 180 μ g weekly $\times$ 48 weeks	First-line, finite course	None (no viral mutation)
Entecavir	Oral 0.5 mg/day (1 mg/day if lamivudine-resistant)	First-line	$\leq 1.2\%$ through year 6 (much higher if lamivudine-resistant)
Tenofovir disoproxil fumarate (TDF)	Oral 300 mg/day	First-line	0% through year 8
Tenofovir alafenamide (TAF)	Oral 25 mg/day (= 300 mg TDF potency)	First-line	Same as TDF
Lamivudine	Oral 100 mg/day	No longer preferred	$\sim 30\%$ yr 1, $\sim 70\%$ yr 5
Adefovir	Oral 10 mg/day	No longer preferred (supplanted by tenofovir)	0% yr 1, $\sim 30\%$ yr 5

Agent	Route / dose	Status	Resistance
Telbivudine	Oral 600 mg/day	No longer preferred / withdrawn	up to 22% by yr 2

- ▶ **Three first-line drugs: PEG IFN- α , entecavir, and tenofovir (TDF or TAF)** — all share a high genetic barrier to resistance.
- ▶ Lamivudine, adefovir and telbivudine are **no longer recommended as first-line** because of high resistance rates and/or weaker potency.
- ▶ Between entecavir and tenofovir, comparative data are limited; an observational signal that TDF lowers HCC risk more than entecavir is **not robustly confirmed** after adjustment for confounders.
- ▶ **TAF is preferred over TDF** when CrCl <50 mL/min, reduced bone density, or renal-risk patients (decompensated cirrhosis, poorly controlled hypertension/diabetes, proteinuria, nephrotoxic drugs, solid-organ transplant); EASL extends TAF preference to patients >60 years (higher TDF nephrotoxicity risk).

PEG IFN versus oral nucleos(t)ide analogues

Feature	PEG IFN	Oral nucleos(t)ide analogues
Administration	Weekly SC injection	Daily, oral
Tolerability	Poorly tolerated, intensive monitoring	Well tolerated, limited monitoring
Duration	Finite (48 weeks)	≥ 1 year, usually indefinite
Mean HBV DNA suppression	$\sim 4.5 \log_{10}$	$\sim 6.9 \log_{10}$ (more profound)
Effective in high-level HBV DNA ($\geq 10^9$)	No	Yes
Use in cirrhosis / transplant / immunosuppression	No	Yes
Resistance	None	None—minimal with entecavir/tenofovir

- ▶ **PEG IFN advantage:** finite course, no resistance, higher 1-year HBeAg seroconversion — but injectable, poorly tolerated, and **contraindicated in decompensated (and avoided in compensated) cirrhosis** (risk of sepsis/decompensation).
- ▶ **Oral-agent advantage:** convenient, very well tolerated, deeper DNA suppression, effective even in IFN non-responders; by the **end of year 2**, entecavir/tenofovir yield HBeAg (and even HBsAg) responses comparable to 1 year of PEG IFN. Most patients and physicians prefer oral agents first-line.

Duration, monitoring and stopping rules

- ▶ **HBeAg-positive, non-cirrhotic:** oral therapy may be stopped after HBeAg loss/seroconversion plus ≥ 12 months consolidation, with close post-treatment monitoring (monthly $\times 6$, then 3-monthly through the first year). Durable seroconversion is maintained in $\sim 88\text{--}92\%$.
- ▶ **HBeAg-negative, non-cirrhotic:** indefinite oral therapy; stop only after the rare event of HBsAg loss (virologic relapse after stopping is otherwise $69\text{--}83\%$).
- ▶ **Cirrhosis (compensated or decompensated):** treat indefinitely; stopping risks decompensation.
- ▶ **Untreated/"gray-zone" patients** (HBV DNA $2 \times 10^3\text{--}2 \times 10^4$ IU/mL) need HBV DNA + ALT every 3–6 months; immune-tolerant patients at least every 6 months.
- ▶ For tenofovir/TAF, periodic ($\geq$ annual) monitoring of serum creatinine (and renal function) is recommended.

Special populations

- ▶ **Pregnancy:** Tenofovir (TDF) is the drug of choice (category B), also used in the third trimester for mothers with high HBV viral load to prevent perinatal transmission. Lamivudine is also category-tolerated; PEG IFN and adefovir/entecavir are avoided.
- ▶ **Children (2 to <18 yr):** treat if HBV DNA is detectable and ALT is elevated (not if ALT normal). Approved ages — PEG IFN- $\alpha 2a$ ≥ 5 yr; entecavir and tenofovir ≥ 2 yr.
- ▶ **HBV–HIV co-infection:** treat both infections even if HIV criteria not yet met; use tenofovir $\pm$ emtricitabine; TAF preferred over TDF for safety.
- ▶ **Immunosuppression / chemotherapy:** screen all patients for HBsAg and anti-HBc before cytotoxic/immunosuppressive/anti-TNF/B-cell-depleting therapy. Give pre-emptive prophylaxis with entecavir or tenofovir for any HBsAg-positive patient (reactivation risk $\sim 25\%$, up to 68%); start before and continue beyond completion of immunosuppression. Highest-risk agents: B-cell-depleting drugs, anthracyclines, moderate/high-dose corticosteroids ≥ 4 weeks.
- ▶ **Liver transplantation:** prevent graft re-infection with short-term IV HBIG (5–7 days) + lifelong entecavir/TDF/TAF; high-risk (HDV–HBV, HIV–HBV, non-adherent) or anti-HBc-positive-donor grafts warrant tailored long-term oral $\pm$ HBIG regimens.
- ▶ **HBV–HDV co-infection:** nucleos(t)ide analogues are ineffective against HDV; 12 months of PEG IFN is recommended (response is modest); bulevirtide (an NTCP-receptor entry inhibitor) is approved in the EU.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Natural-history / treatment-decision flow of CHB** — boxes labelled: HBsAg+ ≥ 6 months
→ branch on HBeAg status → (HBeAg-positive: “immune-tolerant” → “immune-active/clearance” → HBeAg seroconversion) and (HBeAg-negative chronic hepatitis $\leftrightarrow$

inactive carrier); arrows labelled *HBV DNA*, *ALT*, *Cirrhosis*; endpoints labelled *Treat*, *Monitor*, *HBeAg seroconversion*, *HBsAg loss (functional cure)*.

- ▶ **Treatment-threshold grid** — axes labelled *HBV DNA (IU/mL)*: 2×10^3 and 2×10^4 cut-offs vs *ALT: ULN / $2 \times ULN$* , with shaded “**Treat**”, “**Gray zone**” and “**Monitor**” regions; separate cells labelled *Compensated cirrhosis — treat (oral)* and *Decompensated cirrhosis — treat + transplant referral*.

Clinical / Diagnostic significance

- ▶ Baseline work-up: HBeAg/anti-HBe, HBV DNA, ALT, HBsAg quantification (where available), liver fibrosis assessment (biopsy or non-invasive), HDV and HIV serology, and HCC surveillance in at-risk groups.
- ▶ The HBV DNA level is the dominant risk factor for cirrhosis and HCC — hence sustained DNA suppression is the therapeutic core even when ALT is near-normal.
- ▶ PEG IFN must never be used in decompensated cirrhosis; the entecavir/tenofovir class is the safe choice there.
- ▶ Always screen before immunosuppression — failure to give prophylaxis causes potentially fatal reactivation flares.
- ▶ Choice of agent balances resistance barrier, renal/bone safety (TAF vs TDF), pregnancy, co-infection, and patient preference.

High-yield exam pointers

- ▶ Three first-line agents: PEG IFN- α , entecavir, tenofovir (TDF/TAF); lamivudine, adefovir, telbivudine are obsolete first-line.
- ▶ Doses: PEG IFN- α 2a 180 μ g SC weekly $\times$ 48 wk; entecavir 0.5 mg/day (1 mg if lamivudine-resistant); TDF 300 mg/day; TAF 25 mg/day.
- ▶ AASLD HBeAg-positive trigger: HBV DNA $>2 \times 10^4$ IU/mL + ALT $>2 \times ULN$; HBeAg-negative trigger: HBV DNA $>2 \times 10^3$ + ALT $>2 \times ULN$; EASL thresholds are lower.
- ▶ Compensated cirrhosis + detectable HBV DNA = treat (oral, indefinitely); decompensated = treat + transplant referral.
- ▶ Stop rules: HBeAg-positive — stop after HBeAg seroconversion + 12-month consolidation (non-cirrhotic); HBeAg-negative — only after HBsAg loss; cirrhotics — never stop.
- ▶ Resistance: entecavir $\leq 1.2\%$ at 6 yr, tenofovir 0% at 8 yr — highest barrier.
- ▶ Pregnancy DOC = tenofovir; HIV co-infection = tenofovir $\pm$ emtricitabine, TAF preferred; chemo/immunosuppression = pre-emptive entecavir/tenofovir after HBsAg/anti-HBc screening.

- ▶ Transplant prophylaxis = HBIG (5–7 days) + lifelong oral antiviral; HDV = PEG IFN ×12 months / bulevirtide (nucleos(t)ides ineffective).

SOURCE & COVERAGE

Harrison's Principles of Internal Medicine, 22e (2025) — Ch 352 "Chronic Hepatitis" (Tables 352-3, 352-4, 352-5 and the "Treatment Recommendations / Populations with Unique Treatment Considerations" sections). Treatment thresholds, drug doses, resistance rates and special-population guidance are all sourced from this chapter. *Coverage note:* the chapter is fully sufficient for this LAQ; HCC surveillance specifics and HBV vaccination are cross-referenced to other chapters (Chaps 87, 350, 356) and are not detailed here.

Diagnostic approach in patients presenting with acute hepatitis

Asked in: Paper II Jul 2021 — RGUHS MD General Medicine

Definition / Introduction — *Acute hepatitis* is a hepatocellular injury syndrome of <6 months duration, biochemically characterised by a predominant rise in serum aminotransferases (AST/ALT), usually with jaundice. Although the great majority of cases are caused by one of the five hepatotropic viruses (HAV, HBV, HCV, HDV, HEV), the differential is broad and includes drug/toxin injury, alcohol-associated hepatitis, ischaemic ("shock") liver, autoimmune hepatitis, Wilson disease and pregnancy-related liver disease. A *structured approach* — clinical assessment, a focused biochemical "liver panel" to define the pattern (hepatocellular vs cholestatic vs mixed), a small battery of serologic tests, and selective imaging/biopsy — establishes the cause and, crucially, identifies the minority progressing to acute liver failure.

Step 1 — Define the clinical syndrome (history & examination)

- ▶ **Symptom phases:** a *prodromal (preicteric)* phase of constitutional symptoms — anorexia, nausea, vomiting, malaise, fatigue, arthralgia/myalgia, headache, low-grade fever (38–39°C; commoner in HAV/HEV and in the HBV serum-sickness syndrome), classically with **aversion to smoking** and altered taste/smell — followed by an *icteric* phase (dark urine and clay/acholic stools 1–5 days before jaundice), then a *convalescent* phase.
- ▶ **Examination:** tender hepatomegaly, scleral icterus, and in 10–20% splenomegaly and cervical/epitrochlear lymphadenopathy; a few transient spider angiomas may appear. Many patients are **anicteric** (commoner in HCV than HBV).
- ▶ **Risk-factor history (key to aetiology):** travel to endemic areas, exposure to jaundiced contacts, day-care/shellfish/contaminated water (HAV, HEV); injection drug use, transfusion (pre-1992 for HCV, pre-1986 for HBV), tattooing, multiple sexual partners/MSM, maternal-infant

transmission, needlestick (HBV, HCV, HDV); a full drug, herbal and alcohol history (CAGE questionnaire); and “repeated episodes” of hepatitis suggesting underlying chronic/autoimmune disease.

- ▶ **Red-flag features (impending acute liver failure):** altered sleep/personality, confusion, asterixis, fetor hepaticus, rapidly shrinking liver, ascites/oedema — encephalopathy in a previously healthy liver is the defining criterion of acute liver failure (ALF) and demands urgent referral.

Step 2 — Confirm and pattern the liver injury (biochemistry)

- ▶ Order the standard battery: **AST, ALT, alkaline phosphatase (AlkP), total/direct bilirubin, albumin and prothrombin time (PT/INR)**; add γ -glutamyl transpeptidase (γ GT) to confirm a hepatic source of raised AlkP.
- ▶ **Aminotransferases** rise in the prodrome and peak (≈ 400 to >4000 IU/L) as jaundice appears; the height does *not* correlate with severity. A predominant **AST/ALT elevation relative to AlkP = hepatocellular pattern**; predominant **AlkP/ γ GT elevation = cholestatic pattern**; both raised = **mixed**.
- ▶ **Magnitude clue** — aminotransferases ≥ 1000 IU/L narrow the differential to: **acute viral hepatitis, ischaemic hepatitis, drug-induced liver injury (especially acetaminophen) and acute biliary obstruction**. Alcohol-associated hepatitis is usually <400 IU/L with **AST $>$ ALT (ratio ≥ 2)**.
- ▶ **Bilirubin:** visible jaundice when >2.5 mg/dL ($43 \mu\text{mol/L}$); typically 5–20 mg/dL, divided $\approx$ equally between conjugated and unconjugated. Bilirubin may keep rising as aminotransferases fall.
- ▶ **Prognostic/synthetic markers:** a **prolonged PT/INR**, hypoglycaemia, falling albumin and very high bilirubin signify severe hepatocellular necrosis. PT that **fails to normalise with parenteral vitamin K** points to hepatocellular (not obstructive/cholestatic) disease.
- ▶ **Haematology:** transient neutropenia/lymphopenia then relative lymphocytosis with **atypical lymphocytes (2–20%)**; thrombocytopenia suggests underlying cirrhosis rather than acute hepatitis.

Step 3 — Targeted serologic algorithm (the “five-test” panel)

Every patient with acute hepatitis should have five tests: **HBsAg, IgM anti-HAV, IgM anti-HBc, anti-HCV and HCV RNA** (Harrison Table 350-6). Test for **anti-HEV ($\pm$ HEV RNA)** if these are negative and risk factors exist, and for **anti-HDV/HDV RNA** when HBsAg is positive with severe/fulminant or exacerbating disease.

HBsAg	IgM anti-HAV	IgM anti-HBc	Anti-HCV / HCV RNA	Interpretation
+	–	+	–	Acute hepatitis B

HBsAg	IgM anti-HAV	IgM anti-HBc	Anti-HCV / HCV RNA	Interpretation
+	–	–	–	Chronic hepatitis B
+	+	–	–	Acute hepatitis A on chronic hepatitis B
+	+	+	–	Acute hepatitis A and B
–	+	–	–	Acute hepatitis A
–	+	+	–	Acute hepatitis A and B (HBsAg below threshold)
–	–	+	–	Acute hepatitis B (HBsAg below detection threshold)
–	–	–	+ (either)	Acute hepatitis C (vs chronic HCV)

- ▶ **HAV:** diagnosis = **IgM anti-HAV**; IgG anti-HAV alone = past infection/immunity.
- ▶ **HBV:** **HBsAg + IgM anti-HBc = acute hepatitis B**. IgM anti-HBc may be the *only* marker in the “window period” (HBsAg gone, anti-HBs not yet up) or when HBsAg is below threshold ($\leq 1-5\%$ of cases). IgG anti-HBc with HBsAg > 6 months = chronic. HBeAg/HBV DNA mark replication/infectivity (chiefly useful in chronic disease).
- ▶ **HCV:** **anti-HCV** detected reliably by current assays during acute illness; **HCV RNA** is the gold standard, becomes positive earliest, and distinguishes true- from false-positive anti-HCV and active from resolved (“cured”) infection (anti-HCV+, HCV RNA–).
- ▶ **HDV:** defective virus needing HBV — test anti-HDV/HDV RNA in HBsAg-positive patients; **co-infection** = IgM anti-HBc + anti-HDV, **superinfection** = IgG anti-HBc + anti-HDV.
- ▶ **HEV:** IgM/IgG anti-HEV $\pm$ HEV RNA — suspect in travellers, the elderly, undercooked pork/game exposure, pregnancy, or chronic hepatitis in the immunosuppressed.

Step 4 — Imaging, biopsy and tests for non-viral causes

- ▶ **Ultrasound** (first-line) excludes biliary obstruction (acute cholecystitis, common-duct stone, cholangitis) and detects vascular causes; MRCP/ERCP if duct dilatation or stones suspected; Doppler US for Budd-Chiari/congestion.
- ▶ If all viral serologies are negative, pursue **non-viral acute hepatitis**: serum **acetaminophen level** and drug history (DILI); **ANA**, **anti-smooth-muscle antibody**, **IgG** (autoimmune hepatitis);

ceruloplasmin, slit-lamp for Kayser-Fleischer rings, 24-h urinary copper (Wilson — especially young patient with haemolysis + low AlkP); EBV/CMV serology, monospot (mononucleosis-like illness); pregnancy-related (AFLP, HELLP, eclampsia, cholestasis of pregnancy).

- ▶ **Liver biopsy** is *rarely* required in acute hepatitis — reserved for diagnostic uncertainty, suspected autoimmune hepatitis, or when an alternative diagnosis (e.g., alcoholic hepatitis showing steatosis, neutrophilic infiltrate and Mallory hyaline) must be confirmed.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Diagnostic algorithm flow-chart:** “Acute hepatitis (illness <6 months, raised ALT/AST)” → branch on biochemical pattern: *Hepatocellular* ($\uparrow\uparrow$ ALT) vs *Cholestatic* ($\uparrow\uparrow$ AlkP/ γ GT) vs *Mixed* → under hepatocellular box list the five core tests (IgM anti-HAV, HBsAg, IgM anti-HBc, anti-HCV, HCV RNA) plus second-line (anti-HEV, anti-HDV, ANA/SMA, ceruloplasmin, acetaminophen level, drug/alcohol history) → outputs: specific viral diagnosis / DILI / autoimmune / Wilson; under cholestatic box: US → MRCP/ERCP, AMA, drug history. Label a side-box “Red flags → ALF: encephalopathy + INR >1.6 + shrinking liver.”
- ▶ **Serologic time-course of acute hepatitis B:** x-axis “weeks after exposure,” plotted curves labelled HBsAg, HBeAg, HBV DNA, IgM anti-HBc, IgG anti-HBc, anti-HBe, anti-HBs, with the shaded “window period” between HBsAg disappearance and anti-HBs appearance, and the ALT/jaundice curve overlaid.

Clinical / Diagnostic significance

- ▶ The pattern (hepatocellular vs cholestatic) plus disease duration (<6 vs >6 months) is the *pivot* of the whole work-up — it tells you which serologic/imaging arm to follow.
- ▶ **IgM anti-HBc** is the single most useful test to call HBV “acute”: it covers the window period and low-level HBsAg, but high-titre IgM anti-HBc can *reappear* in acute exacerbations of chronic HBV, so correlate with history.
- ▶ **HCV RNA** detects infection before anti-HCV and before ALT rises — essential after needlestick and in people who inject drugs (where anti-HCV+/RNA+ may mean re-infection, not chronicity).
- ▶ Recognise mimics: ischaemic hepatitis (shock, very high but rapidly falling AST), acetaminophen DILI, ascending cholangitis/choledocholithiasis, Budd-Chiari/right heart failure with congestion, AFLP/HELLP in pregnancy, and Wilson disease (haemolytic jaundice + low AlkP + low uric acid).
- ▶ **Severity triage:** hospitalise/refer for transplant assessment when there is **encephalopathy**, **INR >1.6**, **intractable vomiting/dehydration**, **hypoglycaemia** or **very high bilirubin** — these define or predict ALF.

High-yield exam pointers

- ▶ Order the **five tests** in every acute hepatitis: HBsAg, IgM anti-HAV, IgM anti-HBc, anti-HCV, HCV RNA — memorise Harrison's Table 350-6.
- ▶ **Acute HAV** = IgM anti-HAV; **Acute HBV** = HBsAg + IgM anti-HBc; **Acute HCV** = anti-HCV + HCV RNA.
- ▶ Aminotransferase height does **not** equal severity — PT/INR, bilirubin, albumin and mental status do.
- ▶ ALT/AST ≥ 1000 IU/L $\Rightarrow$ think viral, ischaemic, drug (acetaminophen) or acute biliary obstruction.
- ▶ AST:ALT ≥ 2 with values < 400 IU/L $\Rightarrow$ alcohol-associated hepatitis.
- ▶ HDV only co-exists with HBV: **co-infection** (IgM anti-HBc) vs **superinfection** (IgG anti-HBc).
- ▶ HEV in pregnancy $\rightarrow$ fulminant hepatitis in up to 20%; chronic HEV occurs only in the immunosuppressed.
- ▶ PT not correcting with **vitamin K** $\Rightarrow$ hepatocellular (not cholestatic/obstructive) injury.
- ▶ **Acute liver failure** = acute injury + coagulopathy + encephalopathy — the most feared outcome; CMTD admission triggers are encephalopathy, INR > 1.6 , inability to maintain hydration.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Acute Viral Hepatitis” (serologic markers, “Simplified Diagnostic Approach in Patients Presenting with Acute Hepatitis”, clinical/laboratory features, differential diagnosis, prognosis) and “Approach to the Patient with Liver Disease” (history/examination, hepatocellular-vs-cholestatic pattern, diagnostic tests algorithm, imaging, biopsy).
- ▶ **Sleisenger & Fordtran's Gastrointestinal and Liver Disease, 11e** — “Jaundice” (stepwise evaluation, aminotransferase vs alkaline-phosphatase pattern, PT response to vitamin K) and “Acute Liver Failure” (clinical definition: encephalopathy + acute injury + coagulopathy).
- ▶ **CMTD 2026** — “Liver, Biliary Tract & Pancreas Disorders” (essentials of diagnosis, causes of severe aminotransferase elevation, differential diagnosis, when-to-admit criteria).

Discuss Billirubin metabolism. Describe approach to Conjugated Hyperbilirubinemia

Asked in: Paper II Nov 2021 — RGUHS MD General Medicine

Definition / Introduction — **Bilirubin** is a tetrapyrrole pigment that is the end product of **heme catabolism**; about **4 mg/kg/day** is produced, of which **80–85%** (range 70–90%) derives from the haemoglobin of senescent red cells and the remainder from ineffective erythropoiesis and turnover of hepatic haemoproteins (myoglobin, cytochromes). **Jaundice** is yellow staining of tissues by deposited bilirubin and becomes clinically detectable (scleral icterus) once serum bilirubin exceeds **51 $\mu\text{mol/L}$ (3 mg/dL)**. **Conjugated (direct) hyperbilirubinaemia** is defined as a *direct fraction* **>15%** of total serum bilirubin and, unlike unconjugated hyperbilirubinaemia, always implies hepatobiliary disease (or a rare inherited canalicular defect) and is accompanied by **bilirubinuria**.

Formation of bilirubin (heme degradation)

- ▶ Bilirubin is the breakdown product of **heme (ferroprotoporphyrin IX)**; formation occurs in **reticuloendothelial cells**, chiefly in the **spleen and liver**.
- ▶ **Step 1 — Heme oxygenase** (microsomal): oxidatively cleaves the **α -methene bridge** of the porphyrin ring, opening the heme ring $\rightarrow$ yields **biliverdin + carbon monoxide (CO) + iron**.
- ▶ **Step 2 — Biliverdin reductase** (cytosolic): reduces the central methylene bridge of biliverdin $\rightarrow$ **bilirubin**.
- ▶ Bilirubin so formed is **virtually water-insoluble** owing to tight **internal hydrogen bonding** (propionic-acid carboxyls bonded to imino/lactam groups of the opposite dipyrrole), which buries the polar residues.
- ▶ For transport in blood, bilirubin is **solubilised by reversible, non-covalent binding to albumin**; this albumin-bound **unconjugated bilirubin** is carried to the liver (the albumin itself is *not* taken up).

Hepatic handling — the four sequential steps (Fig. 349-1)

- ▶ **1. Hepatocellular uptake** — bilirubin enters the hepatocyte by **carrier-mediated (facilitated) and simple diffusional** processes; the definitive bilirubin uptake transporter remains unidentified.
- ▶ **2. Intracellular binding** — within the cytosol bilirubin is held in solution by binding as a non-substrate ligand to the **glutathione-S-transferases (GST)**, formerly “**ligandins**”, which reduce efflux back to plasma and present bilirubin for conjugation.
- ▶ **3. Conjugation** — in the endoplasmic reticulum, **bilirubin UDP-glucuronosyltransferase (UGT1A1)** conjugates bilirubin with one or two glucuronic-acid moieties $\rightarrow$ **bilirubin mono- and diglucuronide**. This disrupts the internal hydrogen bonding and renders the pigment **water-soluble**; conjugation is **obligatory** for excretion across the canalicular membrane. *UGT1A1* is encoded by the **UGT1 gene complex on chromosome 2** (exon A1 + common exons 2–5).
- ▶ **4. Biliary excretion** — conjugates are actively pumped across the canalicular membrane into bile by the **ATP-dependent transporter MRP2 (ABCC2)**. A portion of glucuronides is alternatively extruded into the sinusoid/portal blood by **MRP3 (ABCC3)** and re-internalised by the sinusoidal uptake proteins **OATP1B1 (SLCO1B1) and OATP1B3 (SLCO1B3)**.

Intestinal fate and enterohepatic circulation

- ▶ Conjugated bilirubin drains into the **duodenum** and passes unchanged through the proximal small bowel; being hydrophilic and large, it is **not reabsorbed** by intestinal mucosa.
- ▶ In the **distal ileum and colon**, bacterial **β -glucuronidases** deconjugate it, and gut flora reduce the unconjugated pigment to colourless **urobilinogens** (and related tetrapyrroles).
- ▶ ~80–90% of urobilinogen is excreted in faeces (oxidised to orange **urobilins**, giving stool its colour); 10–20% undergoes **enterohepatic cycling**, of which a small fraction (<3 mg/dL) escapes hepatic re-uptake, is filtered at the glomerulus and excreted in **urine as urobilinogen**.
- ▶ **Unconjugated bilirubin is never found in urine** (too tightly albumin-bound to be filtered); **any bilirubin in urine is conjugated** — hence bilirubinuria signifies hepatobiliary disease.

Measurement and fractionation — the van den Bergh reaction

- ▶ Serum bilirubin is measured by the **van den Bergh diazo reaction** with diazotised sulfanilic acid.
- ▶ **Direct (conjugated)** = fraction reacting *without* an accelerator (alcohol); **Total** = fraction reacting *after* alcohol releases albumin-bound pigment; **Indirect (unconjugated)** = Total – Direct.
- ▶ Normal total bilirubin is 17–26 $\mu\text{mol/L}$ (1–1.5 mg/dL) by van den Bergh (95% of normals 0.2–0.9 mg/dL).
- ▶ **Unconjugated hyperbilirubinaemia: direct <15% of total; conjugated: direct >15%.**
- ▶ **Delta bilirubin (biliprotein):** conjugated bilirubin covalently bound to albumin, formed when hepatic excretion is impaired; its clearance follows the albumin half-life (18–20 days) rather than bilirubin's (~4 h). It explains why some recovering cholestatic patients have **persistent jaundice without bilirubinuria** (delta bilirubin is not filtered) and a slow fall in bilirubin.

Classification of hyperbilirubinaemias

Predominant fraction	Mechanism	Representative causes
Unconjugated (indirect >85%)	↑ production	Haemolysis; ineffective erythropoiesis; resorption of haematoma; massive transfusion
	↓ hepatic uptake	Drugs — rifampin, probenecid
	↓ conjugation	Gilbert (UGT1A1 10–35%); Crigler-Najjar I (absent UGT1A1, kernicterus) and II ($\leq 10\%$, phenobarbital-responsive); physiologic neonatal jaundice

Predominant fraction	Mechanism	Representative causes
Conjugated / mixed (direct >15%)	↓ canalicular excretion (inherited)	Dubin-Johnson (MRP2/ABCC2); Rotor (OATP1B1 + 1B3 deficiency)
	Hepatocellular injury	Viral/alcoholic/drug/ischaemic hepatitis, cirrhosis
	Cholestasis (intra-/extrahepatic)	PBC, PSC, drug cholestasis, choledocholithiasis, pancreatic/biliary malignancy

Approach to conjugated hyperbilirubinaemia (Fig. 52-1)

- ▶ **Step 1 — Confirm and fractionate.** Establish that the *direct fraction* is >15% of total bilirubin; **bilirubinuria** on dipstick (Ictotest) corroborates a true conjugated rise. Order the *core panel*: bilirubin with fractionation, ALT, AST, ALP, prothrombin time (PT), albumin.
- ▶ **Step 2 — Is the rise isolated or accompanied by other abnormal liver tests?**
 - **Isolated conjugated hyperbilirubinaemia (other LFTs normal)** → think of the two benign inherited canalicular disorders: **Dubin-Johnson** (defective MRP2 canalicular export) and **Rotor** (deficient OATP1B1/1B3 reuptake). Both present as asymptomatic jaundice; distinction is possible but **clinically unnecessary** given their benign course.
 - **Conjugated rise with other liver tests deranged** → proceed to Step 3.
- ▶ **Step 3 — Hepatocellular vs cholestatic pattern** (enzymes are the discriminator):
 - **Hepatocellular:** aminotransferases (ALT/AST) elevated *out of proportion* to ALP. AST:ALT >2:1 with AST rarely >300 U/L suggests **alcoholic hepatitis**; ALT/AST >500–1000 U/L (ALT ≥ AST) suggests **acute viral or toxin/drug injury** (e.g. acetaminophen).
 - **Cholestatic:** ALP elevated *out of proportion* to aminotransferases (confirm hepatic origin with GGT or 5'-nucleotidase).
- ▶ **Step 4 — Targeted serology / toxicology (hepatocellular work-up):** hepatitis A IgM; HBsAg + anti-HBc IgM; HCV RNA; ± hepatitis E IgM; **acetaminophen level**; **ceruloplasmin** if age <40 (Wilson disease); ANA, anti-smooth-muscle antibody, SPEP (autoimmune hepatitis); EBV/CMV if indicated.
- ▶ **Step 5 — Imaging (cholestatic work-up): ultrasound first** to assess the biliary tree.
 - **Dilated ducts** → **extrahepatic cholestasis** → define level/cause with CT / MRCP / ERCP (± EUS, PTC). ERCP is the **gold standard** for **choledocholithiasis** and is therapeutic (stone extraction, stenting); MRCP has replaced diagnostic ERCP in most cases.
 - **Non-dilated ducts** → **intrahepatic cholestasis** → **AMA** (primary biliary cholangitis, positive in ~95%), hepatitis serologies, **drug review**, and **liver biopsy** if serology unrevealing; MRCP shows pathognomonic segmental strictures of PSC.

- **Step 6** — Assess severity/chronicity with **albumin** (low → chronic, e.g. cirrhosis/cancer) and **PT** (prolonged, *non-correcting with parenteral vitamin K* → severe hepatocellular dysfunction; correcting → cholestatic vitamin-K malabsorption).

Inherited conjugated hyperbilirubinaemias — Dubin-Johnson vs Rotor

Feature	Dubin-Johnson (DJS)	Rotor (RS)
Gene / defect	ABCC2 (MRP2) — defective canalicular export	SLCO1B1 + SLCO1B3 (OATP1B1 + 1B3) — defective sinusoidal reuptake
Inheritance	Autosomal recessive	Autosomal recessive
Liver appearance	Grossly black ; coarse dark pigment in centrilobular lysosomes	Normal , no pigmentation
Total bilirubin	34–85 $\mu\text{mol/L}$ (2–5 mg/dL), occasionally up to 20–25 mg/dL; predominantly conjugated	Mild, predominantly conjugated
Urinary coproporphyrin	Total normal , but $\geq 80\%$ isomer I	Total markedly increased , isomer I usually $< 70\%$
Oral cholecystogram	Gallbladder not visualised	Gallbladder visualised
BSP (sulfobromophthalein)	Secondary rise at 90 min (reflux of conjugated dye)	Delayed clearance, no 90-min reflux
Course	Benign; may become overt in pregnancy / OCP use	Benign

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- **Bilirubin metabolism flow diagram** (left→right). Labels: *Senescent RBC* → *Heme (in reticuloendothelial cell)* → *Heme oxygenase (releases CO + Fe)* → *Biliverdin* → *Biliverdin reductase* → *Unconjugated bilirubin* → *Albumin-bound transport in blood* → *Hepatocyte uptake* → *Ligandin/GST binding* → *UGT1A1 conjugation (ER)* → *Bilirubin mono-/diglucuronide* → *MRP2* → *Bile canaliculus* → *Gut* → *β -glucuronidase/bacteria* → *Urobilinogen* → (80–90% faeces as urobilin / enterohepatic cycle / kidney → urine urobilinogen). Add side-arrows: *MRP3* → *portal blood* → *OATP1B1/1B3 reuptake*.
- **Algorithm box for conjugated hyperbilirubinaemia**. Labels: *Direct >15%* → *fractionate* → “isolated LFTs normal = DJS/Rotor” branch; “other LFTs abnormal” → *Hepatocellular (ALT/AST $\gg$ ALP) vs Cholestatic (ALP $\gg$ ALT/AST)* → *Ultrasound* → *Dilated ducts = Extrahepatic (CT/MRCP/ERCP) vs Non-dilated = Intrahepatic (AMA, biopsy)*.

Clinical / Diagnostic significance

- ▶ **Bilirubinuria** is an early, sensitive sign of conjugated hyperbilirubinaemia and may precede clinical jaundice; its **absence in deep jaundice** suggests delta-bilirubin predominance (prolonged cholestasis).
- ▶ **Serum bilirubin level/ratio** does NOT distinguish intra- from extrahepatic cholestasis — that decision rests on the *enzyme pattern* and *imaging (ductal dilatation)*.
- ▶ **MRP2 (DJS) vs OATP1B1/1B3 (Rotor)** deficiencies are clinically benign but matter for **drug handling**: OATP transporters mediate hepatic uptake of statins and other drugs, so Rotor predisposes to drug accumulation.
- ▶ A **non-correcting prolonged PT** after parenteral vitamin K flags severe hepatocellular failure and is prognostically ominous.
- ▶ **Pigment (calcium bilirubinate) gallstones** complicate chronic haemolysis and can superimpose choledocholithiasis, producing a *secondary conjugated/obstructive* picture.

High-yield exam pointers

- ▶ Bilirubin = end product of heme catabolism; heme oxygenase → biliverdin (+CO+Fe) → biliverdin reductase → bilirubin.
- ▶ Unconjugated bilirubin is albumin-bound, lipid-soluble, NOT in urine; conjugated is water-soluble, appears in urine.
- ▶ Conjugating enzyme = UGT1A1; excretory canalicular pump = MRP2 (ABCC2).
- ▶ Conjugated hyperbilirubinaemia = direct >15% of total and is *always* pathological (hepatobiliary) except the benign inherited DJS/Rotor.
- ▶ DJS = MRP2 defect, black liver, urinary coproporphyrin ≥80% isomer I, BSP 90-min reflux; Rotor = OATP1B1/1B3 defect, normal-coloured liver, ↑ total coproporphyrin, gallbladder visualised.
- ▶ Approach: fractionate → isolated vs other-LFTs → hepatocellular (ALT/AST >> ALP) vs cholestatic (ALP >> ALT/AST) → ultrasound → dilated = extrahepatic, non-dilated = intrahepatic.
- ▶ ERCP = gold standard for choledocholithiasis (diagnostic + therapeutic); AMA = key test for primary biliary cholangitis.
- ▶ Delta bilirubin (albumin-bound conjugated bilirubin, t_{1/2} 18–20 days) explains slow resolution of jaundice and absent bilirubinuria in recovering cholestasis.

SOURCE & COVERAGE

Harrison 22e — Ch 349 “The Hyperbilirubinemias” (bilirubin metabolism, 4-step hepatic transport, UGT1A1, MRP2/MRP3/OATP1B1-1B3, Dubin-Johnson and Rotor syndromes) + Ch 52 “Jaundice” (heme catabolism, van den Bergh fractionation, delta bilirubin, Fig. 52-1 diagnostic algorithm for conjugated hyperbilirubinaemia, hepatocellular vs cholestatic patterns). Coverage

note: All specifics (transporters, enzyme names, coproporphyrin/BSP findings, bilirubin cut-offs, algorithm steps) are drawn from these two chapters; standard ancillary points (GGT/5'-nucleotidase to confirm hepatic ALP origin; AST:ALT and aminotransferase ranges) are from the same chapters' liver-test discussion (Table 348-1). No data fabricated beyond the provided text.

Discuss the complications of Chronic Pancreatitis

Asked in: Paper II May 2022 — RGUHS MD General Medicine

Definition / Introduction — **Chronic pancreatitis (CP)** is a disease process characterised by *irreversible* damage to the pancreas — chronic inflammation, fibrosis, and progressive destruction (atrophy) of both **exocrine and endocrine tissue** — in contrast to the reversible changes of acute pancreatitis. Pancreatic stellate cell (PSC) activation driven by TNF- α , IL-1, IL-6 and oxidant stress perpetuates collagen deposition even after the noxious stimulus (alcohol, smoking) is withdrawn. The cardinal manifestations are abdominal pain, steatorrhoea, weight loss and diabetes; complications arise both from loss of glandular function and from the local fibro-inflammatory/structural sequelae. There is currently **no therapy to reverse or delay disease progression**, so management is centred on *screening for and treating disease-related complications*.

Spectrum of complications (Harrison Table 359-7)

Functional (loss of gland function)	Structural / local	Systemic / metabolic
Chronic abdominal pain	Pseudocyst	Splanchnic (splenic/portal/SMV) venous thrombosis
Exocrine pancreatic insufficiency (EPI) / steatorrhoea	Pancreatic duct stricture	Metabolic bone disease (osteoporosis/osteopenia)
Diabetes mellitus (endocrine insufficiency)	Biliary stricture and/or biliary cirrhosis	Malnutrition, micronutrient/fat-soluble vitamin deficiency
	Pancreatic ascites/duct disruption	Pancreatic cancer

- Useful exam framework: group complications as (1) **exocrine**, (2) **endocrine**, (3) **pain**, (4) **ductal/structural**, (5) **vascular & haemorrhagic**, (6) **metabolic-systemic**, (7) **malignant**.

Exocrine pancreatic insufficiency (EPI) and malnutrition

- **Cumulative prevalence of EPI exceeds 80%**; clinically EPI manifests only after a large functional reserve is lost.

- ▶ Presents as **maldigestion** — chronic diarrhoea, **steatorrhoea** (overt steatorrhoea is highly suggestive of EPI) and **weight loss**; eating may aggravate pain, producing fear of eating and further weight loss.
- ▶ **Fat-soluble vitamin (A, D, E, K) deficiencies** and **micronutrient deficiency (zinc)** are increasingly recognised and drive malnutrition.
- ▶ *Diagnosis*: serum amylase/lipase are usually **not** strikingly elevated in CP; low serum pancreatic enzyme levels are moderately specific but insensitive. **Fecal elastase-1 (FE-1)** on a *formed* stool: **>200 µg/g normal, 100–200 µg/g mild–moderate EPI, <100 µg/g severe EPI** (false positives in unformed stool, diabetes, IBS). The **direct secretin pancreatic function test** is the most sensitive test and becomes abnormal once **≥60% of exocrine function is lost**.
- ▶ *Management pearl*: **pancreatic enzyme replacement therapy (PERT)** is the cornerstone for steatorrhoea — start **25,000–50,000 units of lipase per meal**, up to **100,000 units**, often combined with a **proton-pump inhibitor**; monitor weight, fat-soluble vitamins, zinc and bone mineral density.

Pancreatogenic (type 3c) diabetes mellitus

- ▶ **Lifetime prevalence of CP-related diabetes exceeds 80%** — reflects progressive islet-cell loss.
- ▶ Hyperglycaemia results chiefly from **insulin deficiency** due to destruction of islet cells; loss of glucagon-secreting cells contributes to *brittle* control and hypoglycaemia risk on insulin.
- ▶ Characteristically, **diabetic ketoacidosis and diabetic coma are uncommon**, and **micro/macrovascular end-organ damage (retinopathy, neuropathy, nephropathy) is also uncommon**.
- ▶ **Non-diabetic retinopathy may occur from vitamin A and/or zinc deficiency** — a distinguishing point from primary type 1/type 2 diabetes.

Chronic abdominal pain

- ▶ Pain is the dominant symptom prompting medical attention — variable in site, severity and frequency, constant or intermittent with pain-free intervals; **narcotic dependence is a frequent consequence**, and there is often a *disparity* between severe reported pain and only non-focal tenderness on examination.
- ▶ Mechanisms are complex (ductal hypertension, neural inflammation, ongoing parenchymal injury); **enzyme therapy has no consistent benefit for pain** in meta-analyses.
- ▶ *Stepwise management*: analgesia + **pregabalin** (reduces pain and opioid requirement in a short-term RCT); **celiac plexus block** (conditional, low-quality evidence — not durable); **endoscopic therapy** (sphincterotomy, pancreatic duct stenting, stone extraction, pseudocyst drainage) for a dominant downstream stricture/obstructing stone; **surgical ductal decompression** for a dilated duct — **~80% obtain immediate relief but pain recurs in half by 3 years**, and randomised trials show **surgery superior to endoscopy** for pain relief.

Ductal and structural complications

- ▶ **Pseudocyst** — a persistent peripancreatic fluid collection; <10% of acute collections persist beyond 4 weeks to become a pseudocyst. Most resolve; **only symptomatic collections require intervention** (endoscopic transgastric/transduodenal or surgical drainage). Pseudocysts may cause pain, gastric outlet/biliary obstruction, infection, rupture or haemorrhage.
- ▶ **Pancreatic duct stricture** — fibrotic narrowing causing upstream ductal dilation, pain and contributing to EPI; complications of stenting (migration, occlusion, stent-induced strictures) limit endoscopic therapy.
- ▶ **Biliary stricture, cholestasis and secondary biliary cirrhosis** — chronic inflammation/fibrosis around the **intrapancreatic common bile duct** produces jaundice with raised bilirubin and alkaline phosphatase, and may progress to biliary cirrhosis.
- ▶ **Pancreatic duct disruption** → **pancreatic ascites / pleural effusion** — leak from a disrupted duct produces ascitic fluid with a **high amylase** level (confirmed on MRCP/ERCP); managed with a **bridging pancreatic stent** (>90% effective), parenteral nutrition and octreotide.

Vascular complications and gastrointestinal haemorrhage

- ▶ **Splanchnic venous thrombosis** — peripancreatic inflammation causes **splenic vein thrombosis** (→ left-sided/sinistral portal hypertension and **isolated gastric varices**), and **portal and superior mesenteric vein thrombosis**. Gastric varices rarely bleed but bleeding can be life-threatening.
- ▶ **Pseudoaneurysm** (splenic/gastroduodenal artery) — rupture causes life-threatening haemorrhage, diagnosed and treated with **mesenteric angiography and embolization**.
- ▶ **Gastrointestinal bleeding in CP** may arise from: peptic ulceration, gastritis, a **pseudocyst eroding into the duodenum**, arterial bleeding into the pancreatic duct (**hemorrhagic pancreatitis**), or ruptured varices secondary to **splenic vein thrombosis**.

Metabolic bone disease, micronutrient deficiency and pancreatic cancer

- ▶ **Metabolic bone disease** — strikingly common: ~65% of CP patients have osteopenia or osteoporosis, driven by shared risk factors (alcohol, smoking), **vitamin D deficiency** and chronic inflammation. Periodic **bone mineral density** measurement is advised.
- ▶ **Malnutrition / micronutrient deficiency** — fat-soluble vitamin and zinc deficiency (see EPI) and overall impaired quality of life with significant morbidity.
- ▶ **Pancreatic adenocarcinoma** — a feared long-term complication: **20 years after the diagnosis of chronic calcific pancreatitis the cumulative risk of pancreatic cancer is ~4%**. Risk is *higher* in **hereditary (PRSS1) pancreatitis** and **tropical pancreatitis** (often SPINK1-associated, with bulky calcifications) than in other forms. New jaundice, weight loss or a dominant stricture should prompt exclusion of malignancy.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Diagram 1** — “Complications of chronic pancreatitis” spider/concept map. Central node *Chronic pancreatitis (fibrosis + acinar/islet atrophy)* with labelled spokes: Exocrine insufficiency → steatorrhea, weight loss, fat-soluble vitamin deficiency; Endocrine insufficiency → type 3c diabetes; Chronic pain ± narcotic dependence; Pseudocyst; Pancreatic duct stricture; Biliary stricture → cholestasis/biliary cirrhosis; Pancreatic ascites (duct disruption); Splenic vein thrombosis → gastric varices; Pseudoaneurysm; Hemorrhage pancreaticus; Metabolic bone disease (osteoporosis); Pancreatic cancer.
- ▶ **Diagram 2** — Splenic vein thrombosis schematic. Label: *pancreas (inflamed body/tail), thrombosed splenic vein, spleen (congested), short gastric veins → isolated gastric (fundal) varices, patent portal vein*; caption “sinistral (left-sided) portal hypertension”.

Clinical / Diagnostic significance

- ▶ **Investigation cascade:** noninvasive → invasive — **abdominal CT first** (calcifications, ductal dilation, atrophy, pseudocyst; also excludes cancer), then **MRI/MRCP**, **EUS** (≥5 of 9 endosonographic features = diagnostic; can be combined with EUS-ePFT), and **direct secretin function testing** (most sensitive). **Diffuse pancreatic calcifications on plain film are pathognomonic of CP.**
- ▶ **Cholestatic LFTs** (raised bilirubin + ALP) flag a CBD/biliary stricture; **high-amylase ascites** flags duct disruption; **isolated gastric varices** should trigger a search for splenic vein thrombosis.
- ▶ **Surveillance:** screen for and treat diabetes, EPI, osteoporosis (DXA), fat-soluble vitamin/zinc deficiency; counsel **alcohol and smoking cessation** (independent, dose-dependent driver of progression, fibrosis and calcification).
- ▶ **Management cornerstones:** PERT for steatorrhea; insulin for type 3c diabetes (with caution re: hypoglycaemia); stepwise pain control; endoscopic/surgical drainage for symptomatic pseudocyst or dominant stricture; angio-embolization for pseudoaneurysm/haemorrhage; maintain a low threshold to exclude malignancy.

High-yield exam pointers

- ▶ Two functional complications — **EPI (cumulative prevalence >80%)** and **diabetes (lifetime prevalence >80%)** — dominate; both reflect glandular destruction.
- ▶ **FE-1:** >200 normal, 100–200 mild–moderate, <100 severe EPI; secretin test abnormal once ≥60% of exocrine function lost.
- ▶ CP diabetes (type 3c): insulin-deficient; **DKA, coma and microvascular end-organ damage are uncommon**; *non-diabetic retinopathy* points to vitamin A/zinc deficiency.
- ▶ **Hemorrhage pancreaticus** = arterial bleeding into the pancreatic duct; **splenic vein thrombosis** → **isolated gastric varices** (sinistral portal hypertension).

- ▶ **Pancreatic cancer cumulative risk** ~4% at 20 years in chronic calcific pancreatitis; highest in hereditary PRSS1 and tropical (SPINK1) pancreatitis.
- ▶ ~65% of CP patients have osteopenia/osteoporosis — order DXA and replace vitamin D.
- ▶ Pseudocyst: only **symptomatic** collections need drainage; PERT dose **25,000–50,000 (up to 100,000) units lipase/meal**.
- ▶ Surgery beats endoscopy for pain from a dilated duct; **pregabalin** lowers pain and opioid need.

SOURCE & COVERAGE

Harrison's Principles of Internal Medicine, 22e — Ch 359 "Acute and Chronic Pancreatitis" (Complications of Chronic Pancreatitis, Table 359-7; Clinical Features, EPI/FE-1 and secretin-test data; Treatment of Chronic Pancreatitis; Perivascular/duct-disruption complications). *Coverage note:* All numbers, eponyms (hemorrhagic pancreatitis, splenic portal hypertension), prevalence figures and PERT doses are taken from Ch 359. The descriptor "**type 3c (pancreatogenic) diabetes**" is universally accepted standard internal-medicine terminology used here for clarity; Harrison Ch 359 names it "chronic pancreatitis-related diabetes." The 9-feature EUS criterion and Cambridge/secretin diagnostics are referenced in Ch 358/359.

Oral Antiviral Therapy in the Management of Hepatitis C Infection

Asked in: Paper II May 2025 — RGUHS MD General Medicine

Definition / Introduction — Chronic hepatitis C virus (HCV) infection persists in 50–85% of those acutely infected and progresses to cirrhosis in ~20–25% over two decades, with hepatocellular carcinoma (HCC) developing in cirrhotics at 1–4%/year. Because HCV has an entirely **cytoplasmic life-cycle with no integrated archival template** (unlike HBV), suppression of replication in the absence of resistance permanently clears the virus — i.e. **HCV is curable**. The modern treatment of HCV is therefore an all-oral, interferon-free regimen of **direct-acting antivirals (DAAs)** taken for 8–12 weeks, achieving cure (sustained virologic response, SVR) in >95% of patients.

Goal of therapy and definition of cure

- ▶ The endpoint is the **sustained virologic response (SVR12)** — undetectable serum HCV RNA measured **12 weeks after completion** of therapy (the threshold was shortened from the older SVR24 once all-oral DAAs became available). HCV RNA must be tracked with a sensitive real-time RT-PCR assay (limit of quantification ≤25 IU/mL).
- ▶ An SVR is **tantamount to virologic cure**; late relapse beyond 6–12 months is very rare and almost unheard of after 2 years.

- ▶ SVR translates into reduced fibrosis progression, **regression of fibrosis and even cirrhosis**, lower rates of hepatic decompensation, HCC and liver transplantation, improved all-cause and liver-related survival, and improvement in extrahepatic disease (cryoglobulinaemic vasculitis, type 2 diabetes, renal disease).
- ▶ The **WHO global elimination goal** is a 90% reduction in HCV prevalence by 2030; broad DAA use since 2013 has already reversed HCV-related mortality in many regions.

Molecular targets and classes of DAAs

The HCV polyprotein is cleaved into 3 structural and 7 non-structural proteins; current DAAs hit **three** non-structural targets, identifiable by drug suffix.

Class (suffix)	Molecular target	Representative drugs	Genotype coverage / barrier to resistance
NS3/4A protease inhibitors (- <i>previr</i>)	NS3/4A serine protease (polyprotein cleavage)	Glecaprevir, grazoprevir, voxilaprevir, paritaprevir (ritonavir-boosted), simeprevir	Variable–pangenotypic; low-to-moderate barrier; contraindicated in decompensated cirrhosis
NS5A inhibitors (- <i>asvir</i>)	NS5A phosphoprotein of the replication complex	Velpatasvir, pibrentasvir, ledipasvir, elbasvir, daclatasvir, ombitasvir	High potency at picomolar doses; coverage broader with 2nd-generation agents
NS5B polymerase inhibitors (- <i>buvir</i>)	NS5B RNA-dependent RNA polymerase (replicase)	Nucleotide: sofosbuvir (pangenotypic, high barrier); non-nucleoside: dasabuvir (genotype 1, weak, low barrier)	Nucleos(t)ide = pangenotypic, high barrier (chain termination)

- ▶ Modern practice combines drugs from **two (or three) classes in a single fixed-dose pill** to give a high genetic barrier and pangenotypic activity.
- ▶ **Resistance-associated substitutions (RASs)** matter chiefly for NS5A (e.g. Y93H in genotype 3; NS5A polymorphisms in ~11% of genotype 1a). Protease-inhibitor RASs generally do **not** persist (low fitness, wild-type re-emerges); nucleotide (sofosbuvir) RASs are rare and unfit.

Pre-treatment evaluation

- ▶ HCV RNA (confirms active infection) and HCV **genotype** — though pangenotypic regimens exist, genotype still guides regimen/duration and insurance.
- ▶ **Fibrosis staging** by non-invasive means — **FIB-4 score**, transient elastography (liver stiffness); biopsy is no longer routine. Presence of cirrhosis changes drug choice, duration and the rare need for ribavirin.

- ▶ **HBsAg + anti-HBc** — DAAs can trigger **HBV reactivation**; co-infected patients meeting criteria must receive HBV antiviral cover before/with HCV therapy.
- ▶ **HIV status, renal function (eGFR), pregnancy status, and a drug–drug interaction check** (www.hep-druginteractions.org).

Current first-line oral regimens (AASLD–IDSA / EASL)

Five all-oral regimens are recommended; two pangenotypic fixed-dose combinations dominate as a “simplified, one-size-fits-all” algorithm.

Regimen (once-daily)	Components & doses	Usual duration	Notes
Sofosbuvir–velpatasvir (preferred, pangenotypic)	Sofosbuvir 400 mg + velpatasvir 100 mg	12 weeks	Genotypes 1–6; SVR12 ~99% (95% in genotype 3); ribavirin only if decompensated
Glecaprevir–pibrentasvir (preferred, pangenotypic)	Glecaprevir 300 mg + pibrentasvir 120 mg	8 weeks (treatment-naïve, incl. compensated cirrhosis)	Genotypes 1–6; SVR ~99%; preferred in severe renal disease/dialysis ; contains protease inhibitor
Sofosbuvir–ledipasvir	Sofosbuvir 400 mg + ledipasvir 90 mg	8–12 weeks	Genotypes 1, 4, 5, 6; 8 weeks if naïve, non-cirrhotic, HCV RNA <6×10 ⁶ IU/mL
Elbasvir–grazoprevir	Elbasvir 50 mg + grazoprevir 100 mg	12 weeks	Genotypes 1 and 4; baseline NS5A RAS testing in genotype 1a (extend ±ribavirin if present); good in renal failure
Sofosbuvir–velpatasvir–voxilaprevir	Sofosbuvir 400 mg + velpatasvir 100 mg + voxilaprevir 100 mg	12 weeks	Rescue/retreatment after NS5A-inhibitor or DAA failure; ~97% SVR; take with food

- ▶ The **simplified algorithm** (sofosbuvir–velpatasvir ×12 wk or glecaprevir–pibrentasvir ×8 wk) is used when the patient has **none** of: prior treatment failure, cirrhosis, HBsAg positivity, pregnancy, HCC, or prior liver transplant — often without genotyping or on-treatment monitoring.
- ▶ **Ribavirin** (an oral guanosine nucleoside) is now rarely required — reserved for decompensated cirrhosis or selected DAA-failure retreatment; its dose-limiting toxicity is **haemolytic anaemia**, and it is strictly **teratogenic** (contraindicated in pregnancy, contraception mandatory).

Treatment in special populations

- ▶ **Compensated (Child-Pugh A) cirrhosis** — respond as well as non-cirrhotics; pangenotypic regimens used, treatment-experienced cirrhotics may need 12 weeks.
- ▶ **Decompensated (Child-Pugh B/C) cirrhosis** — **protease-inhibitor-containing regimens are contraindicated** (hepatotoxicity, risk of further decompensation). Use **sofosbuvir + an NS5A inhibitor (velpatasvir or ledipasvir)**: add ribavirin to a 12-week course if ribavirin-eligible, or extend to 24 weeks if ribavirin-ineligible. Refer to a transplant centre.
- ▶ **Renal impairment** — no dose change for mild–moderate disease. For severe impairment (CrCl <30 mL/min, dialysis): **glecaprevir–pibrentasvir** (all genotypes) or **elbasvir–grazoprevir** (genotypes 1, 4) preferred; sofosbuvir-containing regimens, initially avoided, are now FDA-approved (2019) for this group.
- ▶ **HCV/HIV co-infection** — treat with the **same DAAs and durations** as mono-infection (response is now equivalent); avoid the abbreviated 8-week sofosbuvir–ledipasvir course; mind antiretroviral interactions (avoid ribavirin with didanosine/stavudine/zidovudine).
- ▶ **Prior DAA failure (retreatment)** — sofosbuvir-experienced patients are re-treated with **sofosbuvir–velpatasvir–voxilaprevir ×12 wk** or **glecaprevir–pibrentasvir ×16 wk**; multiple-DAA failures may need glecaprevir–pibrentasvir + sofosbuvir + ribavirin ×16 wk; RAS-guided, specialist-referred.
- ▶ **Pregnancy** — DAAs **not routinely recommended** (limited data); ribavirin absolutely contraindicated. **Acute hepatitis C** and **people who inject drugs (PWID)** should be treated (active injection drug use is no longer a contraindication — treatment reduces onward transmission).

Adverse effects, interactions and cautions

- ▶ DAAs are **very well tolerated**; commonest effects are mild **headache, fatigue, nausea**, comparable to placebo.
- ▶ **Sofosbuvir + amiodarone** → **severe, potentially fatal bradycardia** — sofosbuvir-containing regimens are contraindicated with amiodarone (especially with beta-blockers).
- ▶ **P-glycoprotein / CYP3A4 inducers** (rifampin, St John's wort, carbamazepine, phenytoin, phenobarbital) lower DAA levels and **contraindicate** all DAA regimens.
- ▶ **Gastric acid suppression**: ledipasvir and velpatasvir lose solubility at high gastric pH — limit/separate antacids, H₂-blockers and PPIs (e.g. omeprazole ≤20 mg).
- ▶ Protease inhibitors can raise aminotransferases/bilirubin → monitor and stop for marked rises.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **HCV genome and DAA drug targets** (linear genome): label structural proteins **Core (C)**, **E1, E2, p7** and non-structural proteins **NS2, NS3, NS4A, NS4B, NS5A, NS5B**; mark the

three drug targets — NS3/4A protease (→ -previr), NS5A replication-complex protein (→ -asvir), NS5B RNA-dependent RNA polymerase (→ -buvir).

- ▶ **Treatment-decision flow chart:** label *Confirm chronic HCV (HCV RNA +ve)* → *Pre-treatment work-up (genotype, FIB-4/elastography, HBsAg+anti-HBc, HIV, eGFR, DDI check)* → branch *No cirrhosis / treatment-naïve* → *simplified regimen (sof-velpatasvir 12 wk OR glecaprevir-pibrentasvir 8 wk)* vs *Cirrhosis / prior failure / special population* → *tailored regimen* → *Confirm SVR12 at 12 weeks post-treatment.*

Clinical / Diagnostic significance

- ▶ Achieving SVR halts and can reverse fibrosis/cirrhosis and reduces HCC, decompensation, transplant need and mortality — but in patients with **advanced fibrosis/cirrhosis the HCC risk is reduced, not eliminated**, so **6-monthly ultrasound HCC surveillance continues even after cure.**
- ▶ **Screen and protect against HBV reactivation** before DAA therapy; vaccinate against hepatitis A and B.
- ▶ DAAs cure HCV in patients awaiting or after **liver/kidney transplantation**, and enable transplantation of HCV-positive donor organs into HCV-negative recipients with subsequent cure.
- ▶ Treating **mild disease is justified and cost-effective** — delaying until fibrosis is advanced forfeits the chance to prevent end-stage complications.

High-yield exam pointers

- ▶ SVR12 = undetectable HCV RNA 12 weeks post-treatment = **cure**.
- ▶ Three DAA targets/suffixes: NS3/4A protease (-previr), NS5A (-asvir), NS5B polymerase (-buvir).
- ▶ Sofosbuvir = pangenotypic NS5B **nucleotide** inhibitor, high resistance barrier, 80% renally excreted.
- ▶ Two pangenotypic preferred fixed-dose regimens: **sofosbuvir-velpatasvir ×12 wk** and **glecaprevir-pibrentasvir ×8 wk**, SVR >95%.
- ▶ **Protease-inhibitor regimens (glecaprevir/grazoprevir/voxilaprevir) are contraindicated in decompensated cirrhosis** — use sofosbuvir + velpatasvir/ledipasvir ± ribavirin.
- ▶ Sofosbuvir + amiodarone = **severe bradycardia** (contraindicated).
- ▶ Sofosbuvir-velpatasvir-voxilaprevir = **rescue therapy for prior NS5A/DAA failure**.
- ▶ Always check **HBsAg/anti-HBc** (reactivation), genotype, fibrosis (FIB-4/elastography), eGFR, and drug interactions before therapy.
- ▶ **Ribavirin** — main toxicity **haemolytic anaemia; teratogenic** (avoid in pregnancy).

- ▶ Continue HCC surveillance after SVR if cirrhosis/advanced fibrosis present.

Diseases associated with *Helicobacter pylori* infection and its management

Asked in: Paper II Nov 2020 — RGUHS MD General Medicine

Definition / Introduction — *Helicobacter pylori* is a spiral, flagellated, microaerophilic, urease-producing **gram-negative bacillus** that colonises the gastric mucous layer of roughly **40% of the world's population**, usually acquired in childhood and persisting for life unless eradicated. Essentially **all colonised persons develop histological chronic gastritis**, but only **~10–15% develop overt disease** — the outcome being decided by an interplay of bacterial virulence (*cagA*, *vacA*), host genetics and environment. It is the principal cause of peptic ulcer disease, an **IARC class I (definite) gastric carcinogen**, and the driver of gastric MALT lymphoma; it also has recognised extragastric and some *protective* associations. Marshall and Warren's 1984 discovery (Nobel Prize 2005) transformed these from chronic relapsing diseases into curable infections.

Pathogenesis — how one organism causes opposite diseases

- ▶ **Virulence factors:** the *cag* pathogenicity island encodes a **type IV secretion system** that injects the effector **CagA** into epithelial cells (driving proliferative, cytoskeletal and inflammatory changes); **CagL** binds host integrins; peptidoglycan fragments activate intracellular **Nod1**, amplifying cytokine release. The vacuolating cytotoxin **VacA** forms membrane pores, and adhesin **BabA** binds blood-group antigens. *cagA*+/ *vacA*-active strains carry the highest ulcer and cancer risk.
- ▶ **Host/environment:** IL-1 β gene polymorphisms (high IL-1 producers) and the **PSCA rs2294008** SNP increase cancer risk; smoking, high-salt/preserved-food diets raise risk, while vitamin C/antioxidants are protective.
- ▶ **Topography determines disease (key concept):**

- **Antral-predominant gastritis** → loss of somatostatin-secreting **D cells** → unrestrained gastrin → ↑ acid from spared corpus → **duodenal ulcer**.
- **Corpus-predominant / pangastritis** → hypochlorhydria, atrophy → **gastric ulcer, atrophic gastritis and adenocarcinoma**.

Spectrum of associated diseases (with strength of association)

Disease group	Specific condition	Association / Odds ratio (Harrison Fig 168-1)
Gastric	Chronic superficial (then atrophic) gastritis	Virtually 100% of colonised
	Peptic ulcer disease	~70% of duodenal, ~50% of gastric ulcers; DU OR 3–6
	Functional (non-ulcer) dyspepsia	Symptom resolution in up to ~10–15% over placebo
	Gastric MALT (marginal-zone B-cell) lymphoma	OR 6–50
	Non-cardia gastric adenocarcinoma	OR 3–8
	Iron-deficiency anaemia, vitamin B12 deficiency	Occult loss + hypochlorhydria/malabsorption
Extragastric	Immune (idiopathic) thrombocytopenic purpura	Platelet rise/normalisation after eradication
Protective (inverse)	GERD, Barrett's oesophagus, oesophageal & cardia adenocarcinoma	OR 0.2–0.6 (cagA+ strains)
	Childhood-onset asthma, hay fever, atopy	Inverse association (cagA+); causal in animal models

- ▶ *H. pylori* is **neither necessary nor sufficient** for PUD but is a very strong risk factor; eradication virtually abolishes long-term ulcer relapse (recurrence falls from ~85%/yr to <20%/yr).
NSAIDs/aspirin and *H. pylori* are **independent, synergistic** ulcer risks.

Gastric MALT lymphoma & adenocarcinoma — the malignant end of the spectrum

- ▶ **Gastric MALT lymphoma (extranodal marginal-zone B-cell lymphoma)**: arises from chronic antigenic stimulation of acquired lymphoid tissue; the stomach is the commonest extranodal lymphoma site. Cells are CD19/CD20/CD79a positive, CD5/CD10/CD23/cyclin D1 negative, forming *lymphoepithelial lesions*, commonly antral.
- **H. pylori eradication alone induces remission in ~60–80%** of low-grade, localised (mucosa-confined) cases — first-line therapy even if tests are falsely negative.

- **t(11;18)(q21;q21)** (the *API2-MALT1* fusion) and **t(1;14)(p22;q32)** (deregulating *bcl-10*) predict **non-response** to eradication and indicate need for radiotherapy/rituximab-based chemotherapy; CagA+ strains associate with t(11;18)-positive tumours.
- ▶ **Gastric adenocarcinoma (Correa cascade)**: the intestinal type evolves over decades — **chronic gastritis** → **atrophic gastritis** → **intestinal metaplasia** → **dysplasia** → **carcinoma**, driven by inflammation-derived reactive oxygen/nitrogen species and nitrosamines from bacterial overgrowth in the achlorhydric stomach. The **diffuse type** (signet-ring cells, *linitis plastica*) may arise directly from chronic gastritis. Eradication **does not treat established cancer** but reduces incidence, especially after endoscopic resection of early gastric cancer.

Diagnosis

Invasive (endoscopic biopsy)	Non-invasive
Rapid urease test (CLO) — quick, biopsy in urea-indicator gel	¹³C-urea breath test — accurate; ideal for confirming cure
Histology (modified Giemsa/silver/immunostain) — also grades atrophy/metaplasia/dysplasia	Stool antigen test (monoclonal) — cheap, good for children & cure-testing
Culture + sensitivity — most specific; guides resistant cases	Serology (IgG) — cannot confirm cure (titres fall slowly); least reliable for active infection

- ▶ **Pitfall**: breath/stool/biopsy tests depend on bacterial load — false negatives if performed **within 4 weeks of antibiotics/bismuth or 2 weeks of stopping a PPI**, or <4 weeks post-treatment. Serology is *not* used to monitor cure.
- ▶ After **gastric ulceration**, repeat **endoscopy** to confirm healing and exclude carcinoma; duodenal ulcers need only a non-invasive cure test.

Management — eradication regimens (PPI/vonoprazan + ≥2 antibiotics × 10–14 days)

Regimen	Components	Notes
Bismuth quadruple (BQT) — preferred first-line (ACG 2024)	PPI + bismuth + tetracycline + metronidazole, 14 d	Effective even in metronidazole-resistant strains; >85% cure
Rifabutin triple (Talaria)	Omeprazole + rifabutin + amoxicillin, q8h × 14 d	Rifabutin resistance rare; >85% cure
Vonoprazan triple / dual (Voquezna)	Vonoprazan + amoxicillin ± clarithromycin, 14 d	PCAB gives faster/stronger acid block; dual preferred empirically
Clarithromycin triple	PPI + clarithromycin + amoxicillin (or metronidazole), 14 d	Only if clarithromycin resistance <15% or strain proven sensitive

Regimen	Components	Notes
Concomitant quadruple	PPI + clarithromycin + amoxicillin + nitroimidazole, 14 d	Non-bismuth alternative
Levofloxacin-based	PPI + levofloxacin + amoxicillin	Mainly salvage/second-line therapy

- **Resistance drives choice:** clarithromycin resistance is now ~50% (US) and high in much of the world — hence the shift away from clarithromycin triple therapy; metronidazole resistance is partial (overcome by higher dose/quadruple therapy); amoxicillin and tetracycline resistance remain rare.
- **Keys to success:** strict **compliance**, avoiding antibiotics the strain has seen before, **high-dose acid suppression** (PPI or vonoprazan), and **confirming cure** ≥ 4 weeks after antibiotics and ≥ 2 weeks off PPI.
- **Salvage strategy:** for persistent infection, re-treat empirically with a *different* regimen (e.g., BQT after a clarithromycin regimen; rifabutin triple after BQT) or, ideally, **culture / molecular (PCR) susceptibility-guided** therapy.

Indications for eradication (Maastricht VI / ACG)

- **Definite:** all peptic ulcers (active or healed); low-grade gastric MALT lymphoma; after endoscopic resection of early gastric cancer.
- **Recommended:** functional dyspepsia (test-and-treat in <60 yr without alarm features); long-term NSAID/low-dose-aspirin users (especially prior PUD); first-degree relatives of gastric-cancer patients; atrophic gastritis/intestinal metaplasia.
- **Offer:** unexplained **iron-deficiency anaemia**, **immune thrombocytopenic purpura**, and vitamin B12 deficiency with other causes excluded.
- Mass population screening is **not** routinely recommended (uncertain cancer-risk reduction, antibiotic resistance, loss of possible protective effects against GERD/atopy).

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- **Diagram 1** — “Disease outcomes of *H. pylori* colonisation” (branching tree). Centre: *H. pylori* → **Chronic gastritis** ($\approx 100\%$). Branch by gastritis pattern: *Antral-predominant* → $\uparrow$ gastrin/ $\uparrow$ acid → **Duodenal ulcer** (OR 3–6); *Corpus-predominant/pangastritis* → atrophy/hypochlorhydria → **Gastric ulcer**, **Atrophic gastritis** → **intestinal metaplasia** → **dysplasia** → **Non-cardia adenocarcinoma** (OR 3–8), and **MALT lymphoma** (OR 6–50). Add a *protective* arrow: $\downarrow$ acid → **lower GERD / Barrett’s / oesophageal adenocarcinoma** (OR 0.2–0.6). Labels: *cagA*, *vacA*, *BabA*; *D-cell loss*; *somatostatin* $\downarrow$; *gastrin* $\uparrow$.

- ▶ **Diagram 2 — “Correa cascade”.** Linear arrow: **Normal mucosa** → **Chronic active gastritis** → **Atrophic gastritis** → **Intestinal metaplasia** → **Dysplasia** → **Intestinal-type adenocarcinoma**, with labels *H. pylori*, *reactive oxygen/nitrogen species*, *nitrosamines*, *achlorhydria*.

Clinical / Diagnostic significance

- ▶ In a young dyspeptic without alarm features, **non-invasive test-and-treat** (UBT/stool antigen) avoids endoscopy; **alarm symptoms** (age ≥60, weight loss, anaemia, dysphagia, bleeding, vomiting) mandate **upper GI endoscopy** to exclude malignancy.
- ▶ Always **test for and eradicate** *H. pylori* before/at the start of long-term NSAID/aspirin therapy in those with ulcer history — but eradication **alone does not remove** ongoing NSAID risk, so co-prescribe a PPI in high-risk patients.
- ▶ A non-healing/refractory ulcer should prompt search for **NSAID use (often surreptitious)**, **gastrinoma** (Zollinger-Ellison — fasting serum gastrin), **malignancy (re-biopsy)**, **Crohn’s**, **vasculitis**.
- ▶ Unexplained refractory **iron-deficiency anaemia** or **ITP** warrants *H. pylori* testing — eradication can correct both.

High-yield exam pointers

- ▶ *H. pylori* = **gram-negative, urease-positive, microaerophilic, flagellated spiral bacillus**; urease (→ ammonia) is its acid-defence and the basis of the **rapid urease & ¹³C-urea breath tests**.
- ▶ **70% of duodenal ulcers, 50% of gastric ulcers** are *H. pylori*-related; eradication cuts ulcer recurrence from ~85%/yr to <20%/yr.
- ▶ **Antral gastritis = duodenal ulcer; corpus/pangastritis = gastric ulcer + cancer.**
- ▶ **IARC Group 1 carcinogen**; intestinal-type cancer follows the **Correa cascade**; diffuse type = signet-ring/linitis plastica.
- ▶ **Low-grade gastric MALT lymphoma regresses in 60–80% with eradication alone**; t(11;18)(q21;q21) predicts non-response.
- ▶ **OR memory aid:** B-cell lymphoma **6–50** > gastric adenoca **3–8** > duodenal ulcer **3–6**; *protective* against oesophageal disease **0.2–0.6**.
- ▶ **First-line eradication = bismuth quadruple therapy** (PPI + bismuth + tetracycline + metronidazole × 14 days); clarithromycin triple only where resistance <15%.
- ▶ **Confirm cure** by UBT/stool antigen ≥4 weeks after antibiotics and ≥2 weeks off PPI; never use serology to confirm cure.
- ▶ Extragastric eradication indications: **unexplained IDA, ITP, B12 deficiency**.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “*Helicobacter pylori* Infections” (virulence factors, disease odds ratios, diagnosis, eradication regimens, indications) and “Peptic Ulcer Disease and Related Disorders” (PUD/*H. pylori* interaction, ACG/Maastricht VI indications, treatment tables).
- ▶ **Sleisenger & Fordtran's Gastrointestinal and Liver Disease, 11e** — “Gastrointestinal Lymphomas” (MALT lymphoma immunophenotype, t(11;18)(q21;q21) and t(1;14)(p22;q32), 60–80% regression), “Adenocarcinoma of the Stomach and Other Gastric Tumours” (Correa pathway, IARC class I carcinogen, Lauren intestinal/diffuse types), “Gastritis and Gastropathy” and “Peptic Ulcer Disease”.
- ▶ **CMDT 2026** — “Gastrointestinal Disorders” (ACG 2024 regimens: bismuth quadruple, rifabutin triple [Talicia], vonoprazan triple/dual [Voquezna]; resistance data; cure-confirmation rules).

Extra-intestinal Manifestations of Inflammatory Bowel Disease

Asked in: Paper II Jul 2021 — RGUHS MD General Medicine

Definition / Introduction — Extra-intestinal manifestations (EIMs) are inflammatory or metabolic disorders arising *outside* the gut in patients with ulcerative colitis (UC) or Crohn's disease (CD). Up to **one-third** of IBD patients have at least one EIM (population estimates 6–25%), and about **one-fourth of those affected have more than one**. EIMs are commoner in CD than UC and in patients with **colonic involvement**. Pathogenically, the inflammatory mucocutaneous, joint and ocular EIMs reflect an influx of **mononuclear cells activated in the intestine that home aberrantly** to extra-intestinal organs; a few (e.g. enteric hyperoxaluria stones, cholelithiasis) are direct metabolic consequences of bowel disease. EIMs may **precede, parallel or run independently** of luminal activity — an important clue to whether treating the bowel will help.

Classification by relationship to bowel activity

This is the single most examinable framework — EIMs split into those that **parallel** gut inflammation (treated by controlling the bowel) and those that run an **independent** course.

Parallels bowel activity (treat the bowel)	Independent of bowel activity (treat separately)
Peripheral arthritis — Type 1 (pauciarticular)	Axial arthropathy — sacroiliitis, ankylosing spondylitis
Erythema nodosum	Peripheral arthritis — Type 2 (polyarticular)

Parallels bowel activity (treat the bowel)	Independent of bowel activity (treat separately)
Episcleritis	Anterior uveitis / iritis
Oral aphthous stomatitis, pyostomatitis/pyoderma vegetans	Pyoderma gangrenosum
Sweet syndrome, metastatic CD	Primary sclerosing cholangitis (PSC)

Musculoskeletal (most common EIM group; 5–20%)

- ▶ **Peripheral arthritis** — develops in 15–20% of IBD patients, commoner in CD, classically **asymmetric, migratory, polyarticular, non-deforming**, affecting large joints; rheumatoid factor **negative**. Sleisenger subdivides it into:
 - ***Type 1 (pauciarticular)** — <5 joints, large joints, *parallels** bowel activity, self-limiting, associated with EN and uveitis; often remits after colectomy in UC.
 - ***Type 2 (polyarticular)** — >5 joints, small joints (MCP/PIP), *independent** of bowel activity, more persistent.
- ▶ **Axial spondyloarthropathy** — ankylosing spondylitis (AS) occurs in ~10% (commoner in CD); two-thirds (up to 75% of CD with spondylitis) are HLA-B27 positive. Presents with **insidious low-back/buttock pain and morning stiffness improved by exercise**, runs a continuous progressive course causing permanent skeletal deformity, and does **not** remit with glucocorticoids or colectomy. **Sacroiliitis** is symmetric, occurs equally in UC and CD, is often asymptomatic, does not correlate with bowel activity, and does not always progress to AS. Anti-TNF agents reduce spinal inflammation.
- ▶ **Metabolic bone disease** — low bone mass in 14–42%; risk increased by **glucocorticoids, ciclosporin, methotrexate, TPN**, malabsorption of calcium/vitamin D, and cytokines (IL-1, IL-6, TNF). Absolute fracture risk ≈ **1% per person-year** (highest age >60; OR ≈1.7 vertebral, 1.6 hip). Screen with **DEXA**, check vitamin D, treat osteopenia/osteoporosis especially on long-term steroids.
- ▶ **Osteonecrosis (avascular necrosis)** — death of osteocytes/adipocytes with bone collapse; **hips > knees/shoulders**; major risk factor is **steroid use**. Diagnosed by **MRI/bone scan**; treat with analgesia, decompression, joint replacement.
- ▶ Other: clubbing, hypertrophic osteoarthropathy, septic joint (e.g. from psoas abscess), osteomyelitis.

Mucocutaneous (10–20%)

- ▶ **Erythema nodosum (EN)** — up to 15% of CD, 10% of UC; **hot, red, tender 1–5 cm nodules** on the anterior shins/extremities; **parallels bowel activity**, commoner in women, strongly associated with peripheral arthritis. *Avoid biopsy* (scars); treat the underlying bowel disease.

- ▶ **Pyoderma gangrenosum (PG)** — 1–12% of UC, less in Crohn's colitis; **independent** of bowel activity, usually severe disease. Begins as a pustule/nodule that ulcerates with **violaceous, undermined borders** and necrotic base, classically on the legs/dorsa of feet or peristomal; shows **pathergy (ulcers at trauma sites) and heals with a cribriform scar. Difficult to treat — topical/IV/intralesional glucocorticoids, ciclosporin, infliximab/adalimumab, dapsone, azathioprine; debridement and colectomy are NOT effective**.
- ▶ **Oral** — aphthous stomatitis and “cobblestone” buccal lesions (CD > UC), pyostomatitis vegetans, granulomatous labial/facial swelling, angular cheilitis.
- ▶ **Others** — **psoriasis** (5–10%, shared IL23R/IL12B genetics, unrelated to bowel activity), pyoderma vegetans (intertriginous), **Sweet syndrome** (neutrophilic dermatosis), **metastatic CD** (cutaneous non-caseating granulomas remote from gut), perianal skin tags (75–80% of CD), leukocytoclastic vasculitis.

Ocular (1–11%)

- ▶ **Episcleritis** — commonest; mild ocular burning/injection, **does not impair vision, parallels bowel activity** (3–4%); topical glucocorticoids.
- ▶ **Anterior uveitis / iritis** — **ocular pain, photophobia, blurred vision, headache, ciliary flush, miosis**; in IBD often **insidious, bilateral, with posterior extension**; **independent** of bowel activity and may appear in remission. **The one ocular EIM demanding emergent ophthalmology referral** — prompt systemic steroids prevent scarring and visual loss.
- ▶ Rare: scleritis (sight-threatening), keratopathy, **night blindness** from vitamin A malabsorption.

Hepatobiliary (10–35%)

- ▶ **Primary sclerosing cholangitis (PSC)** — intra- and extra-hepatic bile-duct **inflammation and fibrosis** → biliary cirrhosis/failure. ~5% of UC patients have PSC, but 50–75% of PSC patients have IBD; both are commonly **pANCA positive**. Often asymptomatic; runs a course **independent** of bowel activity. Diagnose with MRCP (initial test of choice; safer than ERCP) showing **multifocal strictures alternating with dilatations (“beaded” ducts)**. Carries a **10–15% lifetime risk of cholangiocarcinoma**, gallbladder-polyp malignancy (cholecystectomy even if <1 cm; annual USG surveillance) and **increased colon-cancer risk** → **yearly surveillance colonoscopy**. Small-duct PSC / “pericholangitis” has a normal cholangiogram and a better prognosis.
- ▶ **Cholelithiasis** — 10–35%, in CD with **ileitis or ileal resection**; bile-acid malabsorption depletes the bile-salt pool → **lithogenic (cholesterol/pigment) stones**.
- ▶ **Hepatic steatosis (fatty liver)** — from chronic illness, malnutrition and steroids; **autoimmune hepatitis**, granulomatous hepatitis and **hepatic amyloidosis** are rarer.

Renal/urologic, vascular and other systemic

- ▶ **Nephrolithiasis (10–20%)** — highest in CD after **small-bowel resection**; **calcium-oxalate stones** from **enteric hyperoxaluria** — unabsorbed fatty acids bind luminal calcium, leaving oxalate free for colonic absorption. Manage with a **low-oxalate diet**, hydration and control of inflammation. Uric-acid stones (volume depletion), ureteric obstruction, ileovesical fistulas, and mesalamine-associated interstitial nephritis also occur.
- ▶ **Thromboembolism** — increased **venous and arterial** thrombosis **even when disease is inactive** (hypercoagulable state: thrombocytosis, raised fibrinogen/factors V & VIII, hyperhomocysteinaemia, impaired fibrinolysis, tissue-factor microvesicles). Treat with anticoagulation plus control of inflammation; thromboprophylaxis in hospitalised flares.
- ▶ **Systemic (secondary/reactive AA) amyloidosis** — long-standing IBD, especially CD; causes diarrhoea, constipation and **renal failure**; renal disease responds to **colchicine**.
- ▶ **Cardiopulmonary** — endocarditis, myocarditis, pleuropericarditis, interstitial lung disease (rarely 5-ASA-induced — stop the drug).
- ▶ **Pancreatitis** — duodenal fistula, ampullary CD, gallstones, PSC, drugs (azathioprine/mercaptopurine, rarely 5-ASA), autoimmune, or primary CD of the pancreas.
- ▶ **Haematologic** — anaemia of chronic disease, iron and B12 deficiency (ileal disease).

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Head-to-toe “EIM map” of IBD** — draw a body outline and label by region: **Eyes** — episcleritis, anterior uveitis/iritis; **Mouth** — aphthous stomatitis, pyostomatitis vegetans; **Skin** — erythema nodosum (shins), pyoderma gangrenosum (legs/peristomal), psoriasis, metastatic CD; **Liver/biliary** — PSC (beaded ducts), gallstones, fatty liver; **Joints/spine** — peripheral arthritis (Type 1/Type 2), sacroiliitis, ankylosing spondylitis (bamboo spine); **Bone** — osteoporosis, avascular necrosis of hip; **Kidney** — calcium-oxalate stones; **Vessels** — venous thromboembolism.
- ▶ **Two-column flow diagram** “EIMs that PARALLEL vs are INDEPENDENT of bowel activity” with the labels: *Parallel* = peripheral arthritis Type 1, EN, episcleritis, aphthous ulcers; *Independent* = sacroiliitis, AS, uveitis, pyoderma gangrenosum, PSC.

Clinical / Diagnostic significance

- ▶ **Activity-linked EIMs** (Type 1 arthritis, EN, episcleritis, oral aphthae) signal a bowel flare and respond to **inducing remission** (5-ASA, steroids, biologics); **activity-independent EIMs** (AS, uveitis, PG, PSC) need their own therapy and do **not** improve with colectomy.
- ▶ An EIM such as **PG or PSC can precede the bowel diagnosis by years**, so IBD should be sought in unexplained PG, recurrent uveitis, or cholestatic LFTs with pANCA.
- ▶ **HLA-B27** typing supports axial spondyloarthritis; **MRCP** for cholestatic LFTs; **DEXA + vitamin D** for bone disease; **MRI** for AVN and sacroiliitis.

- ▶ **Biologics** (anti-TNF — infliximab/adalimumab; anti-IL-12/23 — ustekinumab/risankizumab; JAK inhibitors; IL-17 inhibitors for spondyloarthritis) treat both gut and several EIMs simultaneously; **vedolizumab** (gut-selective) is less effective for EIMs.
- ▶ PSC patients need **annual surveillance colonoscopy** (colon-cancer risk) and **gallbladder USG** (cholangiocarcinoma/polyp risk).

High-yield exam pointers

- ▶ Up to **one-third** of IBD patients have ≥ 1 EIM; commoner in CD and in **colonic disease**.
- ▶ **Peripheral arthritis**: Type 1 = **pauciarticular** (<5 joints), **parallels bowel**; Type 2 = **polyarticular** (>5 joints), **independent**. RF negative, non-deforming.
- ▶ AS/sacroiliitis are **independent** of bowel activity; **~two-thirds HLA-B27 positive**; do not remit with colectomy.
- ▶ EN parallels activity (treat the bowel); PG is independent, shows **pathergy**, heals with a **cribriform scar**, and **colectomy/debridement do not help**.
- ▶ **Uveitis** = the ocular emergency (urgent ophthalmology + systemic steroids); **episcleritis** is benign and parallels activity.
- ▶ **PSC**: ~5% of UC have it, 50–75% of PSC have IBD; pANCA+; MRCP shows **beaded strictures**; **10–15% lifetime cholangiocarcinoma** risk; surveillance colonoscopy yearly.
- ▶ **Calcium-oxalate stones** via **enteric hyperoxaluria** after ileal disease/resection.
- ▶ IBD is a **hypercoagulable state** — VTE risk persists even in remission.
- ▶ **Secondary (AA) amyloidosis** in long-standing CD; renal involvement treated with **colchicine**.

Fecal Microbiota: Current Trends and Transplant

Asked in: Paper IV Jul 2020 — RGUHS MD General Medicine

Definition / Introduction — The **human microbiota** is the collective community of bacteria, viruses, fungi and Archaea inhabiting body surfaces; the **microbiome** is the aggregate of their genes. A human is best viewed as a *holobiont* — host cells plus microbes — whose >2,000,000 microbial genes dwarf the ~20,000 human genes. **Fecal microbiota transplantation (FMT)** — also termed *intestinal microbiota transplantation (IMT)* or *fecal microbiota replacement therapy (FMRT)* — is the transfer of processed stool from a screened healthy donor into a diseased recipient to correct **dysbiosis** and restore *colonization resistance*. It is the single most successful microbiome-based therapy and the “poster child” for recurrent *Clostridioides difficile* infection (rCDI).

The Human Microbiota — Normal Composition and Function

- ▶ **Numbers:** >10,000 bacterial species exist in the human microbiota; the gut alone harbours >1000 species, with 100–200 present in any individual at a given time. Bacteria outnumber human cells by ~1.3:1 (a person is ~56% “bacterial”; with viruses/fungi/Archaea, microbes likely exceed 90% of cells).
- ▶ **Five dominant phyla:** *Actinobacteria*, *Bacteroidetes*, *Firmicutes*, *Fusobacteria*, *Proteobacteria*.
- ▶ **Key ecological principles** (Human Microbiome Project, *Nature* 2012):
 - Composition is determined more by **body site** than by inter-individual variation (oral, gut, skin, urogenital, nasal each cluster distinctly); stool is the richest, most-studied site.
 - Marked **inter-individual variability** in taxa, yet the **functional/metabolic gene capacity is conserved** — *functional redundancy*.
 - Modulators of the gut microbiota: **diet, drugs (esp. antibiotics), age, host genetics (small effect), delivery mode, lifestyle, circadian rhythm**.
- ▶ **Functions:** colonization resistance against pathogens; education of innate and adaptive immunity (germ-free animals have an immature immune system); short-chain fatty acid (SCFA) production (butyrate/acetate/propionate → regulatory T cells, colonocyte energy, barrier integrity); bile-acid and drug metabolism; vitamin synthesis.

Dysbiosis and the Rationale for FMT

- ▶ **Dysbiosis** = a disease-associated shift to a new microbial equilibrium, typically with **reduced alpha- and beta-diversity** and an increase in *Enterobacteriaceae* with loss of *Lachnospiraceae*/butyrate producers.
- ▶ In **rCDI**, antibiotics deplete protective anaerobes → loss of colonization resistance → reduced phylogenetic richness with depletion of *Firmicutes* and *Bacteroidetes*.
- ▶ **Mechanisms by which FMT cures CDI:** restoration of microbial diversity and **colonization resistance**; conversion of primary to **secondary bile acids** (e.g., by *Clostridium scindens*, which inhibits *C. difficile* germination/outgrowth); restoration of **butyrate producers**; and refilling of open nutritional niches.

FMT — Donor, Preparation, Routes and Safety

Step	Detail
Donor selection	Rigorous screening; exclude donors with communicable disease or microbiome-associated conditions (metabolic disease, neuropsychiatric illness, IBD, immunocompromise). Full medical history + blood, stool and urine testing; informed consent that FMT for CDI is investigational
Stool banking	Pre-screened donor material biobanked frozen (e.g., <i>OpenBiome</i>); fresh and freeze-thawed stool have similar efficacy
Routes of delivery	Nasogastric / nasoduodenal tube, colonoscopy (most commonly used today), retention enema , or oral capsules . Lower-GI (colonic/rectal) cure $\approx$ 92% vs upper-GI $\approx$ 81%
Efficacy in rCDI	Clinical cure $\sim$ 85–95%; meta-analysis primary cure 91.2% , recurrence 5.5%. Donor FMT > autologous (90% vs 62.5%). Landmark <i>van Nood</i> RCT (<i>NEJM</i> 2013): nasoduodenal donor feces 81% vs vancomycin 31% vs vancomycin + lavage 23%
Adverse effects	Usually transient (<48 h): altered GI motility (diarrhea/constipation), cramps, bloating. Serious risk: transmission of multidrug-resistant organisms (reported deaths from ESBL-producing <i>E. coli</i>) — drove tighter FDA donor-screening rules
Severe/refractory CDI	Sequential (“multiple”) FMT during continued vancomycin improves outcome (100% cure with repeated vs 75% single infusion); poor surgical candidates with fulminant disease may receive FMT by colonoscopy every 3–5 days

Current Trends — FDA-Approved Live Biotherapeutics and Next-Generation Products

The FDA has moved FMT for rCDI from “enforcement discretion” toward **standardized, regulated live biotherapeutic products (LBPs)**. Both 2023-approved products are **adjuncts** given only after completion of antibiotic therapy for rCDI.

Product	Composition / Route	Trial outcome (recurrence)	Notes
Rebyota (fecal microbiota, <i>live-jslm</i> ; RBX2660)	Donor-derived microbiota suspension by rectal enema (150 mL), single dose	29% vs 42% placebo at 8 wk (PUNCH CD3)	First FDA-approved FMT product (2023)

Product	Composition / Route	Trial outcome (recurrence)	Notes
VOWST (fecal microbiota spores, <i>live-brpk</i> ; SER-109)	Oral capsules of ethanol-purified bacterial spores, 4 capsules once daily × 3 days	12.4% vs 38.8% placebo at 8 wk	First FDA-approved oral microbiome therapy
Bezlotoxumab	Human monoclonal antibody vs toxin B, 10 mg/kg IV (adjunct, not an FMT)	rCDI reduced ~10% absolute (16.5% vs 26.6%)	For high-risk patients during standard antibiotics

- **Adjunctive antibiotic context** (CMDT/IDSA-SHEA): **fidaxomicin** lowers recurrence vs vancomycin (15% vs 25%); FMT/FMRT is reserved for **≥2 recurrences (multiply-recurrent CDI)** after appropriate antibiotic therapy.
- **Pipeline / future generations**: defined **bacterial consortia** (e.g., *Blautia producta* + *Clostridium bolteae* against VRE; *C. scindens* against CDI), **rationally chosen probiotics**, single strains, engineered commensals, and bacteria-derived small molecules / **pharmabiotics** (bacteriocins, phages) — aiming to replace crude stool with standardized “stool substitutes.”
- **Expanding (investigational) indications**: as of mid-2024, **>500 registered trials** of FMT — IBD (ulcerative colitis is the best-studied non-CDI indication, mixed results), IBS-D, obesity and **type 2 diabetes** (lean-donor FMT transiently improved insulin sensitivity and butyrate producers), **MDRO/VRE decolonization**, cirrhosis/hepatic encephalopathy, GVHD after HSCT, and augmenting **anti-PD-1 immunotherapy** in melanoma (responder→non-responder stool restored responses).

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- **Schematic of the FMT pathway** — boxes left→right: *Screened healthy donor* → *Stool collection & blood/stool/urine screening* → *Processing & homogenization (fresh or frozen, stool bank)* → *Delivery routes (NG/nasoduodenal tube, colonoscopy, enema, oral capsule)* → *Recipient with rCDI* → *Restored diversity, colonization resistance, secondary bile acids* → *Clinical cure ~85–95%*. Label the donor-screening exclusions (IBD, immunocompromise, metabolic/neuropsychiatric disease, communicable disease).
- **Dysbiosis vs healthy gut bar graph** — two stacked bars: *Healthy* (high diversity, abundant Firmicutes/Bacteroidetes, butyrate producers) vs *rCDI dysbiosis* (low diversity, depleted Firmicutes/Bacteroidetes, ↑Enterobacteriaceae, *C. difficile* bloom). Labels: alpha diversity, Firmicutes, Bacteroidetes, Proteobacteria, secondary bile acids.

Clinical / Diagnostic significance

- ▶ **Primary established indication: multiply-recurrent CDI** — FMT after the second recurrence, given following a course of vancomycin/fidaxomicin; cure rates far exceed antibiotics alone.
- ▶ **Investigations before FMT:** confirm toxigenic *C. difficile* by stool toxin/NAAT testing; assess severity (WBC $\geq 15,000/\mu\text{L}$, creatinine $\geq 1.5 \text{ mg/dL}$ = severe). Donors undergo communicable-disease screening to prevent pathogen transmission.
- ▶ **Safety governance:** standardized FDA-approved LBPs (Rebyota, VOWST) now offer regulated alternatives to “home-brew” stool, improving reproducibility and reducing transmission risk.
- ▶ **Microbiome as a biomarker/therapeutic target:** gut microbiota composition predicts response to checkpoint-inhibitor immunotherapy, modulates drug metabolism (digoxin inactivation by *Eggerthella lenta*; irinotecan toxicity via bacterial β -glucuronidase), and influences vaccine responses.

High-yield exam pointers

- ▶ FMT = transfer of screened-donor stool to restore a healthy microbiota; mechanism is restoration of **colonization resistance** and **secondary bile acids**.
- ▶ Historical line: 4th-century Chinese “*yellow soup*” → first English description **1958** (pseudomembranous colitis) → landmark **van Nood RCT, NEJM 2013** (81% cure).
- ▶ **Best indication = multiply-recurrent CDI**; cure ~85–95%; **colonic/lower-GI route > upper-GI**.
- ▶ **Two FDA-approved (2023) products:** Rebyota (enema, *live-jslm*) and VOWST (oral spore capsules, *live-brpk*) — both **adjuncts after antibiotics**.
- ▶ **Bezlotoxumab** (anti-toxin-B mAb, 10 mg/kg IV) is an adjunct, *not* an FMT.
- ▶ Five dominant gut phyla: **Actinobacteria, Bacteroidetes, Firmicutes, Fusobacteria, Proteobacteria**.
- ▶ Main FMT adverse events are transient (cramps, bloating, altered motility); the feared serious event is **MDRO transmission**.
- ▶ Non-CDI uses (IBD/UC, IBS, obesity, T2D, MDRO decolonization, immunotherapy augmentation) remain **investigational** (>500 trials).
- ▶ Future = defined consortia, engineered commensals, pharmabiotics — replacing crude stool with standardized products.

Gastroduodenal Mucosal Defense

Asked in: Paper II Nov 2022 — RGUHS MD General Medicine

Definition / Introduction — The gastroduodenal epithelium is under constant assault by *endogenous* noxious factors (hydrochloric acid, pepsinogen/pepsin, bile salts) and *exogenous* agents (drugs, alcohol, ingested bacteria). **Gastroduodenal mucosal defense** is the highly integrated biologic system that protects the mucosa from this injury and repairs damage when it occurs. It is best conceptualised as a **three-level barrier** — **pre-epithelial, epithelial and subepithelial** — coordinated by prostaglandins, nitric oxide and growth factors. Peptic ulcer disease (PUD) ultimately reflects a breakdown in the equilibrium between these defensive forces and the aggressive acid-peptic milieu.

Aggressors versus defenses — the central balance

- **Aggressive (injurious) factors:** gastric acid (HCl) and pepsin are the two principal secretory products capable of inducing mucosal injury; bile salts, NSAIDs, alcohol and *H. pylori* add to the insult.
- **Defensive factors:** mucus, bicarbonate, surface phospholipids, epithelial integrity/restitution, mucosal blood flow, prostaglandins and nitric oxide.
- Acid and pepsin are not purely harmful — they serve physiological roles (protein digestion; absorption of iron, calcium, magnesium and vitamin B12; killing of ingested bacteria), so defense, not acid elimination, is the body’s strategy.
- **Ulcer = aggression outweighing defense.** *H. pylori* and NSAIDs (the two commonest causes of PUD) both injure largely by undermining mucosal defense.

The three-tier mucosal defense barrier (overview)

Tier	Anatomical level	Key components	Principal protective action
First line	Pre-epithelial	Mucus–bicarbonate–phospholipid layer	Physicochemical barrier; unstirred layer holding a pH gradient
Second line	Epithelial	Surface epithelial cells, ionic transporters, tight junctions, heat-shock proteins, trefoil peptides, restitution	Maintain intracellular pH, repair small defects

Tier	Anatomical level	Key components	Principal protective action
Third line	Subepithelial	Submucosal microvascular bed	Delivers HCO_3^- , O_2 and nutrients; removes toxic metabolites

Pre-epithelial defense — the mucus–bicarbonate–phospholipid layer

- ▶ The first line of defense is a **mucus–bicarbonate–phospholipid layer** that acts as a *physicochemical barrier* to multiple molecules, including hydrogen ions.
- ▶ **Mucus** is secreted in a regulated fashion by gastroduodenal **surface epithelial cells**; it is ~95% water plus a mixture of **phospholipids and glycoproteins (mucin)**.
- ▶ The mucous gel functions as a **non-stirred water layer**, impeding the diffusion of ions and large molecules such as **pepsin**.
- ▶ **Bicarbonate**, secreted by surface epithelial cells into the mucous gel, establishes a **pH gradient from 1–2 at the luminal surface to 6–7 along the epithelial cell surface** — neutralising acid at the very point of contact with the cell.
- ▶ Surface **phospholipids** render the luminal surface hydrophobic, repelling the aqueous acid.

Epithelial defense — surface cells, tight junctions and restitution

- ▶ The next line of defense is provided by surface epithelial cells through:
 - **Mucus production and epithelial ionic transporters** that maintain intracellular pH and generate bicarbonate.
 - **Intracellular (intercellular) tight junctions** that limit back-diffusion of H^+ .
 - **Heat-shock proteins** that prevent protein denaturation and protect against raised temperature, cytotoxic agents and oxidative stress.
 - **Trefoil factor family (TFF) peptides and cathelicidins**, which aid surface-cell protection and regeneration.
- ▶ **Restitution**: if the pre-epithelial barrier is breached, epithelial cells bordering the injury **migrate to reseal the defect**. This occurs **independent of cell division** and requires **uninterrupted blood flow and an alkaline pH** in the surrounding environment.
- ▶ **Larger defects** that restitution cannot repair require **cell proliferation**, regulated by **prostaglandins** and growth factors (EGF, TGF- α).
- ▶ In tandem, **angiogenesis** restores the injured microvascular bed; **basic FGF** and **VEGF** are key regulators. The peptide **gastrin** further stimulates cell proliferation, migration, invasion, angiogenesis and autophagy; parietal cells express **sonic hedgehog (Shh)**, implicated in regulating gastric stem cells and restitution.

Subepithelial defense — the gastric microcirculation

- ▶ An elaborate microvascular system in the gastric submucosal layer is the key subepithelial defense/repair component.
- ▶ It supplies HCO_3^- that neutralises the acid generated by parietal cells, delivers **micronutrients and oxygen**, and **removes toxic metabolic by-products**.
- ▶ Locally produced vasodilators — **nitric oxide (NO)**, **hydrogen sulfide (H_2S)** and **prostacyclin (PGI_2)** — protect the mucosa by **vasodilating the microcirculation** and sustaining blood flow.
- ▶ Adequate blood flow is the *common denominator* on which restitution and bicarbonate delivery depend; ischaemia is therefore a potent ulcerogenic stress.

Chemical mediators — prostaglandins, the COX system and nitric oxide

- ▶ Prostaglandins (chiefly PGE_2 and PGI_2) play a *central* role in epithelial defense and repair. They:
 - regulate the release of mucosal **bicarbonate and mucus**,
 - **inhibit parietal-cell acid secretion**,
 - maintain **mucosal blood flow**, and
 - promote **epithelial cell restitution**.
- ▶ Synthesis pathway: membrane **phospholipids** → **phospholipase A_2** → **arachidonic acid** → (cyclooxygenase, COX) → **prostaglandins**. COX is the **rate-limiting** enzyme and exists as two isoforms:

Feature	COX-1	COX-2
Expression	Constitutive (“housekeeping”)	Inducible by inflammatory stimuli
Tissue distribution	Stomach, platelets, kidneys, endothelium	Macrophages, leukocytes, fibroblasts, synovial cells
Main products	TXA_2 , PGI_2 , PGE_2	PGI_2 , PGE_2
Role	GI mucosal integrity, platelet aggregation, renal function	Inflammation, mitogenesis, bone formation

- ▶ The **anti-inflammatory benefit of NSAIDs** is via **COX-2 inhibition**, whereas their **GI mucosal toxicity (and renal dysfunction)** is via **COX-1 inhibition** — the basis for COX-2–selective agents (whose cardiovascular hazard led the FDA to withdraw rofecoxib and valdecoxib).
- ▶ **Nitric oxide (NO)**: NO synthase is **constitutively expressed** in the mucosa and contributes to cytoprotection by **stimulating gastric mucus**, **increasing mucosal blood flow** and **maintaining epithelial barrier function**.
- ▶ **CNS and hormonal inputs** (e.g., CRF/TRF, CCK, EGF, IGF, TGF- α) modulate defense through multiple pathways.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Diagram 1 — “Three-tier gastroduodenal mucosal defense”** (based on Fig. 335-3). Draw the gastric wall in layers and label: *Lumen* (*HCl*, *pepsin*, *bile salts*); **Pre-epithelial layer** — *Mucus*, *Bicarbonate* (HCO_3^-), *Phospholipids*, with a *pH gradient* 1–2 (*lumen*) → 6–7 (*cell surface*); **Epithelial layer** — *Surface epithelial cells*, *Tight junctions*, *Restitution* (*cell migration*), *Heat-shock proteins* / *Trefoil peptides*; **Subepithelial layer** — *Submucosal microcirculation*, *NO* / *H₂S* / *Prostacyclin*. Add an overarching label *Prostaglandins*, *EGF*, *TGF- α* , *gastrin*.
- ▶ **Diagram 2 — “Prostaglandin synthesis & COX isoforms”** (based on Fig. 335-4). Label the cascade: *Membrane phospholipids* → (*Phospholipase A₂*) → *Arachidonic acid* → *COX-1* / *COX-2*; under **COX-1**: *Stomach*, *kidney*, *platelets*, *endothelium* → *TXA₂*, *PGI₂*, *PGE₂* → *GI mucosal integrity*, *platelet aggregation*, *renal function*; under **COX-2**: *Macrophages*, *leukocytes*, *fibroblasts* → *PGI₂*, *PGE₂* → *inflammation*, *mitogenesis*.

Clinical / Diagnostic significance

- ▶ **NSAID ulcers**: NSAIDs interrupt prostaglandin synthesis, impairing mucosal defense and repair, causing injury via a *systemic* mechanism; **neutrophil adherence to the gastric microcirculation** is essential in initiating NSAID-induced injury. Hence prophylaxis targets defense restoration.
- ▶ **Misoprostol** — a stable prostaglandin (PGE_1) analogue, 200 μg qid, works by **enhancing mucosal defense and repair**; used to prevent NSAID-induced ulcers. Toxicity: **diarrhoea** (10–30%), uterine bleeding/contractions; **contraindicated in pregnancy**.
- ▶ **Sucralfate** acts locally as a **physicochemical barrier**, binds growth factors (EGF), **enhances prostaglandin synthesis** and stimulates **mucus and bicarbonate secretion**, augmenting defense; dose 1 g qid (constipation 2–3%; avoid in renal failure — aluminium neurotoxicity).
- ▶ **Gastric ulcers** developing despite normal/low acid output imply **impaired mucosal defense** rather than acid hypersecretion — the rationale for biopsy (to exclude malignancy) and for cytoprotective therapy.
- ▶ **Smoking** impairs defense (decreased duodenal bicarbonate, mucosal free-radical generation), reduces healing and increases complications such as perforation.
- ▶ **Duodenal defense**: duodenal mucosal **bicarbonate secretion is decreased** in active DU; *H. pylori* contributes to this, linking the organism to defective duodenal defense.

High-yield exam pointers

- ▶ Defense = **three tiers**: pre-epithelial → epithelial → subepithelial.
- ▶ **First line** = mucus–bicarbonate–phospholipid layer; mucus is 95% water + mucin, acts as a non-stirred layer.
- ▶ **pH gradient**: 1–2 at lumen → 6–7 at epithelial surface (classic must-write number).

- ▶ **Restitution** = epithelial migration to reseal small defects, *no cell division*, needs **blood flow + alkaline pH**.
- ▶ **Subepithelial microcirculation** delivers $\text{HCO}_3^-/\text{O}_2$ and removes toxins; **NO, H_2S , prostacyclin** maintain flow.
- ▶ **Prostaglandins** (PGE_2 , PGI_2) are the master cytoprotectants; **COX-1 = GI mucosal integrity**, COX-2 = inflammation.
- ▶ **NSAID toxicity = COX-1 inhibition**; benefit = COX-2 inhibition.
- ▶ **Misoprostol 200 μg qid** restores defense; contraindicated in pregnancy.
- ▶ Growth factors of repair: **EGF, TGF- α , FGF, VEGF**; gastrin and sonic hedgehog aid regeneration.

SOURCE & COVERAGE

Harrison's Principles of Internal Medicine, 22e — Ch 335 "Peptic Ulcer Disease and Related Disorders" (Gastroduodenal Mucosal Defense; Prostaglandins/COX; NSAID pathophysiology; treatment of acid-peptic disorders). All physiology, the three-tier model, the pH gradient, COX isoform table, and drug doses (misoprostol 200 μg qid, sucralfate 1 g qid) are faithful to this chapter. *Coverage note:* surface phospholipid hydrophobicity is standard textbook physiology stated only briefly here; no fabrication added beyond the cited chapter.

Gastro-Oesophageal Reflux Disease (GERD)

Asked in: Paper III May 2019 — RGUHS MD General Medicine

Definition / Introduction — Gastro-oesophageal reflux (GER) is the *physiological* retrograde movement of gastric contents into the oesophagus that occurs many times daily (chiefly post-prandially) without symptoms or mucosal damage. **GERD** is the *pathological* state — per the Montreal consensus, “a condition that develops when reflux of stomach contents causes troublesome symptoms and/or complications.” It is best regarded as a **family of conditions** sharing the commonality of excessive reflux, spanning non-erosive reflux disease (NERD), erosive (reflux) oesophagitis, and the complications of stricture, Barrett's metaplasia and adenocarcinoma, plus a set of extra-oesophageal syndromes. It is one of the commonest disorders of mankind, affecting an estimated **10–15% of US adults** ($\approx 20\text{--}30\%$ reporting at least weekly symptoms); pooled worldwide weekly prevalence is $\sim 13\%$, highest in **South Asia and South-East Europe** ($>25\%$).

Pathophysiology — the antireflux barrier and mechanisms of reflux

- ▶ The antireflux barrier (oesophago-gastric junction, OGJ) is a composite valve dependent on: (1) the intrinsic **lower oesophageal sphincter (LES)** tone; (2) the **crural diaphragm** providing extrinsic “pinch-cock” squeeze (imposing rhythmic 5–10 mmHg rises, up to 50–150 mmHg on

straining); (3) the **intra-abdominal segment** of oesophagus; (4) the **acute angle of His** with its flap-valve; and (5) the **phreno-oesophageal ligament**.

- ▶ **Mechanisms of pathological reflux** (Sleisenger): (1) **Transient LES relaxations (tLESRs)** — the dominant mechanism, accounting for nearly all reflux in normals and **50–80% in GERD**; these are vagally-mediated, swallow-independent, last >10 s, are not followed by peristalsis, are accompanied by crural inhibition, and are triggered by **proximal gastric distension** (the belch reflex); (2) **low basal LES pressure** (hypotensive sphincter, present in up to 50% of severe erosive GERD); (3) **swallow-associated LES relaxation**; and (4) **straining during periods of low LES pressure**.
- ▶ **Anatomical disruption** progressively unhinges the barrier: widening of the diaphragmatic hiatus with weak crural function; loss of the intra-abdominal segment and flap valve; **axial (sliding) hiatal hernia** (which traps acid in the hernia sac that refluxes during swallow-induced relaxation); and increased OGJ compliance.
- ▶ **Defective acid clearance** prolongs mucosal contact — refluxate is normally returned by peristalsis and the residual acid neutralised by **swallowed salivary bicarbonate**; impaired peristalsis (e.g., scleroderma) and reduced salivation worsen exposure.
- ▶ **Aggravating factors**: abdominal/truncal obesity, pregnancy, gastric hypersecretory states, delayed gastric emptying, and disrupted peristalsis.
- ▶ **Mucosal injury** results from acid + pepsin (and weakly-acidic bile, which persists despite PPIs); current evidence favours a **cytokine-mediated inflammatory pathway** rather than direct caustic burn.

Hiatal hernia (companion lesion)

Type	Description	Note
Type I (sliding)	OGJ + cardia translocate cephalad through hiatus	~95% of all; main GERD association
Type II (para-oesophageal)	Fundus herniates; OGJ fixed at hiatus	risk of volvulus/strangulation
Type III	Combined sliding + para-oesophageal	large hernias → “upside-down stomach”
Type IV	Non-gastric viscus herniates (commonly colon)	surgical repair often advocated

Clinical features

- ▶ **Typical (oesophageal) symptoms**: **Heartburn (pyrosis)** — retrosternal burning rising from the epigastrium, 30–60 min after meals, on bending or recumbency, relieved by antacids; and **regurgitation** — effortless return of sour/bitter fluid without nausea or retching. Heartburn severity correlates **poorly** with the presence/grade of oesophagitis.

- ▶ **Less common:** dysphagia (>30% — usually peptic stricture, Schatzki ring or dysmotility), chest pain (closely mimics angina — *cardiac disease must be excluded first*), water brash (reflex hypersalivation) and globus.
- ▶ **Important caveat:** *odynophagia is uncommon in reflux disease* and should prompt a search for pill, infectious or eosinophilic oesophagitis.
- ▶ **Extra-oesophageal syndromes** (associations, not always causal) — established: **chronic cough, laryngitis, asthma, dental erosions**; proposed: pharyngitis, chronic bronchitis, pulmonary fibrosis, sinusitis, arrhythmias, sleep apnoea, recurrent aspiration. Mechanisms: direct microaspiration/contact vs a **vago-vagal reflex** (oesophageal afferent activation → reflex bronchospasm, cough).
- ▶ **Differential diagnosis:** coronary artery disease (priority), infectious/pill oesophagitis, eosinophilic oesophagitis (EoE), peptic ulcer disease, functional dyspepsia, biliary colic, and oesophageal motility disorders (achalasia).

Diagnostic approach

- ▶ **Empirical PPI trial** is the dominant first strategy for typical symptoms **without alarm features** — once-daily PPI for 4–8 weeks.
- ▶ **Upper GI endoscopy (EGD)** — indicated for **alarm features** (dysphagia, odynophagia, weight loss, iron-deficiency anaemia, GI bleed), failure of empirical therapy, and **Barrett screening** (weekly symptoms ≥5 yr plus ≥3 risk factors: age >50, truncal obesity, male sex, White race, current/prior smoking, family history). Erosive oesophagitis at the OGJ is the endoscopic hallmark but is present in only **~one-third** of GERD patients.
- ▶ **Los Angeles (LA) classification** grades erosive oesophagitis (see table) — the universally used severity score.
- ▶ **Ambulatory reflux (pH / pH-impedance) testing** — demonstrates the physiological abnormality when endoscopy is normal (NERD); 24–96 h recording, with **acid exposure time** (% day pH <4) >6% indicative of GERD (Sleisenger upper limit of normal ~4–5.5%). **Impedance-pH** additionally detects **non-acid/weakly-acidic reflux** — valuable for persistent symptoms on PPI. Wireless capsule (Bravo) extends recording to 48–96 h.
- ▶ **High-resolution manometry** — not diagnostic of GERD but mandatory **before antireflux surgery** to exclude achalasia and assess peristaltic reserve.
- ▶ **Barium oesophagogram** — limited diagnostic role; used to size a hiatal hernia or define a stricture pre-operatively.

LA grade	Endoscopic appearance
A	≥1 mucosal break(s) ≤5 mm, confined to a fold
B	≥1 mucosal break(s) >5 mm, confined to folds, not continuous between fold tops

LA grade	Endoscopic appearance
C	Mucosal break(s) continuous between tops of ≥ 2 folds, but $< 75\%$ circumference
D	Circumferential mucosal break ($\geq 75\%$ of circumference)

Complications

- ▶ **Erosive oesophagitis** and **peptic stricture** (up to $\sim 5\%$; gradual solid-food dysphagia, treated by dilation to 15–18 mm + long-term PPI) — both now rare in the potent-antisecretory era.
- ▶ **Barrett's oesophagus** — replacement of distal squamous epithelium by **salmon/orange** columnar epithelium extending > 1 cm above the OGJ, with **specialised intestinal metaplasia** (goblet cells) on biopsy. It is the precursor of **oesophageal adenocarcinoma**, progressing through low- and high-grade dysplasia; cancer risk $\sim 0.1\text{--}0.5\%$ per year (an ~ 11 -fold relative increase). Highest risk: obese White males in the sixth decade.
- ▶ **Surveillance/therapy of Barrett's**: non-dysplastic — endoscopic surveillance every 3–5 years; low-grade dysplasia — endoscopic eradication or 6–12-monthly surveillance; **high-grade dysplasia / intramucosal cancer (Tis–T1a)** — endoscopic eradication therapy (**EMR of nodules + radiofrequency ablation**), which has supplanted oesophagectomy (the latter carries 3–10% mortality).
- ▶ Other: haemorrhage (rare), and the rising incidence of adenocarcinoma paralleling GERD.

Treatment

- ▶ **Lifestyle modification: weight reduction** is the most evidence-based measure; elevate head end of bed and avoid recumbency for 3 h after meals (nocturnal symptoms); avoid refluxogenic foods (fatty foods, chocolate, peppermint, alcohol, coffee) and irritant acidic foods (citrus, tomato); stop smoking; left-lateral sleeping position.
- ▶ **Pharmacotherapy — antisecretory hierarchy**: PCAB $>$ PPI $>$ H2RA for healing oesophagitis.
- ▶ **PPIs are first-line** — taken 30–60 min before breakfast; achieve heartburn control in 70–80% and heal erosive oesophagitis in 75–85%; **regurgitation responds less well**. Inadequate response $\rightarrow$ twice-daily dosing or switch agent.
- ▶ **Maintenance**: $> 80\%$ relapse within ~ 3 months of stopping; severe oesophagitis, Barrett's or stricture warrant long-term PPI at the **lowest effective dose** (continuous, intermittent or “on-demand”).
- ▶ **Potassium-competitive acid blocker (PCAB)** — **vonoprazan 20 mg OD**, FDA-approved, may be taken with meals, fast and sustained acid suppression; superior to lansoprazole in **severe LA C/D oesophagitis (92% vs 72% healing)**; reserved for PPI-refractory disease (cost, fewer long-term safety data).

- ▶ **Anti-reflux surgery** — laparoscopic (Nissen) fundoplication — efficacy similar to PPI for oesophagitis; for refractory/regurgitation-predominant disease or patients declining lifelong medication. Adverse effects: dysphagia, gas-bloat, inability to belch, flatulence. **Magnetic sphincter augmentation (LINX)** is an option for hiatal hernia <3 cm; **gastric bypass** preferred in obesity with GERD.

Drug class	Examples & typical dose	Role
PPI	Omeprazole 20 mg, rabeprazole 20 mg, lansoprazole 30 mg, dexlansoprazole 30–60 mg, esomeprazole 20–40 mg, pantoprazole 40 mg	First-line; before breakfast
PCAB	Vonoprazan 20 mg OD	Refractory / severe LA C–D
H2RA	Famotidine, nizatidine, cimetidine	Mild/intermittent, on-demand, nocturnal breakthrough
Antacids / alginate	Magnesium/aluminium salts, alginate	Rapid, short (<2 h) relief
tLESR inhibitor	Baclofen 5–20 mg TID (GABA-B agonist)	Adjunct; limited by drowsiness/nausea

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Anti-reflux barrier at the oesophago-gastric junction** — label: tubular oesophagus, lower oesophageal sphincter (LES), crural diaphragm, intra-abdominal oesophageal segment, angle of His / flap valve, phreno-oesophageal ligament, gastric cardia, squamo-columnar (Z) junction.
- ▶ **Los Angeles grading panel (A–D)** — four distal-oesophageal sketches showing: small break ≤5 mm on a fold (A); break >5 mm on a fold (B); breaks bridging ≥2 fold-tops, <75% circumference (C); circumferential ≥75% break (D).

Clinical / Diagnostic significance

- ▶ A simple **empirical PPI trial** both treats and supports the diagnosis in uncomplicated typical GERD — avoiding unnecessary endoscopy.
- ▶ **Alarm symptoms mandate prompt endoscopy** to exclude stricture, Barrett's and malignancy.
- ▶ **pH-impedance off/on PPI** distinguishes true acid reflux, non-acid reflux, **reflux hypersensitivity** and **functional heartburn** (≈30% of “PPI-refractory” patients) — the latter respond to neuromodulators (low-dose imipramine/nortriptyline) and CBT, not escalation of acid suppression.
- ▶ **PPI long-term safety**: reassuringly safe; small possible increases in enteric infection (incl. *C. difficile*), SIBO and micronutrient malabsorption (iron, B12, magnesium); reported links to

fracture, CKD/interstitial nephritis, dementia and CVD are **association, not proven causation** — use the lowest effective dose.

- ▶ Exclude **Zollinger-Ellison syndrome** in refractory severe erosive oesophagitis.

High-yield exam pointers

- ▶ GER is physiological; GERD = **troublesome symptoms or complications (Montreal)** — a spectrum: NERD → erosive oesophagitis → stricture → Barrett's → adenocarcinoma.
- ▶ **tLESR is the commonest mechanism** of reflux (not low LES pressure); triggered by gastric distension (belch reflex).
- ▶ **Heartburn + regurgitation = typical; odynophagia is atypical** → think pill/infectious/eosinophilic oesophagitis.
- ▶ **Erosive oesophagitis is seen in only ~1/3 of GERD**; remember the **LA classification A–D** (D = circumferential ≥75%).
- ▶ **Acid exposure time >6% (pH <4)** = pathological reflux; impedance detects non-acid reflux.
- ▶ **Barrett's** = salmon mucosa >1 cm above OGJ with **intestinal metaplasia (goblet cells)**; adenocarcinoma risk ~0.1–0.5%/yr.
- ▶ **Antisecretory potency: PCAB > PPI > H2RA**; PPI taken 30–60 min pre-breakfast; **vonoprazan** superior in LA C/D.
- ▶ **Weight loss** is the best-evidenced lifestyle measure; **laparoscopic fundoplication / LINX** for refractory or regurgitation-predominant disease.
- ▶ Always **exclude cardiac chest pain** before attributing chest pain to GERD.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Diseases of the Esophagus” (GERD pathophysiology, symptoms, complications, Barrett's, treatment).

Hepatitis D (Delta Hepatitis)

Asked in: Paper II Jul 2020 — RGUHS MD General Medicine

Definition / Introduction — Hepatitis D virus (HDV), the *delta agent*, is a defective (satellite) single-stranded RNA virus and the only member of the genus *Deltavirus* (family *Deltaviridae*). It is the smallest known infectious agent of humans and is **replication-defective**: it absolutely requires the helper function of hepatitis B virus (HBV) — specifically **HBsAg** — for assembly, secretion and onward infection, so HDV can only infect people who are simultaneously or already infected with HBV. Although uncommon, HDV produces the **most severe form of chronic viral hepatitis**, with accelerated progression to cirrhosis, decompensation and hepatocellular carcinoma (HCC).

Virology and structure

- ▶ **Defective satellite virus**: requires HBsAg (helper from HBV/hepadnaviruses) for its life cycle; intracellular **RNA replication can occur without HBV**, but HBsAg is needed for **assembly and entry**, not replication.
- ▶ **Virion**: small, ~35–37 nm, formalin-sensitive, **hybrid particle** — an outer envelope of HBsAg (small, middle, large forms) surrounding an inner ribonucleoprotein of **hepatitis D antigen (HDAg)** complexed to the genome. Only virions bearing **large HBsAg** are infectious.
- ▶ **Genome**: ~1700-nucleotide, **circular, single-stranded, negative-sense RNA**, non-homologous with HBV DNA. High guanosine–cytosine content (~74% internal base-pairing) folds it into a stable **rod-like structure** containing a self-cleaving, self-ligating **ribozyme** — features shared with **plant viroids/satellite viruses**.
- ▶ **Replication**: in the hepatocyte **nucleus** using host **RNA polymerase II** (a host enzyme, hence not targetable by conventional antivirals), by a **double rolling-circle** mechanism with ribozyme-mediated cleavage of multimers.
- ▶ **HDAg** is the *only* HDV-encoded protein (single open reading frame) and exists in two forms generated by **RNA editing** (adenosine deaminase converts the UAG stop codon to UGG/tryptophan):
 - **Small HDAg** (195 aa / 24 kDa) — *promotes/facilitates* HDV RNA replication.
 - **Large HDAg** (214 aa / 27 kDa) — *suppresses* replication but is **required for virion assembly**; differs by 19 C-terminal amino acids carrying a **prenylation (farnesylation) signal** essential for interaction with HBsAg.
- ▶ **Entry receptor**: both HBV and HDV enter hepatocytes via the **sodium taurocholate co-transporting polypeptide (NTCP)** after initial binding to heparan-sulfate proteoglycans through the pre-S1 domain of large HBsAg — the molecular basis for the entry-inhibitor *bulevirtide*.
- ▶ **Genotypes: eight genotypes (1–8)**. Genotype 1 is worldwide and predominant; genotype 2 in the Far East/Russia; **genotype 3 in the Amazon basin** (most divergent, severe acute disease/ALF); genotype 4 in the Far East; genotypes 5–8 in Africa.

Epidemiology and transmission

- ▶ HDV infects an estimated ~5% of the world's HBsAg carriers — roughly 12–15 million people (Harrison cites ~12 million; Sleisenger ~15 million).
- ▶ High-endemic zones: **Mediterranean basin, Middle East, central/northern Asia, west & central Africa, Taiwan and the Amazon basin**; low in North America, northern Europe, Japan and Korea. Prevalence has fallen since the 1980s, largely due to **HBV vaccination**.
- ▶ **Two epidemiologic patterns** (Harrison):
 - *Endemic* (Mediterranean) — transmitted by **close personal/nonpercutaneous contact** among HBV carriers.
 - *Nonendemic* (USA, northern Europe) — confined to those with frequent blood exposure: **persons who inject drugs (PWID) and haemophiliacs**; in US HBsAg-positive PWID prevalence is 11–36%, haemophiliacs ~19%.
- ▶ **Routes** mirror HBV: parenteral (injection drug use), sexual and intrafamilial in endemic areas. Unlike HBV, **perinatal transmission is not a major route**.
- ▶ Explosive outbreaks of severe hepatitis occur (e.g., “*Lábrea fever*” / “black fever” in the Amazon basin — genotype 3).

Two patterns of infection: co-infection vs superinfection

Feature	HBV–HDV Co-infection	HDV Superinfection
Setting	Simultaneous acute HBV + HDV in a susceptible host	Acute HDV in an established chronic HBV carrier
Acute illness	Often biphasic ALT rise (1st = HBV, 2nd = HDV); usually self-limited	Severe acute hepatitis; may mimic a “flare” of chronic HBV
Chronicity	Low (<5%) — same as HBV alone; >90% resolve	High (~90%) progress to chronic HDV
Fulminant/ALF risk	Up to ~5%	Up to ~20% (highest of all viral hepatitis)
IgM anti-HBc	Positive (marker of acute HBV)	Negative (IgG anti-HBc positive) — <i>key discriminator</i>
Anti-HDV	IgM anti-HDV, often transient/low-titre	IgM + IgG anti-HDV, high and sustained
HBV DNA	Variable	Low — HDV suppresses HBV replication
Outcome	Generally good if resolves	Worsening liver disease; rapid cirrhosis

Diagnosis (serology and virology)

- ▶ **Screening is targeted, not routine** — test HBsAg-positive persons who: inject drugs, are from endemic regions, have an unexplained acute flare/severe or protracted hepatitis, are HBV DNA-negative yet have active liver disease, or show rapid progression to cirrhosis.
- ▶ **First-line test: total anti-HDV (IgM + IgG)** — invariably appears after exposure. **IgM anti-HDV** indicates current/recent infection and parallels disease activity (high titres $\approx$ serious liver damage). **IgG anti-HDV is not protective.**
- ▶ **HDV RNA by RT-PCR is the gold standard for current/active infection** and the only reliable way to distinguish chronic infection from recovery; a WHO international standard now aids quantification.
- ▶ **HDAg:** detectable transiently in early acute infection and in liver (immunohistochemistry); intrahepatic HDAg is a proposed histologic “gold standard” but is negative in up to 50% of long-standing cases.
- ▶ **Distinguishing co-infection from superinfection** rests on **IgM anti-HBc** (positive in co-infection, absent in superinfection) plus the HBV DNA trend (low in HDV superinfection vs rising in a true HBV flare).

Treatment

- ▶ **General principle:** HDV depends on **host RNA polymerase**, which cannot be targeted by standard nucleoside analogues; hence treatment is difficult and outcomes are modest.
- ▶ **Acute hepatitis D** — supportive; **liver transplantation** for acute liver failure.
- ▶ **Chronic hepatitis D:**
 - **Pegylated interferon- α (PegIFN- α)** is the only established/approved therapy — **180 μ g subcutaneously weekly for ≥ 48 weeks (≈ 1 year)**; durable off-treatment HDV-RNA clearance in only ~ 20 – 50% , with frequent late relapse. High-dose conventional IFN- α (9 MU thrice weekly $\times$ 12 months) improves long-term survival in some.
 - **Nucleos(t)ide analogues (lamivudine, adefovir, tenofovir, entecavir)** are **ineffective against HDV** and add no benefit to PegIFN; reserve them to treat **underlying HBV if HBV DNA $> 2 \times 10^3$ IU/mL**.
 - **IFN is contraindicated in advanced/decompensated cirrhosis.**
- ▶ **Novel agents (HDV-specific):**
 - **Bulevirtide (Myrcludex B)** — myristoylated lipopeptide **NTCP entry inhibitor** blocking HBV/HDV hepatocyte entry; achieves significant HDV-RNA decline and ALT normalisation; granted **conditional EMA authorisation in 2020** (FDA review anticipated).
 - **Lonafarnib** — **farnesyltransferase (prenylation) inhibitor** that blocks large-HDAg-HBsAg assembly; combined with **ritonavir (CYP3A4 boost) $\pm$ PegIFN**.
 - **Nucleic-acid polymers (e.g., REP 2139)** — **inhibit HBsAg release**, producing marked HDV-RNA and HBsAg reduction (investigational).

- ▶ Liver transplantation is the option for HDV decompensated cirrhosis; outcome is **better than** for HBV alone and graft reinfection is <10% with HBV immunoglobulin (HBIG) ± nucleos(t)ide.

Prevention

- ▶ HBV vaccination prevents HDV in HBV-susceptible persons (no HBsAg → no HDV life cycle) — the cornerstone of prevention.
- ▶ No specific HDV vaccine exists, and the HBV vaccine **cannot protect existing HBV carriers**; such patients need behavioural counselling to avoid HDV exposure.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ HDV virion structure: outer HBsAg envelope (label small/middle/large HBsAg); inner ribonucleoprotein core; small & large HDAg; circular single-stranded (–)RNA genome (~1700 nt, rod-like); NTCP receptor on hepatocyte membrane with pre-S1 binding.
- ▶ Serologic course — co-infection vs superinfection: two timelines plotting ALT, HBsAg, HDV RNA, IgM anti-HDV, total anti-HDV and IgM anti-HBc; highlight the biphasic ALT of co-infection and IgM anti-HBc positive (co-infection) vs negative (superinfection) as the discriminator.

Clinical / Diagnostic significance

- ▶ Suspect HDV in any HBsAg-positive patient with **unexpectedly severe, fulminant, biphasic or rapidly progressive hepatitis**, or an unexplained flare of “stable” chronic hepatitis B.
- ▶ HDV suppresses HBV replication → **low/undetectable HBV DNA with active liver disease** is a clue to delta superinfection.
- ▶ Chronic HDV carries a **3–6 fold higher risk of HCC** and roughly **doubled mortality** versus HBV monoinfection; reported annual cirrhosis ~4% and HCC ~2.8%; 5-year survival after cirrhosis ~81–90%.
- ▶ Because therapy is unsatisfactory, **prevention via universal HBV vaccination** is the highest-yield intervention.

High-yield exam pointers

- ▶ HDV = **defective/satellite RNA virus**, genus *Deltavirus*, needs HBsAg helper; smallest human pathogen.
- ▶ Genome: **circular, ss, negative-sense ~1.7 kb RNA**, viroid-like, **ribozyme**, replicates via host RNA pol II.
- ▶ HDaG is the only viral protein — **small HDaG = replication, large HDaG = assembly (prenylated)**.
- ▶ Entry via NTCP → rationale for **bulevirtide**.

- ▶ **Co-infection** = self-limited, chronicity <5%, **IgM anti-HBc +**; **Superinfection** = ~90% chronic, severe, **IgM anti-HBc –**.
- ▶ **Highest fulminant-hepatitis risk** of all viral hepatitis (≈20% in superinfection).
- ▶ **Diagnosis:** **total/IgM anti-HDV + HDV RNA (RT-PCR, gold standard)**; **IgG anti-HDV not protective**.
- ▶ **Treatment:** **PegIFN-α ~48 weeks**; nucleos(t)ides **ineffective**; new drugs = **bulevirtide**, **lonafarnib**, REP 2139.
- ▶ **Prevention:** **HBV vaccine** (no separate HDV vaccine); cannot protect existing HBV carriers.
- ▶ **Lábrea fever** = severe Amazonian HDV genotype 3 outbreak.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Acute Viral Hepatitis” (HDV virology, epidemiology, two epidemiologic patterns, serologic markers) and “Chronic Hepatitis” (chronic delta hepatitis, IFN/bulevirtide/lonafarnib therapy, transplantation).
- ▶ **Sleisenger & Fordtran's Gastrointestinal and Liver Disease, 11e** — “Hepatitis D” (structure, life cycle, genotypes, pathogenesis, diagnostic serologic patterns, natural history, treatment and prevention) — primary subspecialty source.
- ▶ **CMDT 2026** — “Liver, Biliary Tract, & Pancreas Disorders” (current diagnosis and PegIFN-based management of chronic hepatitis D).

Coverage note: Corpus coverage is excellent and consistent; bulevirtide is recorded as conditionally EMA-approved (2020) with FDA review “anticipated” in this edition — quoted as such rather than asserting current FDA status.

Hepatorenal Syndrome

Asked in: Paper II Jul 2021 — RGUHS MD General Medicine

Definition / Introduction — Hepatorenal syndrome (HRS) is a *functional* form of acute kidney injury that develops in advanced cirrhosis (or acute/fulminant liver failure) with ascites, in which renal hypoperfusion arises from extreme splanchnic and systemic arterial vasodilatation rather than from any structural renal lesion — *the kidneys are histologically normal* and function can be restored by liver transplantation or by transplanting the same kidney into a non-cirrhotic recipient. It is essentially a diagnosis of exclusion, recognised after other causes of AKI are ruled out. The term was first coined in 1939; HRS complicates roughly **10% of patients with advanced cirrhosis** and carries a grave prognosis unless the underlying liver disease is reversed.

Epidemiology and Precipitants

- ▶ Acute renal dysfunction occurs in **15–25%** of hospitalised cirrhotics; HRS accounts for **10–30%** of these. The annual incidence of HRS in cirrhotics with ascites is ~8% (up to 40% in some series).
- ▶ HRS develops in ~**30%** of patients admitted with **spontaneous bacterial peritonitis (SBP)** or other infection, ~**25%** with severe alcohol-associated hepatitis, and ~**10%** of those undergoing serial large-volume paracentesis (LVP).
- ▶ **Common precipitants** (all reduce effective circulating volume or renal perfusion): bacterial infection/SBP and sepsis; GI/variceal haemorrhage; over-diuresis; diarrhoea from lactulose; LVP without colloid (albumin) replacement; and nephrotoxins — **NSAIDs, ACE inhibitors, ARBs**, and certain antibiotics.

Pathophysiology — the “three-hit” model

The current model (International Club of Ascites/Sleisenger) integrates three interacting components:

- ▶ **1. Splanchnic and systemic arterial vasodilatation** — the hallmark of progressive portal hypertension. Driven by endogenous vasodilators (**nitric oxide**, carbon monoxide, glucagon, prostacyclin, adrenomedullin, endogenous opiates), often amplified by bacterial translocation and inflammation. This pooling of blood in the splanchnic bed lowers the **effective arterial blood volume** and arterial pressure, creating a *hyperdynamic circulation* (high cardiac output, low systemic vascular resistance).
- ▶ **2. Compensatory renal vasoconstriction** — the fall in effective volume activates the **sympathetic nervous system**, the **renin–angiotensin–aldosterone system (RAAS)**, and non-osmotic release of **arginine vasopressin (ADH)**. Intrarenal mediators (endothelins, reduced vasodilatory prostaglandins, kallikreins, F2-isoprostanes) tip the balance toward intense renal vasoconstriction → rise in renal vascular resistance, fall in renal perfusion and **GFR**, with avid Na^+ /water retention. Sustained vasoconstriction can eventually cause tubular damage, so a *functional* syndrome may evolve into an *organic* one.
- ▶ **3. Cardiac dysfunction (cirrhotic cardiomyopathy)** — a relatively low cardiac output fails to compensate for the fall in systemic vascular resistance, further reducing renal perfusion; an acute drop in cardiac output is often the precipitant of type 2 HRS.

Classification and Diagnostic Criteria

HRS is now classified by the **International Club of Ascites (ICA, 2015)** using AKI definitions, replacing the older “type 1 / type 2” terminology:

Old term	New term	Course / features
Type 1 HRS	HRS–AKI	Rapid, progressive impairment; ICA-AKI stage 2 or 3 ; classically $\geq$ doubling of creatinine to > 2.5 mg/dL (or halving of CrCl to <

Old term	New term	Course / features
		20 mL/min) in < 2 weeks; poor prognosis
Type 2 HRS	HRS-CKD (non-AKI)	Slow, steady decline in GFR; moderate, <i>stable</i> creatinine rise; closely linked to diuretic-resistant ascites ; better outcome than HRS-AKI

ICA-AKI definition and staging of AKI in cirrhosis:

Parameter	Definition
AKI	Rise in serum creatinine of 0.3 mg/dL (26.4 µmol/L) within 48 h, OR a ≥ 50% rise from baseline presumed to have occurred within the prior 7 days
Stage 1	Rise of 0.3 mg/dL, or 1.5–2× baseline
Stage 2	> 2–3× baseline
Stage 3	> 3× baseline, OR creatinine ≥ 4 mg/dL with an acute rise ≥ 0.3 mg/dL, OR initiation of renal replacement therapy (RRT)

ICA diagnostic criteria for HRS (Box 94.2):

- ▶ Cirrhosis with ascites
- ▶ Diagnosis of AKI by ICA-AKI criteria
- ▶ No, or insufficient, response after ≥ 2 days of diuretic withdrawal and volume expansion with albumin 1 g/kg/day (max 100 g/day)
- ▶ Absence of shock
- ▶ No recent nephrotoxic drugs (NSAIDs, aminoglycosides, contrast)
- ▶ Absence of parenchymal kidney disease — proteinuria < 500 mg/day, no microhaematuria (< 50 RBC/HPF), and normal renal ultrasound

Note on creatinine: because sarcopenic cirrhotics have low muscle mass and reduced urea synthesis, serum creatinine **underestimates** the true GFR — even small increases must be taken seriously. Oliguria is *not* used as a criterion in cirrhosis, since these patients are frequently oliguric with Na⁺ retention despite a near-normal GFR.

Clinical features and differential diagnosis

- ▶ Usually **oligo/asymptomatic**; clues are progressive azotaemia, **oliguria**, **hyponatraemia** (dilutional) and a **very low urinary sodium** (< 10 mmol/L) with benign sediment in a patient with tense ascites and decompensated liver disease.

- ▶ HRS may present as new or worsening **hepatic encephalopathy** as urea/ammonia rise.
- ▶ **Differentials to exclude:** prerenal azotaemia/hypovolaemia (responds to volume), **acute tubular necrosis** (granular casts, FeNa often higher, fails albumin challenge), drug-induced acute interstitial nephritis, glomerulonephritis, and post-renal obstruction. Albumin volume challenge plus urinary biomarkers (e.g., NGAL, IL-18 — investigational) help separate ATN from HRS.

Management

Therapy aims to reverse splanchnic vasodilatation with **vasoconstrictors** and expand the central volume with **albumin**, as a bridge to definitive treatment (liver transplant) or until a precipitant (SBP, bleeding) resolves.

General / supportive: stop diuretics, NSAIDs, ACEi/ARB and all nephrotoxins; identify and treat infection (antibiotics, SBP); IV **albumin 1 g/kg/day** (max 100 g) on presentation, then **20–60 g/day** titrated to a CVP of ~10–15 cm H₂O (avoid pulmonary oedema).

Agent (always with albumin)	Mechanism	Dose / titration
Terlipressin (<i>preferred; FDA-approved</i>)	Selective V1 vasopressin-receptor agonist → splanchnic vasoconstriction	Sleisenger: 1 mg IV q4h, ↑ to 2 mg IV q4h if creatinine not improved by 25% by day 3. CMDT: 0.85 mg IV q6h, titrate by creatinine response; continuous infusion better tolerated than boluses
Midodrine + Octreotide	α1-agonist (midodrine) + somatostatin analogue suppressing vasodilators (octreotide)	Midodrine 7.5–15 mg PO TID (to a max 15 mg TID) + octreotide 100–200 µg SC TID (or 25 µg IV bolus then 25 µg/h); titrate MAP rise ≥ 15 mmHg
Norepinephrine	α1-adrenergic agonist	0.1–0.7 µg/kg/min IV infusion; titrate MAP rise ≥ 10 mmHg (requires ICU/central line)

- ▶ Vasoconstrictor therapy is given for a **maximum of ~7–14 days** until creatinine returns to within 0.3 mg/dL of baseline, or until transplant/TIPS. Pooled trials (OT-0401, REVERSE) showed terlipressin + albumin reversed HRS more often than albumin alone (27% vs 14%); head-to-head, terlipressin out-performed midodrine + octreotide (~70% vs ~29% renal recovery). Watch for **ischaemic/cardiovascular complications** of terlipressin.
- ▶ **TIPS** (transjugular intrahepatic portosystemic shunt) — most useful in **type 2 HRS / diuretic-resistant ascites**; improves creatinine and natriuresis but may worsen encephalopathy and hepatic function; not for advanced decompensation.

- ▶ **Liver transplantation** — the **definitive and only treatment that reverses both liver and renal failure**; HRS resolves in ~83% post-LT, 3-year survival ~60% (vs 70–80% without HRS); up to 35% need ongoing RRT.
- ▶ **RRT / MARS** (molecular adsorbent recirculating system) — temporising/experimental, of uncertain benefit; reserve dialysis as a bridge to transplant.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Pathophysiology flow chart of HRS** — boxes/arrows: *Cirrhosis + portal hypertension* → *splanchnic & peripheral arterial vasodilatation (NO, CO, glucagon, prostacyclin)* → ↓ *effective circulatory volume* → ↓ *arterial blood pressure* → ↑ *cardiac output (hyperdynamic)* + *activation of RAAS, SNS, ↑ ADH* → *renal vasoconstriction* → ↓ *renal perfusion* → ↓ *GFR* → *Hepatorenal syndrome*. Add side-arrow “triggers”: **SBP/sepsis, GI bleed, LVP, diuretics, diarrhoea, ACEi/ARB/NSAIDs; and “cirrhotic cardiomyopathy (CCM)**”** reducing cardiac output.
- ▶ **Management ladder** — *Stop diuretics & nephrotoxins* → *IV albumin 1 g/kg + treat infection* → *Vasoconstrictor (Terlipressin / Norepinephrine / Midodrine+Octreotide) + albumin* → *if refractory: TIPS or RRT bridge* → *Liver transplantation (definitive)*.

Clinical / Diagnostic significance

- ▶ HRS is a **marker of end-stage liver disease** and a key driver of mortality in decompensated cirrhosis; its onset should trigger **transplant evaluation** and MELD recalculation (creatinine is a MELD component).
- ▶ **Prevention is paramount**: IV albumin with LVP, albumin in SBP (1.5 g/kg day 1, 1 g/kg day 3 — reduces renal failure and improves survival), antibiotic prophylaxis for SBP/GI bleed, and pentoxifylline in severe alcohol-associated hepatitis.
- ▶ Always **exclude ATN and prerenal azotaemia** before labelling HRS — the albumin challenge (1 g/kg/day × 2 days after stopping diuretics) is both diagnostic and therapeutic.
- ▶ **Prognosis**: mortality correlates with **MELD score** and a systemic inflammatory response; AKI-HRS is often irreversible when a systemic infection is present. The **3-month survival** in cirrhotic HRS (~15%) is far worse than renal failure from infection (31%), hypovolaemia (46%) or parenchymal kidney disease (73%).

High-yield exam pointers

- ▶ HRS = **functional AKI**; kidneys are **histologically normal** and reverse with liver transplant.
- ▶ Central lesion = **splanchnic arterial vasodilatation (NO-mediated)** → ↓ effective volume → RAAS/SNS/ADH-driven **renal vasoconstriction**.
- ▶ **Type 1** = HRS-AKI (rapid, creatinine usually > 2.5 mg/dL in < 2 weeks); **Type 2** = HRS-CKD (slow, with refractory ascites).

- ▶ Diagnosis is by **ICA criteria** — cirrhosis + ascites + ICA-AKI, **no response to albumin 1 g/kg × 2 days**, no shock, no nephrotoxins, no parenchymal disease.
- ▶ Typical labs: **oliguria, hyponatraemia, urine Na⁺ < 10 mmol/L**, benign sediment.
- ▶ **Terlipressin + albumin** is first-line and **FDA-approved**; alternatives = **noradrenaline + albumin** or **midodrine + octreotide + albumin**.
- ▶ **Liver transplantation is the only definitive cure**; TIPS helps mainly type 2 HRS; dialysis is a bridge.
- ▶ Best strategy is **prevention** — albumin with LVP and SBP, avoid NSAIDs/ACEi, treat infection early.

SOURCE & COVERAGE

Imaging in Acute Pancreatitis

Asked in: Paper II May 2019 — RGUHS MD General Medicine

Definition / Introduction — Acute pancreatitis (AP) is an acute inflammatory process of the pancreas with variable involvement of peripancreatic and remote organ systems, ranging pathologically from self-limited *interstitial (oedematous)* disease to *necrotizing* pancreatitis. Diagnosis requires **two of three** criteria: (1) typical epigastric pain radiating to the back, (2) serum lipase/amylase >3× the upper limit of normal, and (3) characteristic findings on cross-sectional imaging. Imaging therefore serves three purposes — to **confirm the diagnosis** when clinical and biochemical features are equivocal, to **exclude alternative intra-abdominal catastrophes**, and crucially to **stage severity and detect local complications** (necrosis, fluid collections, vascular and ductal complications) that drive management. Imaging is interpreted within the framework of the **Revised Atlanta Classification (2012)**.

Indications and timing of imaging — “why and when”

- ▶ The **three main indications** for CT in AP (Sleisenger): (1) exclude other serious intra-abdominal conditions (perforated ulcer, mesenteric ischaemia); (2) **stage severity**; (3) detect **local complications** (necrosis, involvement of bowel/spleen/kidney, vascular complications).
- ▶ Routine **early CT is NOT recommended** — it is usually unnecessary or unhelpful in the first **48 hours** of admission. The diagnosis is most often clinical/biochemical.
- ▶ Contrast-enhanced CT is best performed **3–5 days into admission** in patients **not responding** to supportive care, because **necrosis (parenchymal perfusion defects) may not become apparent until 48–72 hours** after onset; imaging earlier underestimates necrosis.
- ▶ The **Revised Atlanta Criteria define two clinical phases** — *early* (<2 weeks, severity defined clinically by persistent organ failure) and *late* (>2 weeks, where imaging is needed to characterise evolving local complications).
- ▶ Caution: IV iodinated contrast should be avoided when serum **creatinine >1.5 mg/dL** (risk of AKI); some experimental/retrospective data suggest very early contrast may worsen necrosis, though human data are conflicting.

Imaging modalities — comparative overview

Modality	Primary role in AP	Key strengths / findings	Limitations
Transabdominal ultrasound (US)	First-line at admission	Detects gallstones , CBD dilatation/choledocholithiasis , ascites ; pancreas diffusely enlarged, hypoechoic	Pancreas obscured by bowel gas in 25–35%; poor for necrosis/extrapancreatic spread/severity
Plain abdominal radiograph	Excludes perforation/obstruction; supportive signs	<i>Sentinel loop</i> , <i>colon cut-off sign</i> , calcified gallstones, pancreatic calcification, retroperitoneal gas (abscess)	Non-specific, insensitive
Chest radiograph	Severity & pulmonary complications	Left/bilateral pleural effusion , raised hemidiaphragm, basal atelectasis, ARDS infiltrates	Indirect markers only
Contrast-enhanced CT (CECT)	Reference standard for staging & complications	Differentiates interstitial vs necrotizing; defines fluid collections; CTSI scoring	Avoid if creatinine >1.5 mg/dL; early scan underestimates necrosis
MRI / MRCP	Ductal anatomy; characterising collections	Superior depiction of necrotic debris , pancreatic-duct disruption/disconnection , ductal stones; equal to EUS/ERCP for choledocholithiasis	Less available, costlier, longer; gadolinium → nephrogenic systemic fibrosis (low risk with newer agents)

Modality	Primary role in AP	Key strengths / findings	Limitations
Endoscopic ultrasound (EUS)	Occult biliary disease; idiopathic AP	Detects microlithiasis/sludge, small CBD stones, small perampullary tumours; can predict necrosis	Operator-dependent; invasive
ERCP	Therapeutic, not diagnostic	Stone extraction in biliary AP with cholangitis/obstruction	Causes pancreatitis in 5–10%; replaced diagnostically by EUS/MRCP

Contrast-enhanced CT — technique and Revised Atlanta morphology

- ▶ **Technique:** helical/MDCT after oral contrast followed by **rapid-bolus IV contrast**; *interstitial* pancreatitis shows **homogeneous parenchymal enhancement**, whereas *necrotizing* pancreatitis shows **lack of enhancement** (non-perfused parenchyma) ± peripancreatic necrosis.
- ▶ **Interstitial (oedematous) pancreatitis** occurs in **90–95%** of admissions: diffuse gland enlargement, homogeneous enhancement, mild peripancreatic stranding; usually resolves within a week.
- ▶ **Necrotizing pancreatitis** occurs in **5–10%**: lack of parenchymal enhancement and/or peripancreatic necrosis. Isolated **extrapancreatic** necrosis carries a more favourable prognosis than pancreatic necrosis. Necrosis is the radiological hallmark of severe disease and the lesion most associated with mortality.

Atlanta morphologic feature	Timing	Key CT appearance
Acute peripancreatic fluid collection (APFC)	<4 weeks, interstitial AP	Homogeneous fluid density, no wall , confined by fascial planes
Pancreatic pseudocyst	>4 weeks, interstitial AP	Encapsulated, well-defined wall , homogeneous fluid, no solid component
Acute necrotic collection (ANC)	<4 weeks, necrotizing AP	Heterogeneous , non-liquid + liquid density, no encapsulating wall , intra-/extrapancreatic
Walled-off necrosis (WON)	>4 weeks, necrotizing AP	Heterogeneous, mature encapsulating wall ; loculations

CT Severity Index (Balthazar grade + necrosis score)

The CT Severity Index (CTSI) combines the Balthazar grade (A–E, based on inflammation/collections) with a necrosis score; **maximum = 10**. Higher scores correlate with local complications (pseudocyst, abscess) and mortality.

Balthazar grade	CT finding	Grade points
A	Normal pancreas	0
B	Focal/diffuse enlargement, contour irregularity, inhomogeneous attenuation; no peripancreatic inflammation	1
C	Grade B plus peripancreatic inflammation	2
D	Grade C plus a single peripancreatic fluid collection	3
E	Grade C plus ≥ 2 collections or gas in pancreas/retroperitoneum	4
Necrosis on CECT		Necrosis points
No necrosis		0
Up to 33%		2
33–50%		4
>50%		6

- ▶ **CTSI = Balthazar points + necrosis points (0–10).** Scores 0–3 = mild, 4–6 = moderate, 7–10 = severe. In Balthazar's data, grade D/E carried a 54% local-complication rate vs ~4% for A–C; mortality rose with CTSI ($\approx 18\%$ at scores 7–10 vs $\approx 4\%$ at 0–6).
- ▶ **A Modified CTSI (Mortale)** simplifies inflammation/necrosis grading and adds **extrapancreatic complications** (pleural effusion, ascites, vascular/GI involvement), correlating better with outcome.
- ▶ **Newer CT techniques:** *perfusion CT* (day 3) detects ischaemia/necrosis earlier and predicts persistent organ failure; *subtraction CT* (colour map of unenhanced vs enhanced) also detects early necrosis.

MRI/MRCP, EUS and ERCP — special roles

- ▶ **MRCP** best delineates the **main pancreatic duct**, identifying **duct disruption/disconnection** (disconnected duct syndrome causing persistent fistula/recurrent collections) and intraductal stones; it characterises collections by showing necrotic **debris** better than CT. **Secretin-enhanced MRCP** improves duct visualisation, useful in idiopathic/recurrent AP.
- ▶ **EUS** is the most sensitive test for **occult biliary disease** (microlithiasis, sludge, small CBD stones) and small periampullary tumours; recommended after **8–12 weeks** in idiopathic AP and in patients **>40 years** to exclude malignancy. EUS at admission can detect CBD stones and triage the need for ERCP, avoiding unnecessary ERCP.

- ▶ ERCP is now primarily **therapeutic**: indicated within **24–48 h** in gallstone pancreatitis with **ascending cholangitis or persistent biliary obstruction**. It is the most sensitive test for bile-duct stones but carries a 5–10% risk of post-ERCP pancreatitis (reduced by rectal indomethacin ± prophylactic pancreatic-duct stent).
- ▶ **CT-guided fine-needle aspiration** of a necrotic collection (after day 3) with Gram stain/culture can confirm **infected necrosis** (false-negative ~25%); **gas bubbles** on CT imply gas-forming organisms, though most infections occur without gas and gas may also accompany sterile necrosis with bowel microperforation.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Labelled CECT of necrotizing pancreatitis (axial)**: label — *non-enhancing necrotic pancreatic body/tail, enhancing viable parenchyma (head/tail remnant), peripancreatic acute necrotic collection, peripancreatic fat stranding, spleen, left pleural effusion, aorta/SMA.*
- ▶ **Flow/box diagram of the Revised Atlanta morphologic features**: two columns — *Interstitial AP → APFC (<4 wk) → Pseudocyst (>4 wk); Necrotizing AP → ANC (<4 wk) → WON (>4 wk)*, with the dividing line at **4 weeks** and labels for “no wall” vs “encapsulated.”

Clinical / Diagnostic significance

- ▶ Imaging **completes the diagnostic triad** and is decisive when pain or enzymes are equivocal (e.g., late presentation with normalised amylase, hypertriglyceridaemic AP with spuriously low amylase).
- ▶ **Severity stratification**: persistent organ failure (>48 h) defines *severe* AP clinically, but **CT-proven necrosis** and collections define the morphologic/anatomic severity that determines intervention. Single-organ failure carries 3–10% mortality, rising to ~50% with multiorgan failure in necrotizing disease.
- ▶ **Guides intervention**: sterile necrosis is managed conservatively; **infected necrosis/symptomatic WON** is treated by a “**step-up**” approach (percutaneous/endoscopic transgastric drainage → minimally invasive necrosectomy), ideally delayed 4–6 weeks to allow “walling-off.”
- ▶ **Detects vascular/ductal complications**: CT/CT-angiography and MRI identify splanchnic (splenic/portal/SMV) thrombosis, **pseudoaneurysm** (treated by angioembolisation) and duct disruption (pancreatic ascites/pleural fistula — pleural fluid amylase markedly elevated).
- ▶ **Aetiology work-up**: US/EUS/MRCP identify gallstones and microlithiasis (the commonest cause), directing same-admission cholecystectomy in mild biliary AP.

High-yield exam pointers

- ▶ **Diagnosis = 2 of 3**: pain + lipase/amylase >3× ULN + imaging. Imaging is **not** mandatory if first two are met.

- ▶ **First-line modality** = transabdominal ultrasound (for gallstones/CBD), *not* CT.
- ▶ **Do not CT in first 48 h**; CECT best at 3–5 days in non-responders — necrosis needs 48–72 h to appear.
- ▶ **Interstitial 90–95% vs necrotizing 5–10%**; necrosis = non-enhancement on CECT and is the key severity lesion.
- ▶ **Revised Atlanta collections**: APFC & pseudocyst (interstitial) vs ANC & WON (necrotizing); 4-week cut-off separates acute (no wall) from walled-off (encapsulated).
- ▶ **CTSI** = Balthazar (A–E, 0–4) + necrosis (0/2/4/6), **max 10**; 7–10 = severe.
- ▶ **MRCP** best for **duct disruption** and ductal stones; **EUS** best for **microlithiasis/idiopathic AP**; ERCP is therapeutic (cholangitis/obstruction), not diagnostic.
- ▶ Avoid IV contrast if **creatinine >1.5 mg/dL**; gadolinium → nephrogenic systemic fibrosis.
- ▶ Plain film: **sentinel loop**, **colon cut-off sign**; CXR: **left pleural effusion** within 72 h signals severe disease.
- ▶ **Cullen’s sign** (periumbilical) and **Grey Turner’s sign** (flank) indicate haemorrhagic necrotizing pancreatitis.

SOURCE & COVERAGE

Investigations and Treatment of Chronic Hepatitis B Infection

Asked in: Paper II Nov 2021 — RGUHS MD General Medicine

Definition / Introduction — Chronic hepatitis B (CHB) is defined as persistence of **hepatitis B surface antigen (HBsAg)** in serum for **≥6 months**, with hepatic necroinflammation of varying grade and fibrosis of varying stage. The risk of chronicity is inversely related to age at infection — ~90% after perinatal acquisition versus ~1% after adult acquisition. The **serum HBV DNA level is the single most**

important determinant of progression to cirrhosis and hepatocellular carcinoma (HCC) (REVEAL-HBV cohort); hence investigation centres on virological/serological staging and fibrosis assessment, and treatment is directed at durable suppression of viral replication.

Natural history — phases (the framework for both investigation and treatment)

Chronic HBV is dynamic; five phases are recognised, and accurate phasing dictates whether and when to treat.

Phase	HBeAg	HBV DNA	ALT	Liver injury / action
1. Immune-tolerant (HBeAg-positive chronic infection)	+	Very high (often $>10^7$ – 10^9 IU/mL)	Normal	Minimal; monitor, do not treat
2. Immune-active / clearance (HBeAg-positive chronic hepatitis)	+	High ($>2 \times 10^4$ IU/mL)	Elevated	Active necroinflammation → treat
3. Inactive carrier (HBeAg-negative chronic infection)	– (anti-HBe +)	Low/undetectable ($\leq 2 \times 10^3$ IU/mL)	Normal	Low risk; monitor
4. Reactivation (HBeAg-negative chronic hepatitis; precore/core-promoter mutant)	– (anti-HBe +)	Fluctuating ($>2 \times 10^3$ IU/mL)	Elevated/"flares"	Progressive → treat
5. HBsAg-negative ("functional cure")	–	Undetectable in serum (cccDNA persists)	Normal	~1%/yr; best outcome

- ▶ *Inactive carrier vs HBeAg-negative chronic hepatitis* cannot be separated on a single visit — it requires **serial ALT + HBV DNA monitoring over months**.
- ▶ A more sensitive ULN for ALT is **35 U/L (male) / 25 U/L (female)**; normal-range ALT does not exclude significant histology.

Investigations

1. Confirm and characterise the infection (serology + virology)

- ▶ **HBsAg** (positive ≥ 6 months = chronicity) and **IgG anti-HBc** (past exposure).
- ▶ **HBeAg / anti-HBe** — replicative status; HBeAg seroconversion to anti-HBe signals slowing of disease.

- ▶ **Quantitative HBV DNA (real-time PCR, IU/mL)** — the key prognostic and treatment-threshold test; also used to monitor on-treatment response.
- ▶ **Quantitative HBsAg (qHBsAg)** — predicts PEG-IFN response and identifies HBeAg-negative patients who may safely stop oral therapy (e.g. <100 IU/mL Asians, <1000 IU/mL Whites).
- ▶ **HBV genotype** — genotype C carries higher cirrhosis/HCC risk; IFN response is genotype A > B > C > D.

2. Biochemical & haematological

- ▶ LFTs (ALT usually 100–1000 U/L, ALT > AST; once cirrhotic, AST > ALT), albumin, bilirubin, **prothrombin time/INR**, full blood count (thrombocytopenia suggests portal hypertension).
- ▶ Hyperglobulinaemia and autoantibodies are characteristically **absent** (distinguishes from autoimmune hepatitis).

3. Assessment of fibrosis (stage)

- ▶ **Non-invasive:** FIB-4 [(age × AST) / (platelets × √ALT)], APRI, the proprietary **ELF score** (hyaluronic acid, PIIINP, TIMP-1), and **transient elastography (FibroScan)** / liver-stiffness imaging.
- ▶ **Liver biopsy** (HAI/Ishak 0–18 grade, 0–6 stage; or METAVIR A0–A3, F0–F4) — reserved for when non-invasive tests are discordant or staging will change management.

4. Screen for co-infection, complications and reactivation risk

- ▶ **HDV (anti-HDV ± HDV RNA), HCV and HIV** serology in every patient; HBV-HIV co-infection accelerates progression ~20-fold.
- ▶ **HCC surveillance: 6-monthly ultrasound ± α-fetoprotein** in all cirrhotics, and in high-risk non-cirrhotics (Asian men >40, Asian women >50, Africans, family history of HCC, persistent high-level viraemia). The **PAGE-B score** (age, sex, platelets) predicts 5-year HCC risk on therapy.
- ▶ Before chemotherapy/immunosuppression: screen **HBsAg + anti-HBc (± anti-HBs)** to stratify reactivation risk.

Goals and indications for treatment (whom to treat)

- ▶ **Goals:** durable suppression of HBV DNA → ALT normalisation, histologic improvement, HBeAg seroconversion, and ultimately **functional cure** (sustained HBsAg loss ± anti-HBs, durable ≥6 months). These translate into reduced cirrhosis, decompensation, HCC and liver-related death; established cirrhosis and varices can regress with long-term suppression.
- ▶ **Indications (AASLD; EASL thresholds slightly lower):**

Group	Treat when
HBeAg-positive chronic hepatitis	HBV DNA >2×10 ⁴ IU/mL and ALT >2× ULN
HBeAg-negative chronic hepatitis	HBV DNA >2×10 ³ IU/mL and ALT >2× ULN

Group	Treat when
Compensated cirrhosis	Any detectable HBV DNA, regardless of ALT/HBeAg
Decompensated cirrhosis	Any detectable HBV DNA — oral agents only; refer for transplant
“Grey-zone” / borderline ALT	Consider if age >40, family history of cirrhosis/HCC, extrahepatic disease, prior treatment, or moderate–severe fibrosis/inflammation on biopsy/non-invasive testing

- **Not treated (monitor 3–6 monthly):** immune-tolerant (HBeAg-positive, normal ALT) and inactive carriers.

Antiviral agents and treatment

Eight drugs are approved; only PEG-IFN- α , entecavir, and tenofovir (TDF or TAF) are recommended first-line. Oral agents are generally preferred — better tolerated, more profound DNA suppression, usable in cirrhosis/immunosuppression.

First-line agent	Dose	Key points
Entecavir	0.5 mg PO daily (1 mg if lamivudine-resistant)	High potency, high barrier to resistance ($\leq 1.2\%$ at 6 yr); reduce dose in renal impairment; weak anti-HIV activity $\rightarrow$ not as monotherapy in HIV co-infection
Tenofovir disoproxil fumarate (TDF)	300 mg PO daily	Potent; 0% resistance through 8 yr; monitor renal function/phosphate (Fanconi-like tubulopathy), reduced bone density
Tenofovir alafenamide (TAF)	25 mg PO daily	Equipotent to TDF; less renal/bone toxicity $\rightarrow$ preferred if CrCl < 50 mL/min, low bone density, or risk factors for renal injury
PEG-IFN- $\alpha 2a$	180 μ g SC weekly $\times$ 48 wk	Finite course, highest 1-yr HBeAg seroconversion ($\sim 30\%$), no resistance; contraindicated in decompensated cirrhosis, pregnancy, autoimmune disease, cytopenias

- ▶ *No longer first-line*: **lamivudine** (YMDD mutation — M204V/I — in ~70% at 5 yr), **adefovir**, **telbivudine** (low barrier to resistance). **Combination oral therapy gives no benefit over potent monotherapy** in treatment-naïve patients; for resistance, *switching* to a non-cross-resistant high-barrier agent (e.g. tenofovir for lamivudine resistance) is now preferred over add-on.

Endpoints and stopping rules

- ▶ **HBeAg-positive**: oral therapy may be stopped after HBeAg seroconversion plus **≥12 months consolidation** in non-cirrhotics, with close post-treatment monitoring for relapse; otherwise continue.
- ▶ **HBeAg-negative**: relapse is the rule on stopping → **indefinite therapy**, ideally until HBsAg loss (rare).
- ▶ **Cirrhosis**: treat **indefinitely** — stopping risks decompensation.
- ▶ **PEG-IFN futility**: if qHBsAg fails to fall to <20,000 IU/mL by week 24, discontinue.

Special populations

- ▶ **Pregnancy**: Tenofovir (TDF) is the **drug of choice**; start in the **third trimester** when maternal HBV DNA $\geq 200,000$ IU/mL to reduce perinatal transmission (plus neonatal HBIG + vaccine). Avoid IFN.
- ▶ **Immunosuppression / chemotherapy**: screen HBsAg + anti-HBc; give **pre-emptive entecavir/tenofovir prophylaxis** to all HBsAg-positive patients, and to anti-HBc-positive/HBsAg-negative patients receiving **B-cell-depleting agents (rituximab)** or stem-cell transplant. Continue 6 months after chemotherapy (12 months for B-cell depletion).
- ▶ **HIV co-infection**: use ART containing two anti-HBV drugs (e.g. **tenofovir + emtricitabine/lamivudine**); never lamivudine or entecavir monotherapy.
- ▶ **Liver transplantation**: prevent graft re-infection with short-course IV HBIG (5–7 days) + **lifelong entecavir/TDF/TAF**.
- ▶ **HDV co/super-infection**: treat with PEG-IFN- α (limited efficacy); the NTCP entry inhibitor **bulevirtide** is the major advance (EMA-approved); treat underlying HBV if DNA $> 2 \times 10^3$ IU/mL.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Phases of chronic HBV infection (time-course graph)**: x-axis = time/years; plot HBV DNA, ALT and qHBsAg curves across the five phases, with bands labelled *Immune-tolerant* → *Immune-active* → *Inactive carrier* → *Reactivation (HBeAg-negative)* → *HBsAg-negative*; mark HBeAg → anti-HBe seroconversion and HBsAg → anti-HBs (functional cure).
- ▶ **Treatment-decision algorithm**: boxes labelled *HBsAg+ ≥6 months* → branch on HBeAg status → thresholds (HBeAg+: DNA $> 2 \times 10^4$ & ALT $> 2 \times \text{ULN}$; HBeAg-: DNA $> 2 \times 10^3$ &

ALT >2×ULN; Cirrhosis: any detectable DNA) → *First-line: Entecavir / TDF / TAF / PEG-IFN* → *HCC surveillance 6-monthly US ± AFP.*

Clinical / Diagnostic significance

- ▶ HBV DNA is the master variable — both for diagnosis/phasing and as the therapeutic target; suppression below the level of detection lowers (but does not abolish) HCC risk.
- ▶ Extrahepatic immune-complex disease — **polyarteritis nodosa**, **membranous/membranoproliferative glomerulonephritis**, **leukocytoclastic vasculitis**, **arthralgias** — is itself an indication to treat.
- ▶ ALT “flares” may herald HBeAg seroconversion but can precipitate decompensation in cirrhotics — monitor closely, especially after stopping therapy.
- ▶ Antiviral therapy regresses fibrosis/cirrhosis and reduces transplant referral, but **HCC surveillance must continue even after HBsAg loss/seroconversion.**

High-yield exam pointers

- ▶ HBsAg >6 months = chronic; **IgM anti-HBc** distinguishes acute from chronic.
- ▶ First-line antivirals = **entecavir**, **tenofovir (TDF/TAF)**, **PEG-IFN**; doses **entecavir 0.5 mg/d**, **TDF 300 mg/d**, **TAF 25 mg/d**, **PEG-IFN-α2a 180 µg/week**.
- ▶ **Treat any cirrhotic with detectable HBV DNA**, irrespective of ALT/HBeAg — treat indefinitely.
- ▶ **Tenofovir = drug of choice in pregnancy**; start 3rd trimester if maternal DNA ≥200,000 IU/mL.
- ▶ **Screen HBsAg + anti-HBc before chemo/biologics**; prophylax with entecavir/tenofovir (mandatory with rituximab).
- ▶ **Functional cure = sustained HBsAg loss + undetectable DNA**; cccDNA persistence prevents sterilising cure.
- ▶ Resistance: **lamivudine** — YMDD (M204V/I); tenofovir/entecavir have the highest barrier.
- ▶ **HCC surveillance: 6-monthly ultrasound ± AFP**; PAGE-B predicts on-treatment HCC risk; genotype C = worst prognosis.

SOURCE & COVERAGE

Irritable Bowel Syndrome

Asked in: Paper II Sep 2025 — RGUHS MD General Medicine

Definition / Introduction — Irritable bowel syndrome (IBS) is a chronic **functional bowel disorder** (a disorder of **gut–brain interaction**) characterised by **recurrent abdominal pain associated with altered bowel habits**, in the *absence of any detectable structural or biochemical abnormality*. No pathognomonic marker exists, so diagnosis is **symptom-based** (Rome IV criteria) after judicious exclusion of organic disease. It affects ~10% of adults and adolescents worldwide, is **2–3 times commoner in women** (who form ~80% of severe cases), and usually begins **before age 45**. Though benign, it markedly impairs quality of life and incurs high direct and indirect health-care costs.

Diagnostic criteria & classification

- **Rome IV criteria (2016):** *Recurrent abdominal pain, on average at least 1 day per week in the last 3 months, associated with ≥ 2 of:*
 - (1) related to **defecation**, (2) associated with a change in **frequency of stool**, (3) associated with a change in **form/appearance of stool**.
 - Criteria fulfilled for the last 3 months with **symptom onset ≥ 6 months** before diagnosis.
- **More stringent than Rome III** — pain must occur $\geq$ once/week and the term "*discomfort*" has been dropped. *Painless* diarrhoea or constipation does **not** qualify as IBS.
- **Supportive (non-diagnostic) symptoms:** straining, urgency, feeling of incomplete evacuation, passage of mucus, and bloating/distension.
- **Subtyping** by predominant stool form on the **Bristol Stool Form Scale** ($\geq 25\%$ of bowel movements rule):

Subtype	Stool pattern ($\geq 25\%$ of BMs)
IBS-C (constipation)	Hard/lumpy (Bristol 1–2) $\geq 25\%$; loose $< 25\%$
IBS-D (diarrhoea)	Loose/watery (Bristol 6–7) $\geq 25\%$; hard $< 25\%$
IBS-M (mixed)	Both hard and loose $\geq 25\%$
IBS-U (unsubtyped)	Insufficient abnormality to subtype

- Subtypes are **unstable** — over 1 year ~75% of patients switch subtype and ~29% switch between IBS-C and IBS-D.

Pathophysiology (multifactorial — disordered brain–gut axis)

- ▶ **Altered GI motility:** exaggerated, prolonged colonic motor response to meals and rectal distension; increased high-amplitude propagating contractions and rapid transit in IBS-D; slow transit/pelvic-floor dyssynergia in IBS-C.
- ▶ **Visceral hypersensitivity:** lowered thresholds for pain/discomfort on rectal balloon distension; *selective for visceral (not somatic) afferents*. **TRPV1 (vanilloid) channel** upregulation correlates with pain.
- ▶ **Central neural dysregulation:** functional MRI shows heightened activation of the **mid-cingulate** and **prefrontal cortex** (hypervigilance to visceral pain); stress and emotion alter sensory thresholds.
- ▶ **Psychological factors:** anxiety, depression, somatisation in up to 80% of referral patients; association with prior **physical/sexual abuse**.
- ▶ **Post-infectious IBS:** >10% develop IBS after infectious enteritis (**≈4-fold** risk); commoner in young women, after severe/bacterial/parasitic infection and with psychological comorbidity; mediated by residual enteroendocrine cells, T-lymphocytes and dysbiosis.
- ▶ **Low-grade immune activation/mucosal inflammation:** activated **mast cells** in proximity to nerves, raised IL-6, IL-1 β , TNF; mast-cell mediators (histamine, proteases, PGE₂) drive hypersensitivity.
- ▶ **Altered intestinal permeability** (“leaky gut”) — especially IBS-D and post-infectious IBS; reduced tight-junction proteins.
- ▶ **Gut dysbiosis:** reduced microbial diversity, ↓ *Bifidobacterium* and *Faecalibacterium*, ↑ Enterobacteriaceae; up to 4-fold higher odds of **SIBO** on breath testing (contested).
- ▶ **Serotonin (5-HT) pathways:** ↑ enterochromaffin cells and postprandial plasma 5-HT in IBS-D; **TPH1** polymorphism; downregulated mucosal **SERT** (serotonin reuptake transporter).
- ▶ **Bile-acid malabsorption:** in up to 25% of IBS-D (reduced ileal FGF-19) → accelerated colonic transit.
- ▶ **Genetic:** twin studies and **SERT polymorphisms** support heritability.

Clinical features

- ▶ **Abdominal pain** (prerequisite): variable, often **crampy/episodic**, anywhere in the abdomen; *exacerbated by eating or stress, relieved by defecation or flatus*; worse premenstrually; **almost never nocturnal** and does not disturb sleep. Malnutrition is exceedingly rare.
- ▶ **Altered bowel habit** (most consistent feature): IBS-C — hard, narrow-calibre, infrequent stools (<3/week), straining, sense of anal blockage; IBS-D — small-volume loose stools (<200 mL), urgency, mucus, occasional incontinence.
- ▶ **Gas/bloating/distension** — common; most generate a *normal* amount of gas but tolerate gas loads poorly.

- ▶ **Upper-GI/extra-intestinal overlap:** dyspepsia, heartburn, nausea in 25–50%; overlap with fibromyalgia, chronic fatigue, headache, backache, urologic and gynaecologic symptoms.

Alarm (“red-flag”) features that argue AGAINST IBS

- ▶ Onset after **age 40–45**, progressive course, **rectal bleeding/hematochezia**, **nocturnal pain** or diarrhoea, significant **weight loss**, fever, persistent diarrhoea after a 48-h fast, steatorrhea.
- ▶ **Anaemia**, raised inflammatory markers, leucocytes/blood in stool, stool volume **>200–300 mL/day**.
- ▶ **Family history** of colorectal cancer, IBD or coeliac disease.
- ▶ *Any* alarm feature mandates targeted investigation (e.g. colonoscopy with random biopsies for microscopic colitis).

Investigations (diagnosis of positive features + limited exclusion)

- ▶ Diagnosis is **clinical**; over-testing in a young patient with typical symptoms and no alarm features is harmful and costly.
- ▶ **Baseline:** complete blood count; **CRP** and **faecal calprotectin** (or lactoferrin) to screen for IBD — IBD risk $\leq 1\%$ if CRP ≤ 0.5 mg/dL or calprotectin ≤ 40 $\mu\text{g/g}$ (>50 $\mu\text{g/g}$ warrants endoscopy).
- ▶ **Coeliac serology** (tissue-transglutaminase IgA) in IBS-D.
- ▶ **Stool studies** for ova/parasites/*Giardia* only where prevalence is high or history suggestive.
- ▶ **Colonoscopy** if alarm features, onset >45 years, or failure of therapy — with **random biopsies** to exclude microscopic colitis; lactose/glucose **hydrogen breath test** selectively; **SeHCAT/bile-acid** testing in refractory IBS-D; **anorectal manometry + balloon expulsion** if pelvic-floor dyssynergia suspected.

Management (stepwise, severity- and symptom-directed)

- ▶ **Foundation (all patients):** strong **therapeutic relationship**, reassurance, explanation of the gut–brain nature, realistic goals, identifying triggers; regular **exercise**.
- ▶ **Diet:** eliminate identified food triggers (avoid nutritionally depleted diets); **soluble fibre** (psyllium 3–4 g BD — *not* insoluble wheat bran); **low-FODMAP diet** as a 3-step *restriction* → *reintroduction* → *personalised maintenance* protocol relieves symptoms in **50–80%** (avoid in eating disorders).
- ▶ **Antispasmodics** (pain/cramps): dicyclomine, hyoscyamine 30 min before meals; **enteric-coated peppermint oil** (superior to placebo for global symptoms/pain).
- ▶ **For IBS-D:** **loperamide** 2–4 mg (max 12 mg/day, prophylactic before stressful events; does not relieve pain); **bile-acid binders** (cholestyramine/colesevelam) for bile-acid diarrhoea; **eluxadoline** (mixed μ -/ κ -agonist, δ -antagonist; contraindicated post-cholecystectomy, pancreatitis history or heavy alcohol use); **alosetron** (5-HT₃ antagonist; restricted to women with

severe IBS-D — risk of **ischaemic colitis** ~1.03/1000 patient-years); **rifaximin** 550 mg TDS × 14 days (FDA-approved, especially bloating).

- ▶ **For IBS-C:** osmotic laxative **PEG 3350** (*avoid lactulose/sorbitol* — gas); **secretagogues** — lubiprostone (Cl⁻-channel ClC-2 activator), linaclotide and plecanatide (guanylate cyclase-C agonists), tenapanor (NHE3 inhibitor); **tegaserod** (5-HT₄ agonist) re-approved 2019 for women <65 without cardiovascular disease.
- ▶ **Neuromodulators (pain-predominant/severe):** low-dose **tricyclic antidepressants** (amitriptyline/nortriptyline/imipramine 10–50 mg at night — benefit independent of mood effect; TCAs favour IBS-D); **SSRIs** may help IBS-C and comorbid mood disorder. Avoid chronic anxiolytics.
- ▶ **Psychological therapies (refractory/severe):** **cognitive behavioural therapy** (NNT ≈ 3) and **gut-directed hypnotherapy** (NNT ≈ 4).
- ▶ **Severity spectrum:** **mild** (~70%) — primary care, education/diet; **moderate** (~25%) — gut-acting drugs; **severe** (~5%) — referral centres, constant pain + psychosocial difficulty, best managed with neuromodulators and psychological treatment.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Brain–gut axis pathophysiology of IBS** (central hub “IBS” with radiating arrows): label *CNS hypervigilance* — mid-cingulate/prefrontal cortex, *Brain–gut axis* — HPA axis, *autonomic dysfunction*, *Visceral hypersensitivity (TRPV1)*, *Motility abnormalities*, “*Leaky*” gut / *altered permeability*, *Mast-cell activation & low-grade inflammation*, *Gut dysbiosis* (↓*Bifidobacterium*, ↓*Faecalibacterium*, ↑*Enterobacteriaceae*), *Bile-acid malabsorption* (↓*FGF-19*), *Serotonin/SERT polymorphism*, *Psychological* — *anxiety/depression/somatisation*, *Genetic* — *twin studies/SERT*.
- ▶ **Bristol Stool Form Scale & IBS subtyping graph:** Y-axis % *BM hard or lumpy* (Bristol 1–2), X-axis % *BM loose or watery* (Bristol 6–7), with **25% threshold** lines partitioning four quadrants labelled IBS-C, IBS-D, IBS-M, IBS-U; depict Bristol types 1–7 alongside.

Clinical / Diagnostic significance

- ▶ IBS is a **positive clinical diagnosis** by Rome IV plus *absence of red flags* — not purely a diagnosis of exclusion; limited testing avoids reinforcing illness behaviour.
- ▶ **Differential diagnosis** is broad: IBD (UC/Crohn, **microscopic colitis**), coeliac disease, bile-acid diarrhoea, lactase deficiency, SIBO, colorectal neoplasia, thyroid disease, carcinoid, endometriosis/ovarian cancer, and porphyria/lead poisoning (painful constipation).
- ▶ **Subtype-directed therapy** (pain vs constipation vs diarrhoea vs bloating) is the practical framework; agents are *adjunctive, not curative*.

- ▶ Failure to respond to a 2–4 week empiric trial or emergence of alarm features should prompt further evaluation.

High-yield exam pointers

- ▶ **Rome IV**: abdominal pain ≥ 1 day/week $\times$ 3 months + ≥ 2 of (defecation-related / change in stool frequency / change in stool form); onset ≥ 6 months prior.
- ▶ **Subtypes** by Bristol scale, **25% rule**: IBS-C, IBS-D, IBS-M, IBS-U — *unstable over time*.
- ▶ Female:male $\approx$ 2–3:1; prevalence $\sim$ 10%; onset usually <45 years.
- ▶ **Pain is essential**, is **never nocturnal**, relieved by defecation — *painless* altered habit is not IBS.
- ▶ Up to 25% of IBS-D have **bile-acid malabsorption**; $>10\%$ develop **post-infectious IBS** (4-fold risk).
- ▶ Screen IBS-D with **CRP + faecal calprotectin** ($>50 \mu\text{g/g} \rightarrow$ scope) and **coeliac serology**.
- ▶ **Low-FODMAP diet** helps 50–80%; **psyllium** (soluble) not wheat bran (insoluble).
- ▶ Drug pearls: **eluxadoline** contraindicated post-cholecystectomy/alcohol (pancreatitis); **alosetron** $\rightarrow$ ischaemic colitis (restricted); **rifaximin** for IBS-D/bloating; **linaclotide/plecanatide** (GC-C agonists), **lubiprostone** (Cl⁻ channel), **tenapanor** (NHE3) for IBS-C; TCAs for pain.
- ▶ CBT (NNT 3) and **gut-directed hypnotherapy** (NNT 4) for refractory disease.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Irritable Bowel Syndrome” (Owyang & Singh): Rome IV criteria, pathophysiology, drugs/doses, low-FODMAP protocol, severity spectrum.
- ▶ **Sleisenger & Fordtran's Gastrointestinal and Liver Disease, 11e** — “Irritable Bowel Syndrome”: Bristol-scale subtyping, diagnostic algorithm, CRP/calprotectin thresholds, NNT for hypnotherapy/CBT.
- ▶ **CMDT 2026** — “Gastrointestinal Disorders: Irritable Bowel Syndrome”: current pharmacologic management, drug doses, alarm features, FODMAP food groups.

List the complications of chronic pancreatitis? How do you manage them?

Asked in: Paper II 08 Apr 2026 — RGUHS MD General Medicine

Definition / Introduction — Chronic pancreatitis (CP) is an irreversible inflammatory disease characterised histologically by chronic inflammation, fibrosis and progressive destruction (atrophy) of both the exocrine and endocrine pancreas, driven by stellate-cell activation, cytokine release and collagen deposition. Its cardinal manifestations are abdominal pain, steatorrhoea, weight loss and diabetes mellitus. Aetiology is summarised by the **TIGAR-O** system (Toxic-metabolic [alcohol, tobacco,

hypercalcaemia, hypertriglyceridaemia], Idiopathic, Genetic [*PRSS1*, *SPINK1*, *CFTR*, *CTRC*, *CASR*], Autoimmune, Recurrent/severe acute pancreatitis, Obstructive). Because no therapy reverses the disease, management is centred on screening for and treating its complications.

Complications of chronic pancreatitis (Harrison Table 359-7)

Domain	Complication	Key facts
Pain	Chronic abdominal pain	Most common/disabling symptom; complex mechanism; narcotic dependence frequent
Exocrine	Exocrine pancreatic insufficiency (EPI) → steatorrhea, malnutrition	Cumulative prevalence >80%; fat-soluble vitamin (A, D, E, K) deficiency; B12 malabsorption in ~40%
Endocrine	Pancreatogenic (type 3c) diabetes mellitus	Lifetime prevalence >80%; brittle, prone to hypoglycaemia (loss of glucagon reserve); ketoacidosis/end-organ damage uncommon
Ductal/cystic	Pseudocyst; pancreatic duct stricture/stones	Pseudocyst in ~25% (commonest in alcoholic CP); ~70% communicate with the duct
Biliary	Distal CBD stricture → jaundice, cholangitis, secondary biliary cirrhosis	Symptomatic in ~10%; long tapered stenosis of intrapancreatic CBD
Luminal	Duodenal (gastric-outlet) obstruction	~5%; from head fibrosis/inflammatory mass
Vascular	Splanchnic (splenic > portal) vein thrombosis; pseudoaneurysm	Splenic-vein thrombosis → left-sided (“sinistral”) portal hypertension + gastric varices; pseudoaneurysm (splenic artery commonest)
Haemorrhagic	GI bleeding	Pseudoaneurysm, ruptured varices, hemosuccus pancreaticus, peptic ulcer
Fistula	External (pancreaticocutaneous); internal (pancreatic ascites, pancreaticopleural effusion)	High-amylase ascites/effusion; from duct disruption/pseudocyst rupture
Skeletal	Metabolic bone disease	Osteopenia/osteoporosis in ~65% (alcohol, smoking, vitamin-D deficiency, inflammation)

Domain	Complication	Key facts
Malignant	Pancreatic adenocarcinoma	~4–5% cumulative risk at 20 yr; hereditary <i>PRSS1</i> ~10% (rising to ~19% by age 70)

General principles of management

- ▶ **Remove the driver:** absolute alcohol abstinence and **smoking cessation** (both are independent, dose-dependent drivers of progression, fibrosis and calcification).
- ▶ **Diet:** a low-fat or heart-healthy/Mediterranean diet; avoid very-low-fat diets that worsen fat-soluble-vitamin deficiency.
- ▶ **Treat the specific complication** (below); refer all CP patients to a centre offering endoscopic/surgical therapy.

Management of pain

- ▶ **Stepwise analgesia:** acetaminophen and NSAIDs first; **tramadol** if an opioid is needed; *avoid strong opioids* where possible (addiction is common).
- ▶ **Adjuvant pain-modifiers:** **pregabalin** (RCT-proven to reduce pain and opioid need) or gabapentin, tricyclic antidepressants, SSRIs. Antioxidants give mixed results; pancreatic enzymes do **not** reliably relieve pain.
- ▶ **Coeliac plexus block** (CT- or EUS-guided): relief in ~50% but typically **short-lived** — a conditional, low-evidence recommendation.
- ▶ **Endoscopic therapy** for a dominant duct stricture/obstructing stone: pancreatic sphincterotomy, stone extraction ± ESWL, and ductal stenting; successful in ~50%.
- ▶ **Surgery for a dilated duct:** ductal decompression by **lateral pancreaticojejunostomy** (**modified Puestow**) relieves pain in ~80%; head-resecting variants (**Frey / Beger** — duodenum-preserving pancreatic head resection) for an inflammatory head mass. Two RCTs show **surgery is superior to endoscopy** for pain/quality of life in dilated-duct disease, and early surgery may give superior short-term relief.
- ▶ **Total pancreatectomy with islet autotransplantation (TPIAT):** last resort for intractable **small-duct** or hereditary CP; benefits those with shorter symptom duration and low opioid use.

Management of exocrine insufficiency / steatorrhoea

- ▶ **Pancreatic enzyme replacement therapy (PERT)** is the cornerstone — diagnosis of EPI confirmed by **faecal elastase-1 <100 µg/g** (200 = normal; 100–200 = mild-moderate).
- ▶ Start **25,000–50,000 units of lipase with each meal**, titrating up to **90,000–100,000 units/meal**; aim for adequate lipase across the prandial/postprandial phase. Take enzymes spread throughout the meal.

- ▶ Add **acid suppression** (PPI or H₂-blocker) — *mandatory* with non-enteric-coated preparations and useful to improve response with enteric-coated preparations.
- ▶ Judge response clinically (stool consistency, visible fat, weight gain). If refractory: increase dose/change formulation, exclude **coeliac disease** / **SIBO**, and substitute **medium-chain triglycerides** (lipase-independent absorption).
- ▶ **Monitor and replace** fat-soluble vitamins (esp. vitamin D) and zinc; check body weight and **bone mineral density** (DEXA) — treat osteopenia/osteoporosis.

Management of endocrine insufficiency (type 3c diabetes)

- ▶ Annual **fasting glucose** and **HbA1c** screening; C-peptide estimates residual β -cell mass.
- ▶ **Metformin** preferred (associated with lower secondary pancreatic-cancer risk); **insulin** is frequently required, but requirements are lower than in type 1 DM.
- ▶ **Avoid over-tight glycaemic control** — brittle diabetes with impaired glucagon reserve and malnutrition predisposes to dangerous treatment-induced **hypoglycaemia**.

Management of structural / vascular complications

- ▶ **Pseudocyst**: observe if asymptomatic. Drain if symptomatic, complicated, rapidly enlarging or generally >6 cm — preferred is **EUS-guided endoscopic cystogastrostomy/cystojejunostomy** (success 80–90%); surgical drainage (often with a Puestow) where endoscopy fails; **percutaneous drainage is discouraged** (downstream duct stricture → fistula/recurrence). Address an associated duct stricture/disruption (bridging stent) to prevent recurrence.
- ▶ **Biliary obstruction: cholangitis is an absolute indication** for intervention. **Surgical biliary bypass** (choledochojejunostomy/choledochoduodenostomy ± Whipple/head resection) is definitive; endoscopic stenting (multiple plastic stents or a fully-covered SEMS for 6–12 months) is a temporising option with lower long-term success. A new stricture may signal malignancy — assess with EUS.
- ▶ **Duodenal obstruction**: trial of conservative therapy (inflammation may settle); **gastrojejunostomy** (± duct drainage) or head resection if it fails.
- ▶ **Pseudoaneurysm / haemorrhage**: the **splenic artery** is most often involved; beware a **sentinel bleed** preceding exsanguination, and **hemosuccus pancreaticus** (bleeding via the ampulla/duct). CT angiography then **angiographic embolisation or covered stent-graft** is first-line (has replaced surgery); treat once identified even if not yet bleeding — mortality after bleeding is ~40%.
- ▶ **Splenic-vein thrombosis with gastric varices**: therapy only if bleeding (risk ~10%) — **splenectomy is curative**; endoscopic cyanoacrylate injection controls acute bleeding.
- ▶ **Pancreatic fistula**: internal (pancreatic ascites/pleural effusion) or external — bowel rest, parenteral nutrition and **octreotide** (100 μ g SC 8-hourly), with **endoscopic**

transpapillary/bridging stent across the duct disruption; surgery (distal resection or fistulojejunostomy) if endoscopy fails.

- ▶ **Autoimmune pancreatitis** (a treatable cause/mimic): **prednisone 40 mg/day** for 4 weeks then taper; **rituximab** (or azathioprine/MMF) for relapse.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Diagram 1 — “Complications map of the pancreas in CP”**: outline the pancreas (atrophic, with punctate parenchymal calcifications) and label: *dilated main pancreatic duct with intraductal calculus, pancreatic-duct stricture, pseudocyst (tail), distal common bile duct stricture → biliary dilatation, duodenal compression, splenic-vein thrombosis with gastric (fundal) varices, splenic-artery pseudoaneurysm.*
- ▶ **Diagram 2 — “Pain-management ladder in CP”**: stacked steps labelled *Abstinence (alcohol + tobacco) → Acetaminophen/NSAID → tramadol + pregabalin/TCA → Coeliac plexus block → Endoscopy (sphincterotomy, ESWL, stent) → Surgery (Puestow / Frey-Beger) → TPIAT.*

Clinical / Diagnostic significance

- ▶ **Diagnosis of CP**: CT/MRI is first-line (calcifications, ductal dilatation, atrophy); MRCP/EUS for early disease (≥ 5 of 9 EUS / Rosemont features); the **secretin test** (most sensitive functional test) becomes abnormal once $\geq 60\%$ of exocrine function is lost.
- ▶ **Steatorrhea appearing in CP** strongly implies EPI; a **new biliary stricture or unexplained weight loss** must trigger exclusion of **pancreatic cancer** (tumefactive CP can mimic carcinoma).
- ▶ **Any GI bleed or unexplained anaemia** in a CP patient mandates urgent search for a **pseudoaneurysm**.
- ▶ **Surveillance bundle**: annual HbA1c (diabetes), periodic fat-soluble vitamins/zinc and DEXA (bone disease, EPI), and cancer vigilance — especially in hereditary *PRSS1*/tropical CP.

High-yield exam pointers

- ▶ TIGAR-O classifies aetiology; alcohol + smoking drive progression — **abstinence is therapy**.
- ▶ EPI prevalence $>80\%$; diagnose with **faecal elastase-1 $<100 \mu\text{g/g}$** ; treat with PERT 25,000–50,000 → 90,000–100,000 U lipase/meal + PPI.
- ▶ **Type 3c (pancreatogenic) diabetes** is *brittle* — guard against hypoglycaemia; metformin preferred.
- ▶ **Pseudocyst ($\sim 25\%$)** → EUS-guided endoscopic drainage; **percutaneous drainage discouraged**.
- ▶ **Splenic-vein thrombosis** → **sinistral portal hypertension + gastric varices** → **splenectomy is curative**.

- ▶ **Pseudoaneurysm** (splenic artery) — **sentinel bleed**, **hemorrhage pancreaticus**, mortality ~40% — treat by **angiocoilisation/stent-graft**.
- ▶ Biliary stricture (~10%): **cholangitis** = **absolute indication**; surgical bypass is definitive.
- ▶ **Dilated duct + pain** → **surgery (Puestow)** beats **endoscopy** (RCT evidence); intractable small-duct/hereditary → **TPIAT**.
- ▶ Pancreatic cancer cumulative risk ~4–5% at 20 yr (~10–19% in hereditary CP); ~65% have **metabolic bone disease**.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Acute and Chronic Pancreatitis” (chronic pancreatitis pathophysiology, TIGAR-O classification, complications [Table 359-7], steatorrhea/PERT, pain and surgical therapy, hereditary pancreatitis).
- ▶ **Sleisenger & Fordtran's Gastrointestinal and Liver Disease, 11e** — “Chronic Pancreatitis” (deep detail on pseudocyst, GI bleeding, pseudoaneurysm, splenic-vein thrombosis/varices, bile-duct and duodenal obstruction, pancreatic fistulas, diabetes management).
- ▶ **CMDT 2026** — “Liver, Biliary Tract, & Pancreas Disorders” (current management: enzyme [pancrelipase] dosing, pain pharmacotherapy, endoscopic/surgical algorithm — Puestow/Beger/Frey, autoimmune pancreatitis steroids/rituximab, cancer risk).

List the sites of portosystemic anastomosis and explain the clinical relevance

Asked in: Paper I May 2025 — RGUHS MD General Medicine

Definition / Introduction — A **portosystemic (porto-systemic) anastomosis** is a site where tributaries of the valveless **portal venous system** communicate with veins of the **systemic (caval) circulation**. In health these channels carry negligible flow *towards* the portal vein. When the **hepatic venous pressure gradient (HVPG)** rises (portal hypertension is defined as HVPG >5 mmHg; *clinically significant* portal hypertension is HVPG ≥10 mmHg), flow **reverses**, the collaterals dilate, and varices form as decompressing channels. They are the anatomical basis of the lethal complication of cirrhosis — **variceal haemorrhage** (20–30% mortality per episode).

Anatomy of the normal portal circulation (orientation)

- ▶ The **portal vein** is formed behind the neck of the pancreas by union of the **superior mesenteric vein** and the **splenic vein**; it is ~7.5 cm long, runs dorsal to the hepatic artery and bile duct, and divides at the hilum into right and left branches.

- ▶ The **inferior mesenteric vein** usually drains into the splenic vein; the **left gastric (coronary) vein** drains into the portal vein near the splenomesenteric confluence; the **umbilical vein** drains into the *left* portal branch.
- ▶ The portal system drains capillary blood from the **oesophagus, stomach, small and large intestine (to the upper anal canal), pancreas, gallbladder and spleen**, and supplies ~75% of total hepatic blood flow. Being **valveless**, it permits pressure to be transmitted retrogradely into collaterals.

Sites of portosystemic anastomosis (core of the answer)

Site	Portal (visceral) tributary	Systemic vein	Clinical lesion / sign
Lower oesophagus / gastro-oesophageal junction	Left gastric (coronary) & short gastric veins → splenic/portal	Oesophageal tributaries of the azygos/hemiazygos (perioesophageal) veins → SVC	Oesophageal & gastro-oesophageal varices — the principal, bleeding collateral
Gastric fundus / cardia	Short gastric & posterior gastric → splenic vein	Left renal vein via spontaneous spleno-renal shunt	Fundal (gastric) varices ; isolated in splenic-vein thrombosis
Anal canal / rectum	Superior rectal vein (from inferior mesenteric)	Middle & inferior rectal veins → internal iliac / internal pudendal → IVC	Ano-rectal varices (to be distinguished from haemorrhoids)
Peri-umbilical anterior abdominal wall	Para-umbilical veins in the falciform/round ligament (from left portal vein)	Superficial & inferior epigastric / thoraco-epigastric veins	Caput medusae ; <i>Cruveilhier–Baumgarten</i> venous hum
* <i>Retroperitoneum (veins of Retzius)*</i>	Colonic & other splanchnic veins; ovarian veins (esp. in women)	Retroperitoneal, renal, lumbar and iliac veins	Ectopic / retroperitoneal varices; rarely bleed
* <i>Bare area of liver / diaphragm (veins of Sappey)*</i>	Hepatic capsular & diaphragmatic portal twigs	Phrenic veins → IVC	Adhesion collaterals; clinically silent
Patent / recanalised ductus venosus	Left portal vein	IVC	Rare congenital shunt

- ▶ **Mechanistic note (Sleisenger)**: the GE-junction collaterals (left gastric/coronary + short gastric draining to the azygos system) are the dominant route in *intra-hepatic* portal hypertension; an increase in azygos blood flow is a hallmark. The fundus drains via short gastric veins into the splenic vein, hence **splenic-vein thrombosis** (“**left-sided**” portal hypertension) produces *isolated* fundal varices, often with a spleno-renal shunt.

Four venous zones at the gastro-oesophageal junction (why varices bleed here)

- ▶ **Gastric zone** (2–3 cm below junction) — submucosal longitudinal veins draining to short/left gastric veins.
- ▶ **Palisade zone** (2–3 cm of distal oesophagus) — the **dominant portosystemic watershed**; perforating veins do *not* connect to peri-oesophageal veins, so these varices **cannot decompress** and are **most prone to rupture**.
- ▶ **Perforating zone** — network of veins connecting submucosal and external (peri-oesophageal) veins.
- ▶ **Truncal zone** (~10 cm, proximal) — 4 longitudinal veins; communicate with peri-oesophageal veins (which drain to the azygos), so they decompress and **rarely bleed**.

Pathophysiology — pressure thresholds and rupture

- ▶ Collaterals form because portal pressure **exceeds** systemic venous pressure → flow reverses out of the portal bed.
- ▶ **Gradient thresholds**: varices develop at an HVPG ≥ 10 mmHg; bleeding requires a gradient ≥ 12 mmHg (reducing HVPG < 12 mmHg almost abolishes bleeding risk).
- ▶ Rupture follows **Laplace's law**: $\text{wall tension } T = (P \times r)/w$ — large varices (r), thin wall (w), and high transmural pressure (P), with limited soft-tissue support at the GE junction, predispose to rupture. Endoscopic risk stigmata: **red wale signs, cherry-red spots, haematocystic spots, white-nipple sign**.

Gastric varices — Sarin classification

Type	Location	Association
GOV1	Extend 2–5 cm below GE junction, contiguous with oesophageal varices	Commonest (~70% of gastric varices); intra-hepatic portal HTN
GOV2	Cardia/fundus, contiguous with oesophageal varices	Intra-hepatic portal HTN
IGV1	Isolated fundal varices, no oesophageal varices	Splenic-vein thrombosis (left-sided) / cirrhosis
IGV2	Isolated, gastric body/antrum/pylorus	Least common

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Diagram 1** — “Sites of portosystemic anastomosis.” Draw the portal vein (SMV + splenic vein confluence), spleen and gut. Label the four classic sites with their venous pairs: (i) *Lower oesophagus* — left gastric/coronary vein ↔ azygos vein; (ii) *Rectum* — superior

Type	Location	Association
	rectal vein ↔ middle/inferior rectal veins; (iii) <i>Umbilicus</i> — para-umbilical veins ↔ epigastric veins (caput medusae); (iv) <i>Retroperitoneum</i> — colonic/splanchnic veins ↔ renal/lumbar veins (veins of Retzius). Mark arrows showing reversed (hepatofugal) flow and the resulting lesion at each site.	
	▶ Diagram 2 — “Four zones of the gastro-oesophageal junction.” Vertical strip of distal oesophagus/cardia labelled gastric → palisade (watershed, bleeds) → perforating → truncal, with the palisade zone starred as the rupture site and peri-oesophageal veins draining to the azygos system.	

Clinical / Diagnostic significance

- ▶ **Oesophageal/gastric varices:** life-threatening upper-GI bleed; screen at diagnosis of cirrhosis by endoscopy (skip if liver stiffness <20 kPa and platelets normal). **Primary prophylaxis** = non-selective β -blocker (**carvedilol** preferred; or propranolol/nadolol titrated to HR 55–60, SBP >90 mmHg) **or** endoscopic variceal ligation.
- ▶ **Acute variceal bleed:** restrictive transfusion (transfuse at Hb <7 g/dL, target 7–9), **vasoactive drug** (somatostatin/octreotide/terlipressin), **prophylactic ceftriaxone**, urgent endoscopic band ligation; **balloon tamponade** (Sengstaken–Blakemore/Minnesota tube) or self-expanding metal stent as a bridge to **TIPS** (transjugular intrahepatic portosystemic shunt) on endoscopic failure.
- ▶ **Gastric (fundal) varices:** cyanoacrylate glue injection; **BRT**O (balloon-occluded retrograde transvenous obliteration) when a spleno-renal shunt is present, $\pm$ TIPS. **Isolated fundal varices** → **exclude splenic-vein thrombosis** → **splenectomy is curative** for that pattern.
- ▶ **Caput medusae & Cruveilhier–Baumgarten hum:** clinical bedside signs of a recanalised umbilical/para-umbilical collateral — distinguish radiating peri-umbilical veins of portal hypertension from the “**flow away from umbilicus**” of IVC obstruction.
- ▶ **Ano-rectal varices** occur in 10–40% of cirrhotics at colonoscopy: they are dilated **superior and middle rectal (haemorrhoidal) veins**, **collapse with digital pressure**, and must not be confused with haemorrhoids (which do not collapse and are cushions in the anal canal).
- ▶ **Ectopic varices** (duodenum, peristomal after proctocolectomy, biliary) cause <5% of variceal bleeds but are easily missed; suspect with obscure GI bleed or bloody ascites.
- ▶ **Encephalopathy:** large spontaneous or surgical/TIPS shunts divert nitrogenous blood past the liver → portosystemic (hepatic) encephalopathy (occurs in up to ~20% after TIPS).

High-yield exam pointers

- ▶ **Four classic sites:** lower oesophagus, ano-rectum, peri-umbilicus, retroperitoneum (add fundus, bare area of liver).

- ▶ Most clinically important & dangerous collateral = gastro-oesophageal varices (left gastric/coronary + short gastric ↔ azygos).
- ▶ Palisade zone of the distal oesophagus is the watershed that **cannot decompress** → commonest bleeding site.
- ▶ HVPg ≥ 10 mmHg → varices form; ≥ 12 mmHg → varices bleed. Laplace's law governs rupture.
- ▶ Caput medusae = recanalised para-umbilical veins (left portal vein); a venous hum = Cruveilhier–Baumgarten sign.
- ▶ Rectal varices $\neq$ haemorrhoids: varices collapse on digital pressure and connect superior ↔ middle rectal veins.
- ▶ Isolated gastric fundal varices (IGV1) → think splenic-vein thrombosis; treat with splenectomy/BRTO, *not* β -blockers alone.
- ▶ Sarin classification: GOV1 (commonest), GOV2, IGV1, IGV2.
- ▶ “Downhill” oesophageal varices (upper third, from SVC obstruction) are NOT portal-hypertensive — a key differential.

SOURCE & COVERAGE

- ▶ Harrison's Principles of Internal Medicine, 22e — “Cirrhosis and Its Complications” (portal hypertension definition, HVPg thresholds, classification of portal hypertension, complications, variceal-bleed management, TIPS).
- ▶ Sleisenger & Fordtran's Gastrointestinal and Liver Disease, 11e — “Portal Hypertension and Variceal Bleeding” (normal portal anatomy; the four sites of porto-systemic collateral formation; the four gastro-oesophageal venous zones; Laplace's law; Sarin classification of gastric varices; ectopic and ano-rectal varices) and used for collateral/watershed detail.
- ▶ CMDT 2026 — Gastrointestinal & Liver disorders (current management of variceal bleeding; haemorrhoids vs rectal varices).

Coverage note: The named venous eponyms **veins of Retzius** (retroperitoneal), **veins of Sappey** (bare area/diaphragm), the **Cruveilhier–Baumgarten** hum, and “**downhill**” varices are standard, universally accepted internal-medicine/anatomy facts included to satisfy the “list the sites” phrasing; the corpus describes the corresponding retroperitoneal (ovarian–iliac) and para-umbilical collaterals but does not use these eponyms verbatim. Harrison Ch 355's coverage of collateral *anatomy* is thin (as flagged in the spec); the anatomical depth here is drawn chiefly from Sleisenger.

Management of Active Ulcerative Colitis

Asked in: Paper II May 2019 — RGUHS MD General Medicine

Definition / Introduction — Ulcerative colitis (UC) is a chronic, relapsing, idiopathic inflammatory bowel disease characterised by *continuous*, diffuse mucosal inflammation that invariably involves the rectum and extends proximally in an uninterrupted fashion to involve part or all of the colon. The hallmark of active disease is **bloody diarrhoea** with tenesmus, urgency, passage of mucus and crampy lower-abdominal pain. Management of the *active* attack is governed by two axes — the **anatomical extent** (proctitis / left-sided / extensive) and the **severity of the flare** (mild, moderate, severe/fulminant) — and follows a “step-up / accelerated step-up” strategy with three goals: terminate the acute attack, achieve steroid-free clinical and endoscopic (mucosal) remission, and prevent recurrence.

Assessment of disease activity & severity (basis of all treatment decisions)

Severity is graded clinically (*Truelove & Witts*, refined as the *Montreal S-classification*) and endoscopically (*Mayo subscore*), supported by labs (Hb, albumin, ESR, CRP, faecal calprotectin).

Parameter	Mild (S1)	Moderate (S2)	Severe (S3)
Stools/day	≤4	4–6	>6, bloody
Blood in stool	intermittent	frequent	continuous
Pulse	normal	normal	≥90/min
Temperature	normal	normal	≥37.5°C
Haemoglobin	normal	≥10.5 g/dL	<10.5 g/dL
ESR	<30 mm/h	≤30	≥30 mm/h
Mayo endoscopic subscore	1	2–3	3 (ulceration, spontaneous bleeding)

- ▶ **Montreal extent:** E1 — proctitis; E2 — left-sided (distal to splenic flexure); E3 — extensive/pancolitis (proximal to splenic flexure). Extent dictates whether topical, oral or systemic therapy is appropriate.
- ▶ **Truelove & Witts severe attack** = ≥6 bloody stools/day **plus** ≥1 systemic sign (pulse >90, temp >37.8°C, Hb <10.5 g/dL, ESR >30) — the classic trigger for hospital admission.
- ▶ Before treating, **exclude infective mimics:** stool for *Salmonella*, *Shigella*, *Campylobacter*, Shiga-toxin *E. coli*, *Clostridioides difficile* toxin, ova/parasites (multiplex PCR preferred); consider **CMV superinfection** (mucosal biopsy) in steroid-refractory immunosuppressed patients.

Mild–moderate disease (out-patient, oral/topical therapy)

- ▶ **Proctitis / proctosigmoiditis (distal):** topical mesalamine is the drug of choice — suppository 1 g at bedtime (proctitis) or enema 4 g at bedtime (proctosigmoiditis) for 4–8 weeks (~75% improve). Topical mesalamine is *superior to* topical steroids and to oral 5-ASA for distal disease.

- ▶ **Extensive (above sigmoid):** combine oral mesalamine 2–4.8 g once daily with a nightly mesalamine enema/suppository; 50–75% improve, dose-response continues to 4.8 g/day. Sulfasalazine 3–6 g/day (acute) is effective but limited by sulfapyridine intolerance — give **folic acid** supplementation.
- ▶ **Oral budesonide MMX (Uceris) 9 mg/day** for 4–8 weeks (colonic release, minimal systemic steroid effect, no taper needed) or **oral prednisone** if no response to 5-ASA within 4–8 weeks.
- ▶ 5-ASA achieves clinical improvement in ~75% and remission in 20–30%; **maintenance 5-ASA** reduces 12-month relapse from 75% to <40%.

Moderate–severe disease (oral/systemic immunosuppression & biologics)

- ▶ **Oral corticosteroids: prednisone 40 mg/day** (Harrison: 40–60 mg/day); rapid response in ~2 weeks, then taper **5 mg/week** (slower, 2.5 mg/week below 20 mg). Steroids **induce but never maintain** remission; up to 30% become steroid-dependent/refractory.
- ▶ **Thiopurines** (steroid-sparing maintenance, not for induction — slow onset 3–6 months): azathioprine 2–3 mg/kg/day or 6-mercaptopurine 1–1.5 mg/kg/day. Check/keep in mind TPMT status (1 in 300 deficient → marrow toxicity); monitor CBC and LFTs; ~4-fold lymphoma risk.
- ▶ **Biologics / small molecules** are increasingly used early (“treat-to-target”, aiming for deep remission). Choice depends on prior biologic exposure, severity, comorbidity and route preference.

Agent	Class / target	Induction dosing
Infliximab	anti-TNF (chimeric IgG1)	5 mg/kg IV at 0, 2, 6 wk → q8 wk (↑10 mg/kg q4 wk by trough)
Adalimumab	anti-TNF (human IgG1, SC)	160 mg day 0, 80 mg day 14, then 40 mg q2 wk
Golimumab	anti-TNF (human IgG1, SC)	approved for moderate–severe UC
Vedolizumab	anti- $\alpha 4\beta 7$ integrin (gut-selective)	IV; preferred first-line in older/comorbid patients; superior to adalimumab
Ustekinumab	anti-IL-12/23 (p40)	IV induction → SC maintenance
Mirikizumab / risankizumab	anti-IL-23 (p19)	injectable; 2nd/3rd-line
Tofacitinib	pan-JAK inhibitor (oral)	10 mg BID × 8–16 wk
Upadacitinib	selective JAK1 (oral)	45 mg/day × 8 wk
Ozanimod / etrasimod	S1P-receptor modulator (oral)	once-daily (ozanimod needs dose escalation)

- ▶ **Combination therapy** (anti-TNF + immunomodulator) is superior to either alone for moderate–severe UC and reduces anti-drug antibody formation; do **proactive trough/antibody monitoring**.
- ▶ **JAK-inhibitor caution:** boxed warning — thrombosis, MACE, malignancy, serious infection, herpes zoster (give Shingrix); relegated to 2nd-line, avoid in >50 y, smokers, cardiovascular risk.
- ▶ **Pre-biologic screening:** latent TB (PPD/QuantIFERON-TB Gold) and hepatitis B (HBsAg/HBsAb/HBcAb) before anti-TNF.

Acute severe ulcerative colitis (ASUC) — a medical emergency

A hospitalised severe attack (Truelove–Witts criteria) carries real risk of toxic megacolon, perforation and death; **up to 30% require colectomy**. Managed jointly with surgery from day 1.

- ▶ **General measures:** admit; IV fluids and electrolyte correction; transfuse if Hct <25–28%; **stop opioids/anticholinergics/antidiarrhoeals** (precipitate toxic megacolon); plain AXR/CT on admission; stool studies + *C. difficile*; nutritional support (TPN only if malnourished/prolonged NPO — enteral/elemental diets do **not** treat active UC). **VTE pharmacological prophylaxis for ALL hospitalised IBD patients** (high thrombotic risk).
- ▶ **First-line: IV corticosteroids** — methylprednisolone **40–60 mg/day** or hydrocortisone **300 mg/day**; ± hydrocortisone enema for tenesmus. Assess response at **day 3**.
- ▶ **Day-3 non-response (Oxford/Travis criteria)** = >8 stools/day, OR 3–8 stools/day with CRP >45 mg/L → escalate to **rescue therapy** or surgery.
- ▶ **Rescue (salvage) therapy:**
 - **Infliximab 5–10 mg/kg IV** — colectomy at 3 months fell from 69% (placebo) to 47%; intensive/accelerated dosing for hospitalised patients (low albumin → faecal drug loss).
 - **IV cyclosporine 2–4 mg/kg/day continuous infusion** — ~82% respond; trough **150–350 ng/mL** (Harrison) / 200–400 ng/mL (Sleisenger). A *bridge* to thiopurine/vedolizumab maintenance or to surgery.
 - **CYSIF & CONSTRUCT trials:** infliximab and cyclosporine are **equally effective** as rescue therapy — choice rests on local expertise and comorbidity.
 - Add PCP prophylaxis (co-trimoxazole) and monitor renal function/electrolytes/Mg/cholesterol with cyclosporine (seizure risk if cholesterol <120 mg/dL).
- ▶ **Toxic megacolon** (transverse/right colon >6 cm with loss of haustration): NG suction, roll-over manoeuvre, serial films; **colectomy if no improvement in 48–72 h** to pre-empt perforation (perforation mortality ~15%).

Surgery

- ▶ Surgery is **curative** in UC. **Indications:** intractable/steroid-refractory disease, fulminant colitis/toxic megacolon unresponsive to medical therapy (48–72 h), colonic perforation, massive haemorrhage, and dysplasia/carcinoma (cancer prophylaxis).
- ▶ **Operation of choice** = **restorative proctocolectomy with ileal pouch–anal anastomosis (IPAA)** preserving the sphincter; ~6–10 (typically 5–7) bowel motions/day.
- ▶ **Pouchitis** complicates ~30–50% (up to 80% long-term); responds to **metronidazole** or **ciprofloxacin**. Emergency/fulminant cases are usually staged (subtotal colectomy with end ileostomy first).

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **ASUC management algorithm (flowchart):** Box 1 “Severe UC — Truelove & Witts: ≥ 6 bloody stools/day + pulse >90 / temp $>37.8^{\circ}\text{C}$ / Hb <10.5 / ESR >30 ” → “Admit; IV fluids, stop opioids/anticholinergics, VTE prophylaxis, AXR/CT, stool + *C. difficile*/CMV, surgical referral” → “IV methylprednisolone 40–60 mg/day” → **Day 3 assessment:** branch (a) *Responds* → switch to oral prednisone, taper, start maintenance (5-ASA/thiopurine/biologic); branch (b) *No response* (>8 stools/day OR $3-8 + \text{CRP} >45$) → “Rescue: infliximab 5–10 mg/kg OR IV cyclosporine 2–4 mg/kg/day” → response → maintenance; no response → “Colectomy (IPAA)”.
- ▶ **Treatment pyramid by severity:** base “Topical/oral 5-ASA (mesalamine, sulfasalazine)” → “Budesonide MMX / oral prednisone” → “Thiopurines (AZA/6-MP)” → “Biologics (anti-TNF, vedolizumab, ustekinumab) & small molecules (JAK-i, S1P modulators)” → apex “IV steroids → rescue therapy → colectomy”.

Clinical / Diagnostic significance

- ▶ **Severity assessment is the single most important determinant of therapy** — distal mild disease is treated topically, whereas severe disease mandates hospitalisation and parenteral therapy.
- ▶ **Faecal calprotectin >150 mcg/g or CRP >5 mg/L** in a previously remitting patient strongly suggests relapse and warrants endoscopic confirmation; calprotectin tracks mucosal healing and predicts pouchitis.
- ▶ **Avoid colonoscopy in fulminant disease/toxic megacolon** (perforation risk) — flexible sigmoidoscopy suffices to confirm activity.
- ▶ **Cancer surveillance:** colonoscopy from **8 years after diagnosis**, then every 1–5 years (chromoendoscopy enhances dysplasia detection); cumulative cancer risk ~3–4.8% at 20 y, 7–13.9% at 30 y.
- ▶ Antibiotics have **no role** in active or quiescent UC (unlike pouchitis); diet/TPN does not induce remission in UC.

High-yield exam pointers

- ▶ UC is continuous, mucosal, rectum-upward; treatment is by extent × severity.
- ▶ Topical mesalamine = drug of choice for distal/mild-moderate UC, superior to topical steroids.
- ▶ Oral mesalamine 2–4.8 g/day for extensive mild-moderate disease; combine oral + rectal for best effect.
- ▶ Steroids induce, never maintain; budesonide MMX 9 mg/day spares systemic effects.
- ▶ ASUC: IV steroids → reassess day 3 → rescue with infliximab or cyclosporine → colectomy; CYSIF/CONSTRUCT = equal efficacy.
- ▶ VTE prophylaxis for every hospitalised IBD patient; stop opioids/anticholinergics.
- ▶ Toxic megacolon = colon >6 cm + loss of haustration; colectomy if no response in 48–72 h.
- ▶ Screen for TB and hepatitis B before anti-TNF; JAK inhibitors carry thrombosis/MACE warnings.
- ▶ IPAA is the curative operation of choice; pouchitis (30–50%) responds to metronidazole/ciprofloxacin.

Management of Ulcerative colitis

Asked in: Paper II Dec 2023 — RGUHS MD General Medicine

Definition / Introduction — Ulcerative colitis (UC) is a chronic, relapsing idiopathic inflammatory bowel disease limited to the colon, with diffuse mucosal inflammation beginning in the rectum and extending proximally in a continuous manner. It presents chiefly with bloody diarrhea, urgency, tenesmus, mucus, and crampy lower abdominal pain. Management is extent- and severity-based, with the aims of terminating the acute attack, achieving steroid-free clinical and endoscopic remission, preventing relapse, and avoiding cancer, toxic megacolon, and unnecessary colectomy.

Initial assessment and treatment targets

- ▶ **Confirm diagnosis before escalation:** exclude infectious colitis with stool testing for *Salmonella*, *Shigella*, *Campylobacter*, Shiga-toxin-producing *E. coli*, *C. difficile*, and amebiasis; consider CMV on biopsy in corticosteroid-exposed or immunosuppressed patients.
- ▶ **Define extent:** E1 proctitis is limited to rectum; E2 left-sided/distal UC extends distal to the splenic flexure; E3 extensive UC/pancolitis extends proximal to the splenic flexure.
- ▶ **Grade severity:** mild ≤ 4 stools/day, no systemic illness, normal inflammatory markers; moderate ≥ 4 stools/day with minimal systemic toxicity; severe ≥ 6 bloody stools/day with pulse ≥ 90 /min, temperature $\geq 37.5^\circ\text{C}$, hemoglobin < 10.5 g/dL, and ESR ≥ 30 mm/hour.
- ▶ **Baseline activity work-up:** stool frequency and bleeding diary, fever/pulse/BP and volume status, abdominal tenderness or peritonism, Hb, WBC, platelets, ESR/CRP, serum albumin, electrolytes, renal and liver tests, fecal calprotectin/lactoferrin, and flexible sigmoidoscopy with biopsy.
- ▶ **Endoscopy:** sigmoidoscopy is preferred in acute colitis; avoid full colonoscopy in fulminant disease because of perforation risk. Mild endoscopy shows erythema and reduced vascular pattern; severe disease shows spontaneous bleeding and ulceration.
- ▶ **Targets:** symptom control alone is insufficient; aim for **steroid-free remission**, mucosal healing, normalization of CRP/fecal calprotectin, restored nutrition, preserved quality of life, and prevention of dysplasia.

General and supportive measures

- ▶ Explain the chronic relapsing course, adherence, drug adverse effects, need for surveillance, and early reporting of fever, increasing bleeding, distension, or severe pain.
- ▶ Avoid precipitating or worsening factors during acute attacks: NSAIDs, opioids, anticholinergics, unnecessary antidiarrheals in severe colitis, dehydration, hypokalemia, and delayed surgical review.
- ▶ Treat anemia, iron deficiency, hypoalbuminemia, fluid and electrolyte depletion, malnutrition, osteoporosis risk, anxiety/depression, and extraintestinal manifestations.
- ▶ Before immunosuppression or biologics: screen for **latent TB** and **hepatitis B**, update inactivated vaccines including influenza, pneumococcal and recombinant zoster vaccine where indicated, and avoid live vaccines once immunosuppressed.
- ▶ Antibiotics have **no routine role** in active or quiescent uncomplicated UC; use them for documented infection, perioperative indications, or pouchitis.
- ▶ All hospitalized severe UC patients require **VTE prophylaxis**, because active IBD is prothrombotic even when rectal bleeding is present.

Induction therapy by extent and severity

Clinical setting	Preferred induction	Escalation / notes
Mild proctitis	Mesalamine suppository 1 g nightly for 4-8 weeks	If inadequate, add oral 5-ASA or topical steroid.
Mild proctosigmoiditis / left-sided UC	Mesalamine enema 4 g nightly; suppository treats only distal 15-20 cm	Topical 5-ASA is superior to topical steroid; oral + rectal 5-ASA is better than either alone.
Mild-moderate extensive UC	Oral mesalamine 2-4.8 g/day plus rectal mesalamine	Most improve in 4-8 weeks; sulfasalazine 3-6 g/day works but intolerance is common; give folate with sulfasalazine.
5-ASA inadequate after 4-8 weeks	Budesonide MMX 9 mg/day for 8 weeks or oral prednisone	Budesonide has lower systemic exposure; no role for budesonide or prednisone as maintenance.
Moderate nonhospitalized UC	Prednisone 40 mg/day (or 40-60 mg/day equivalent)	Taper after response, usually 5 mg/week, slower below 20 mg if needed.

- ▶ Monitor 5-ASA toxicity with renal function and urinalysis periodically; recognize paradoxical 5-ASA worsening, pancreatitis, nephritis, headache, nausea, and rash.
- ▶ Requiring repeated corticosteroids, inability to taper, severe endoscopic ulceration, low albumin, anemia, or high CRP indicates high-risk disease and should prompt steroid-sparing therapy.

Moderate-to-severe steroid-sparing therapy

- ▶ **Thiopurines:** azathioprine 2-3 mg/kg/day or 6-mercaptopurine 1-1.5 mg/kg/day are slow-onset agents used mainly for maintenance or with anti-TNF therapy. Check TPMT activity if available; monitor CBC and liver tests. Pancreatitis, myelosuppression, hepatotoxicity, infection, lymphoma, HPV-related cervical dysplasia, and nonmelanoma skin cancer are key risks.
- ▶ **Anti-TNF agents:** infliximab 5 mg/kg IV at 0, 2, 6 weeks then every 8 weeks is useful for moderate-severe UC and rescue in acute severe UC; adalimumab and golimumab are subcutaneous alternatives for moderate disease. Combination infliximab + azathioprine improves steroid-free remission and reduces antidrug antibodies in selected patients.
- ▶ **Vedolizumab:** 300 mg IV at 0, 2, 6 weeks then every 8 weeks; gut-selective anti- $\alpha_4\beta_7$ therapy, useful first-line in moderate-severe UC, especially in older patients or those at higher infection risk.
- ▶ **Anti-IL therapy:** ustekinumab weight-based IV induction then 90 mg SC every 8 weeks; IL-23 agents such as mirikizumab, risankizumab, and guselkumab are options after biologic failure or when safety profile is favored.
- ▶ **JAK inhibitors:** tofacitinib 10 mg twice daily induction, then 5 mg twice daily; upadacitinib 45 mg daily for 8 weeks, then 15 or 30 mg daily. Reserve especially after TNF-blocker failure; avoid

in high cardiovascular/thrombosis risk when possible, vaccinate against zoster, and monitor CBC, lipids, liver tests, and infections.

- ▶ **S1P receptor modulators:** ozanimod is titrated **0.23 mg days 1-4, 0.46 mg days 5-7, then 0.92 mg daily**; etrasimod **2 mg daily**. Check ECG/cardiac risk, CBC and liver tests; watch for bradycardia, AV block, hypertension, macular edema, lymphopenia, and herpes reactivation.
- ▶ For anti-TNF loss of response, measure trough and antidrug antibodies: low trough without antibodies needs dose escalation/shorter interval; high antibodies need switch; active disease with therapeutic trough needs another class.

Acute severe UC, fulminant colitis and toxic megacolon

- ▶ **Admit immediately** if ≥ 6 bloody stools/day with systemic toxicity, severe anemia, hypoalbuminemia, fever, tachycardia, weight loss, dehydration, or abdominal tenderness.
- ▶ Initial care: bowel rest for 24-48 hours if very ill, IV fluids, correction of potassium/magnesium, transfusion for significant anemia, stool pathogen testing, CMV assessment if refractory, abdominal radiograph/CT for dilatation, daily labs, strict stool chart, stop opioids/anticholinergics, VTE prophylaxis, and early colorectal surgical consultation.
- ▶ **IV corticosteroid:** methylprednisolone **40-60 mg/day** or hydrocortisone **300 mg/day**. Clinical improvement should be evident within **3 days**.
- ▶ Non-response predictors include **>8 stools/day** or **3-8 stools/day with CRP >45 mg/L** after IV steroids; do not continue ineffective steroids.
- ▶ **Rescue therapy:** infliximab **5-10 mg/kg IV** or cyclosporine **2-4 mg/kg/day IV**. Cyclosporine requires renal, BP, electrolyte, magnesium/cholesterol and drug-level monitoring; give Pneumocystis prophylaxis when using combined intense immunosuppression.
- ▶ **Toxic megacolon:** colonic dilatation **>6 cm** with systemic toxicity; manage with intensive monitoring, serial abdominal films, correction of electrolytes, decompression measures, antibiotics if sepsis/perforation is suspected, and urgent surgery if worsening or no improvement in **48-72 hours**.
- ▶ Colectomy is mandatory for perforation, uncontrolled hemorrhage, peritonitis, progressive distension, hemodynamic instability, carcinoma, or failed steroid/rescue therapy.

Maintenance, monitoring and cancer prevention

- ▶ Continue the drug that achieved remission: oral mesalamine usually **2-4 g/day**; topical mesalamine may be nightly to every 3 days for distal disease. Maintenance 5-ASA reduces relapse substantially; topical steroids are ineffective for maintenance.
- ▶ **Never use corticosteroids for maintenance.** Steroid-dependence, steroid-refractoriness, or >1 steroid course every 1-2 years requires thiopurine, biologic, or small-molecule therapy.

- ▶ Follow remission with stool frequency/bleeding, Hb, albumin, CRP, fecal calprotectin, and proctoscopy/endoscopy when relapse or treatment target assessment is needed. CRP >5 mg/L or fecal calprotectin >150 mcg/g during relapse suggests active inflammation.
- ▶ Cancer surveillance is required for UC proximal to the rectum: begin colonoscopy **8 years after diagnosis**, then every **1-5 years** according to extent, activity, scarring, pseudopolyps, dysplasia, PSC, and family history. Use high-definition colonoscopy with chromoendoscopy or electronic enhancement when available.
- ▶ Endoscopically resectable visible dysplasia can be removed with close surveillance; invisible high-grade dysplasia, multifocal low-grade dysplasia, unresectable lesions, carcinoma, or suspicious strictures generally require colectomy.

Surgery and pouch care

- ▶ Indications include **intractable disease**, fulminant colitis, toxic megacolon, perforation, massive hemorrhage, obstruction/stricture suspicious for cancer, dysplasia/carcinoma, recurrent unmanageable systemic complications, growth failure, and intolerable drug toxicity.
- ▶ Emergency setting: subtotal colectomy with end ileostomy and rectal stump/mucus fistula is safest and allows later reconstruction.
- ▶ Elective operation of choice for most fit patients is **restorative proctocolectomy with ileal pouch-anal anastomosis (IPAA)**; expected function is about 5-10 stools/day, with possible nocturnal seepage early.
- ▶ Total proctocolectomy cures colitis and removes colorectal cancer risk, but pouch patients still need assessment of retained cuff/pouch symptoms.
- ▶ **Pouchitis** presents with increased stool frequency, watery stool, urgency, cramping, nocturnal leakage, fever/malaise/arthritis, or bleeding; confirm endoscopically and treat usually with ciprofloxacin or metronidazole. Chronic refractory pouchitis may need rotating antibiotics, budesonide/mesalamine, biologics, or pouch revision/removal.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Extent-severity-treatment flowchart:** E1 proctitis, E2 left-sided colitis, E3 extensive colitis; mild/moderate/severe; arrows to rectal 5-ASA, oral + rectal 5-ASA, steroids, biologic/small molecule, IV steroid, infliximab/cyclosporine, colectomy.
- ▶ **Toxic megacolon algorithm:** severe UC → abdominal X-ray showing transverse colon >6 cm → stop opioids/anticholinergics, fluids/electrolytes, IV steroids, serial films, rescue therapy, surgery at 48-72 hours or earlier for perforation/peritonitis.

Clinical / Diagnostic significance

- ▶ UC is a diagnosis of exclusion during first presentation and relapse; missing *C. difficile*, CMV, ischemic colitis, STI proctitis, amebiasis, or Crohn colitis leads to dangerous steroid escalation.

- ▶ Severe UC is a medical-surgical emergency: early surgical consultation is good practice, not treatment failure.
- ▶ Extraintestinal disease may determine drug choice: peripheral arthritis, erythema nodosum and pyoderma often parallel colitis; axial spondyloarthritis may need anti-TNF therapy; PSC increases colorectal cancer risk and needs close surveillance.
- ▶ Pregnancy planning: aim remission for 3-6 months before conception; 5-ASA, many biologics and corticosteroids when indicated are generally usable, whereas methotrexate is teratogenic and JAK inhibitors should be avoided.

High-yield exam pointers

- ▶ Write the **three treatment objectives**: stop attack, achieve clinical/endoscopic remission, prevent relapse.
- ▶ Always classify by **extent + severity** before treatment.
- ▶ **Topical mesalamine is first-line and superior to topical steroid** for distal mild-moderate UC.
- ▶ **Oral + rectal mesalamine** is better than either alone for left-sided or extensive mild-moderate UC.
- ▶ **Steroids induce but never maintain remission.**
- ▶ Acute severe UC: reassess after **3 days** of IV steroids; rescue with **infliximab or cyclosporine**, or operate.
- ▶ Toxic megacolon is **colon >6 cm + toxicity**; no improvement by **48-72 hours** means colectomy.
- ▶ Screen for **TB, hepatitis B, vaccination status, zoster risk, skin cancer, CBC/LFT/renal toxicity** before and during immunosuppressive therapy.
- ▶ Surveillance colonoscopy starts **8 years** after diagnosis for colitis beyond rectum.

Non-Alcoholic Fatty Liver Disease (NAFLD / MASLD)

Asked in: Paper II Sep 2025 · Paper II Nov 2021 (2×) — RGUHS MD General Medicine

Definition / Introduction — Non-alcoholic fatty liver disease (NAFLD) is excess macrovesicular triglyceride accumulation in **>5% of hepatocytes** in a person who drinks little to no alcohol and has no competing cause of steatosis. It is regarded as the **hepatic manifestation of the metabolic syndrome** and is now the commonest cause of chronic liver disease worldwide. In 2023 a multi-society consensus replaced the stigmatising terms NAFLD/NASH with **MASLD** (metabolic dysfunction-associated

steatotic liver disease) and **MASH** (steatohepatitis) under the umbrella of *steatotic liver disease (SLD)* — with **≥98% population overlap** between the old and new definitions. It spans a dynamic spectrum from benign **simple steatosis (MASL)** → **steatohepatitis (MASH)** → **fibrosis** → **cirrhosis / hepatocellular carcinoma (HCC)**.

Nomenclature & Diagnostic Criteria

- ▶ **Steatotic liver disease (SLD)** is the new umbrella term for excess hepatic fat; its two main causes are alcohol-associated and metabolic.
- ▶ **MASLD** = hepatic steatosis + drinks little alcohol + **≥1 cardiometabolic risk factor** (overweight/obesity, hypertension, dyslipidaemia, insulin resistance/T2DM — i.e. ≥1 of the 5 metabolic-syndrome criteria).
- ▶ A new intermediate category **MetALD** captures metabolic-risk patients who also drink “social” amounts of alcohol; higher intake regardless of metabolic factors is **ALD** (alcohol-associated liver disease).

Category	Alcohol intake (women / men)	Metabolic risk factor
MASLD	<20 g/d / <30 g/d	≥1 present
MetALD	20–50 g/d / 30–60 g/d	present
ALD	≥50 g/d / ≥60 g/d	irrelevant to definition

- ▶ Reference: 10 g alcohol ≈ one can beer / 4 oz wine / 1.5 oz (one shot) spirits. A diagnosis of MASLD still requires **exclusion** of other causes of steatosis (Table below).

Epidemiology & Risk Factors

- ▶ **Prevalence:** ~25–30% of US adults (global ~30%); **MASH in 3–6%**. Highest in **Hispanics and Asian-Indians (~50%)**, intermediate in whites (~30%), lowest in African-Americans (~25%). Highest regional prevalence: Latin America (44%), MENA (36.5%), South Asia (33.8%).
- ▶ **Lean MASLD** (BMI <25, or <23 in Asians) occurs in 4% (US) to 19% (Asia) — driven by visceral adiposity, insulin resistance and sarcopenia despite normal BMI.
- ▶ **Type 2 diabetes mellitus is the strongest risk factor** for acquisition, fibrosis progression and HCC; the MASLD–T2DM relationship is **bidirectional** (MASLD raises incident T2DM 2–5 fold). Screen every diabetic for MASLD and every MASLD patient for T2DM.
- ▶ Other associations: central (android) obesity, dyslipidaemia, hypertension, **PCOS**, hypothyroidism, hypogonadism, GH deficiency, **obstructive sleep apnoea (OSA)** and cardiovascular disease (CVD).
- ▶ **Genetics:** **PNPLA3 I148M** (adiponutrin, rs738409) — the strongest variant, increases steatosis, MASH and fibrosis; **TM6SF2** and **MBOAT7** also raise risk; **HSD17B13** loss-of-function is

protective. First-degree relatives of MASH-cirrhosis probands carry a **12-fold** higher risk of advanced fibrosis; twin studies attribute ~half of cirrhosis risk to heritability.

Pathogenesis (Multiple-Hit Model)

- ▶ The old “two-hit hypothesis” (Day & James) is now a **multiple-parallel-hit** model: *first hit* = hepatic steatosis from insulin resistance; *subsequent hits* = lipotoxic, oxidative and inflammatory insults causing hepatocyte injury and fibrosis.
- ▶ **Steatosis** results when free fatty acid (FFA) supply exceeds disposal — from (1) dietary fat uptake, (2) adipose lipolysis (driven by peripheral **insulin resistance**), and (3) hepatic **de novo lipogenesis (DNL)**. Dietary fructose is delivered directly via the portal vein and activates ChREBP/SREBP-1 to drive DNL. Triglyceride storage *per se* is a relatively safe, benign biomarker of metabolic dysfunction.
- ▶ **Steatohepatitis** is defined by **lipotoxicity** — toxic lipid intermediates (palmitate, cholesterol, lysophosphatidylcholine, ceramides) cause ER and oxidative stress, hepatocyte apoptosis/ballooning and **hepatic stellate-cell activation** → fibrosis.
- ▶ **Adipokine imbalance**: ↑leptin, TNF- α , IL-6, resistin, PAI-1 with ↓**adiponectin**. Obesity-related **gut dysbiosis** increases intestinal permeability and energy harvest, exposing the liver to inflammatory gut-derived products. Cirrhosis is the result of **futile/maladaptive repair** replacing parenchyma with scar.

Histopathology, Staging & Natural History

- ▶ **Macrovesicular steatosis in >5% hepatocytes** is the minimum. MASH additionally requires **hepatocyte ballooning + lobular (mixed) inflammation**; *Mallory-Denk bodies*, glycogenated nuclei, megamitochondria and lipogranulomas may be seen.
- ▶ Fibrosis is characteristically **perisinusoidal/pericellular “chicken-wire” fibrosis in acinar zone 3**, later becoming portal and bridging.
- ▶ **NAFLD Activity Score (NAS, NASH-CRN/Brunt)**: unweighted sum of steatosis (0–3) + lobular inflammation (0–3) + ballooning (0–2) = 0–8; ≤ 2 “not-NASH”, ≥ 5 “likely NASH”. Fibrosis is **staged separately F0–F4** (F0 none → F1 mild → F2 significant → F3 advanced/bridging → F4 cirrhosis).

Fibrosis stage	Description	Fibrosis progression rate
Simple steatosis (MASL)	fat only, no injury	~1 stage / 14 years
MASH (steatohepatitis)	ballooning + inflammation	~1 stage / 7 years
“At-risk MASH”	MASH + fibrosis $\geq$ F2	high-risk; warrants therapy
F4 cirrhosis	bridging + nodules	decompensation 3–20%/yr; HCC 1–2%/yr

- ▶ **Fibrosis stage is the single strongest predictor of liver-related morbidity and mortality.** Most patients are asymptomatic until cirrhosis; the leading overall cause of death is **cardiovascular disease**, not liver disease.

Diagnosis & Non-Invasive Staging

- ▶ Usually an **incidental finding** — raised ALT or steatosis on imaging. Exclude alternatives: alcohol, hepatitis C (esp. genotype 3), autoimmune hepatitis, Wilson disease, haemochromatosis, α 1-antitrypsin deficiency, drugs (amiodarone, methotrexate, tamoxifen, valproate, glucocorticoids, NRTIs).
- ▶ **Biochemistry:** mild aminotransferase rise; **ALT/AST ratio is usually >1 in MASLD** (reverses to <1 with advanced fibrosis — contrast with the AST>ALT of alcohol). *Normal ALT does not exclude MASLD* (up to 80% have normal enzymes). ANA/SMA and ferritin may each be mildly raised in ~30%.
- ▶ **Two-step non-invasive testing (NITs):**
 - **Step 1 – FIB-4 index** (age, AST, ALT, platelet count): <1.3 → low risk, manage/recheck in primary care; ≥ 2.67 → high risk, refer.
 - **Step 2 – VCTE (transient elastography) liver stiffness:** <8 kPa rules out advanced fibrosis; 8–12 kPa = possible fibrotic MASH; >12 kPa = high likelihood advanced fibrosis. **ELF panel** (hyaluronic acid + TIMP-1 + PIIINP; FDA-approved, ≥ 9.8 = high progression risk) is an alternative blood-based test.
 - Other scores/tools: NAFLD Fibrosis Score, **CAP** (steatosis quantitation with VCTE), **MRI-PDFF** (most accurate fat quantitation) and **MRE** (most accurate fibrosis tool).
- ▶ **Liver biopsy** (gold standard, NAS + fibrosis stage) is now reserved for diagnostic uncertainty, discordant/indeterminate NITs, or suspected competing diagnosis — limited by sampling error and inter-observer variability.

Treatment

- ▶ **Lifestyle modification is foundational for all patients:** graded weight loss — 5% reduces steatosis, 7–10% reduces inflammation/MASH, >10% can regress fibrosis. **Mediterranean diet**, avoid saturated fat / refined carbohydrate / sugar-sweetened (fructose) beverages; ≥ 150 min/week moderate exercise (aerobic and resistance both effective); **coffee ≥ 3 cups/day** lowers fibrosis/HCC risk; abstain from alcohol.
- ▶ **Pharmacotherapy** is reserved for at-risk MASH ($\geq F2$) without cirrhosis — *not* for simple steatosis:

Agent	Class / mechanism	Evidence
Resmetirom	Selective THR- β agonist	FDA accelerated approval (2024) for non-cirrhotic at-risk MASH; MAESTRO-NASH — NASH

Agent	Class / mechanism	Evidence
		resolution 26–30% vs 10%, fibrosis improvement 24–26% vs 14%
Pioglitazone (30 mg/d)	TZD, PPAR- γ ligand	PIVENS — NASH resolution 47% vs 21%; weight gain, fracture, bladder-cancer/CHF caution
Vitamin E (RRR- α -tocopherol 800 IU/d)	Antioxidant	PIVENS — histologic improvement 43% vs 19% (non-diabetics); caution: haemorrhagic stroke, ?prostate cancer
GLP-1 RA (semaglutide, liraglutide); tirzepatide (GLP-1/GIP)	Incretin mimetics	NASH resolution (semaglutide 0.4 mg 59% vs 17%); weight loss, CV benefit; fibrosis benefit not yet proven
SGLT-2 inhibitors	Glycosuric	↓ALT and steatosis; histologic benefit unproven
Statins	—	Safe in MASLD/compensated cirrhosis; treat dyslipidaemia, lower portal pressure, ?↓HCC

- ▶ **Not recommended / no benefit:** metformin (no histologic benefit – TONIC study; may ↓HCC risk), ursodeoxycholic acid, betaine, silymarin.
- ▶ **Bariatric surgery** for BMI ≥ 40 , or ≥ 35 with comorbidity — resolves MASH and improves fibrosis in ~80% at 1 year; avoid in decompensated cirrhosis.
- ▶ **Liver transplantation** for decompensated MASH cirrhosis/HCC; MASLD is now a leading transplant indication and **may recur** in the graft.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Spectrum/natural-history flow diagram:** Normal liver $\rightarrow$ Simple steatosis (MASL) $\rightarrow$ Steatohepatitis (MASH: ballooning + inflammation) $\rightarrow$ Fibrosis (F1 $\rightarrow$ F2 $\rightarrow$ F3 bridging) $\rightarrow$ Cirrhosis (F4) $\rightarrow$ HCC. Label progression rates (1 stage/14 yr for steatosis, 1 stage/7 yr for MASH) and mark “at-risk MASH = MASH + $\geq$ F2”.
- ▶ **Two-step risk-stratification algorithm:** Box 1 FIB-4 (<1.3 low / ≥ 2.67 high) $\rightarrow$ Box 2 VCTE (<8 / 8–12 / >12 kPa) or ELF $\rightarrow$ “refer to hepatology / consider biopsy”. Label axes “Primary care $\rightarrow$ Specialist”.

Clinical / Diagnostic significance

- ▶ **CVD is the leading cause of death** in MASLD — aggressive cardiovascular risk reduction (statins, BP, glycaemic control) is central, not optional.
- ▶ MASLD is an independent risk factor for **incident T2DM, CKD, colorectal cancer and metabolic syndrome**; it can cause **HCC even without cirrhosis**, complicating surveillance.
- ▶ Once **cirrhosis** is diagnosed: 6-monthly **HCC surveillance** (USS ± AFP), endoscopic **variceal screening per Baveno**, and monitoring for decompensation.
- ▶ A large share of “**cryptogenic cirrhosis**” is burnt-out MASH (steatosis disappears as fibrosis advances).
- ▶ Targeted (not universal) screening of high-risk groups — T2DM, obesity-with-metabolic-complications, family history of cirrhosis — using FIB-4 is cost-effective.

High-yield exam pointers

- ▶ **New nomenclature (2023): SLD umbrella** → MASLD / MetALD / MASH; ~98% overlap with old NAFLD/NASH.
- ▶ MASLD = steatosis + ≥1 **cardiometabolic risk factor** + alcohol <20 g/d (F) / <30 g/d (M).
- ▶ >5% **steatotic hepatocytes** = minimum; MASH = **ballooning + lobular inflammation**; “chicken-wire” zone-3 fibrosis.
- ▶ T2DM = **strongest risk factor**; PNPLA3 I148M = key gene; HSD17B13 protective.
- ▶ Fibrosis stage = **best prognostic marker**; CVD = **commonest cause of death**.
- ▶ NAS 0–8 (steatosis+inflammation+ballooning); fibrosis staged separately F0–F4.
- ▶ FIB-4 then VCTE/ELF is the non-invasive pathway; FIB-4 <1.3 excludes advanced fibrosis.
- ▶ **Weight loss 5/7/10%** = steatosis/MASH/fibrosis benefit; **resmetirom** (THR-β agonist) = first FDA-approved drug (2024); pioglitazone & vitamin E from PIVENS.

Portocaval anastomosis and management of portal hypertension

Asked in: Paper I Nov 2022 — RGUHS MD General Medicine

Definition / Introduction — **Portal hypertension** is defined as elevation of the **hepatic venous pressure gradient (HVPG)** to **>5 mmHg**. The portal venous system normally drains blood from the stomach, small and large intestines, spleen, pancreas, and gallbladder into the liver. When portal pressure rises, blood is diverted through **portosystemic (portocaval) collateral channels** — pre-existing communications between the portal and systemic venous systems that dilate to decompress the hypertensive portal bed; these collaterals are the anatomical basis of **varices, caput medusae and shunt-related complications**. The three primary clinical consequences are **gastroesophageal varices with haemorrhage, ascites, and splenomegaly with hypersplenism**.

Sites of portosystemic (portocaval) anastomosis

- ▶ **Lower oesophagus / gastro-oesophageal junction** — left gastric (coronary) and short gastric veins (portal) anastomose with the azygos/hemiazygos system (systemic) → **oesophageal and gastric varices** (the most dangerous, cause variceal haemorrhage).
- ▶ **Anorectal junction** — superior rectal vein (portal, via inferior mesenteric vein) anastomoses with middle and inferior rectal veins (systemic) → **anorectal varices** (distinct from haemorrhoids).
- ▶ **Periumbilical / anterior abdominal wall** — recanalised paraumbilical vein (via left branch of portal vein) anastomoses with superficial epigastric veins → **caput medusae**; a venous hum over it = *Cruveilhier–Baumgarten murmur*.
- ▶ **Retroperitoneal / bare areas** — veins of *Retzius* and *Sappey* between gut/liver and retroperitoneal systemic veins.
- ▶ **Spontaneous splenorenal shunt** — splenic vein to left renal vein; relevant to gastric varices and amenable to BRTO.

Classification of portal hypertension (Harrison Table 355-3)

Anatomical level	Site relative to sinusoid	Representative causes
Prehepatic	—	Portal vein thrombosis; splenic vein thrombosis; massive splenomegaly (<i>Banti's syndrome</i>)
Intrahepatic — presinusoidal	Before sinusoid	Schistosomiasis; congenital hepatic fibrosis
Intrahepatic — sinusoidal	At sinusoid	Cirrhosis (many causes) ; alcoholic hepatitis
Intrahepatic — postsinusoidal	After sinusoid	Hepatic sinusoidal obstruction (veno-occlusive syndrome)

Anatomical level	Site relative to sinusoid	Representative causes
Posthepatic	Hepatic veins → heart	Budd-Chiari syndrome; IVC webs; restrictive cardiomyopathy; constrictive pericarditis; severe congestive heart failure

- ▶ Intrahepatic causes account for >95% of cases, and cirrhosis is overwhelmingly the most common cause of portal hypertension.

Pathophysiology and haemodynamic staging

- ▶ Portal hypertension results from **two simultaneous processes**: (1) **increased intrahepatic resistance** to blood flow (cirrhosis, regenerative nodules, microthrombi), and (2) **increased splanchnic blood flow** from splanchnic vasodilation (mediated by nitric oxide and other vasodilators).
- ▶ In advanced disease, **neurohumoral activation** (renin-angiotensin-aldosterone and sympathetic systems) causes sodium/water retention, expanded blood volume, and a **hyperdynamic circulation** that further raises portal pressure.
- ▶ **Compensated cirrhosis**: HVPg 5–10 mmHg — may be asymptomatic for ≥10 years.
- ▶ **Clinically significant portal hypertension (CSPH)**: HVPg ≥10 mmHg — substantial risk of decompensation (variceal bleed, ascites, encephalopathy).
- ▶ **Variceal haemorrhage risk**: HVPg / gradient >12 mmHg. After decompensation, median survival is <2 years.

Clinical features and diagnosis

- ▶ **Three primary complications**: gastroesophageal varices ± haemorrhage; ascites with peripheral oedema; congestive splenomegaly with **hypersplenism** (thrombocytopenia, leukopenia) — often the *first* indication of portal hypertension.
- ▶ **Variceal haemorrhage** carries a 20–30% mortality per bleeding episode; ~5–15% of cirrhotics develop varices per year, and ~one-third of those with varices will bleed.
- ▶ **Predictors of bleeding**: severity of cirrhosis (Child-Pugh class, MELD score), height of wedged-hepatic-vein pressure, varix size and location, tense ascites, and endoscopic stigmata — *red wale signs, hematocystic spots, diffuse erythema, bluish colour, cherry-red spots, white-nipple spots*.
- ▶ **Diagnosis**: suggested by thrombocytopenia, splenomegaly, ascites, encephalopathy or varices. Endoscopy identifies varices; contrast CT/MRI shows nodular liver and intra-abdominal collateral circulation; HVPg can rarely be measured by interventional radiology.
- ▶ **Ascites work-up**: diagnostic paracentesis with SAAG — a SAAG >1.1 g/dL indicates portal hypertension as the cause; ascitic neutrophils >250/μL indicate spontaneous bacterial peritonitis.

Management of variceal haemorrhage

A. Primary prophylaxis (no prior bleed)

- ▶ Surveillance **endoscopy** at diagnosis of compensated cirrhosis, then every 2 years if liver disease is active or every 3 years if inactive; screening can be omitted if no thrombocytopenia and transient elastography liver stiffness <20 kPa.
- ▶ High-risk varices = medium/large varices, or small varices with high-risk stigmata or decompensated cirrhosis.
- ▶ **Nonselective beta-blockers (NSBB)** — propranolol or nadolol titrated to **heart rate 55–60 beats/min** with systolic BP >90 mmHg. **Carvedilol** is the NSBB of choice (added anti- α 1 vasodilation lowers portal pressure more, needs no HR goal, may prevent decompensation and improve survival in CSPH).
- ▶ **Endoscopic variceal ligation (EVL)** has equivalent efficacy to NSBB for primary prophylaxis; once prophylaxis is started, surveillance endoscopy is unnecessary.

B. Acute variceal bleeding

- ▶ **Resuscitate**: fluid and red-cell replacement using a **restrictive transfusion** strategy (start at Hb <7 g/dL, goal 7–9 g/dL) — reduces rebleeding and mortality. Do **not** correct prolonged PT with FFP unless there is active coagulopathic bleeding.
- ▶ **Vasoconstrictors** — **somatostatin** or **octreotide** improve initial bleeding control, reduce transfusion needs and all-cause mortality.
- ▶ **Prophylactic antibiotics** — **ceftriaxone** before endoscopy reduces infection, rebleeding and mortality.
- ▶ **Urgent upper endoscopy** is first-line — diagnoses and controls bleeding with EVL.
- ▶ **Balloon tamponade** (*Sengstaken-Blakemore* or *Minnesota* tube) or self-expandable metal stents can stabilise the patient as a **bridge to TIPS** after endoscopic failure.

C. TIPS and shunts (portal decompression)

- ▶ **Transjugular intrahepatic portosystemic shunt (TIPS)** is created percutaneously: an expandable metal stent is advanced under angiographic guidance into the hepatic vein and through the hepatic parenchyma to form a **direct portocaval shunt** that decompresses the portal system.
- ▶ Indications: failure of/ineligibility for endoscopic therapy; gastric or proximal-stomach varices where band ligation often fails; refractory recurrent bleeding; bridge to transplant.
- ▶ **Hepatic encephalopathy** occurs in up to 20% after TIPS, especially in the elderly and those with pre-existing encephalopathy.
- ▶ Gastric varices fed by a **splenorenal shunt** can be treated with **balloon-occluded retrograde transvenous obliteration (BRTO)**, sometimes combined with TIPS.
- ▶ Monitor TIPS patency with **Doppler ultrasound** for stenosis; all TIPS candidates should undergo transplant evaluation.

D. Recurrent bleeding (Harrison Fig. 355-3)

- ▶ Endoscopic therapy + pharmacologic therapy to control bleeding, then risk-stratify by Child class: **Child A** → consider TIPS and transplant evaluation; **Child B/C** → transplant evaluation with endoscopic therapy/beta-blockers and consideration of TIPS, progressing to **liver transplantation**.

Management of other portal-hypertensive complications

- ▶ **Ascites**: dietary **sodium restriction** (2 g/day); **spironolactone** 100 mg/d ± **furosemide** 40 mg/d, escalating to spironolactone 400 mg/d and furosemide 160 mg/d. **Refractory ascites** → large-volume paracentesis (give IV **25% albumin** 6–8 g per L removed if ≥5 L) or TIPS (effective but does *not* improve survival and increases encephalopathy). Avoid NSAIDs and aminoglycosides; use ACEi/ARB cautiously.
- ▶ **Spontaneous bacterial peritonitis**: ascitic neutrophils >250/μL; commonest organism *E. coli*; treat with IV **third-generation cephalosporin** × 5 days plus **albumin** (1.5 g/kg day 1, 1.0 g/kg day 3) to prevent renal failure; **quinolone prophylaxis** after an episode and at presentation with GI bleeding.
- ▶ **Hepatorenal syndrome**: stop diuretics, give albumin 1 g/kg/d; treat with **terlipressin** (or low-dose norepinephrine); midodrine + octreotide + albumin are third-line; **liver transplantation** is definitive.
- ▶ **Hepatic encephalopathy**: treat precipitants; **lactulose** titrated to 2–3 soft stools/day; **rifaximin** 550 mg twice daily (has replaced neomycin/metronidazole); closure of large portosystemic shunts in refractory cases; avoid protein restriction.
- ▶ **Portal hypertensive gastropathy**: *snakeskin mosaic* mucosa; treat with NSBB + iron; refractory bleeding → TIPS.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Sites of portosystemic anastomosis** — outline the portal vein with collaterals labelled: *Oesophageal varices* (left gastric/corony → azygos), *Anorectal varices* (superior ↔ middle/inferior rectal), *Caput medusae* (paraumbilical ↔ epigastric), *Retroperitoneal veins of Retzius*, *Splenorenal shunt* (splenic ↔ left renal vein).
- ▶ **TIPS schematic** — label: *Jugular vein* → IVC → *Hepatic vein*, *Expandable metal stent* through hepatic parenchyma, *Portal vein*, *Direct portocaval shunt*.

Clinical / Diagnostic significance

- ▶ HVPG is the gold-standard measure of portal pressure and stratifies risk: >5 = portal hypertension, ≥10 = CSPH/decompensation risk, >12 = variceal bleeding risk.
- ▶ SAAG >1.1 g/dL confirms portal hypertension as the cause of ascites; ascitic protein <1.5 g/dL flags increased SBP risk.

- ▶ Endoscopic surveillance and NSBB/carvedilol or EVL prevent first bleeds; vasoconstrictor + antibiotic + endoscopic therapy is the acute bleeding bundle.
- ▶ TIPS is the key non-surgical portal decompression but precipitates encephalopathy; liver transplantation is the definitive treatment for decompensated portal hypertension.

High-yield exam pointers

- ▶ Portal hypertension = HVPG >5 mmHg; variceal bleeding risk at >12 mmHg; CSPH = ≥ 10 mmHg.
- ▶ Cirrhosis (sinusoidal, intrahepatic) >95% of cases; classify pre-/intra-/post-hepatic.
- ▶ Three complications: varices, ascites, hypersplenism; variceal bleed mortality 20–30%/episode.
- ▶ Acute bleed bundle: restrictive transfusion (Hb 7–9), octreotide/somatostatin, ceftriaxone, urgent EVL.
- ▶ Carvedilol is now the NSBB of choice for primary prophylaxis of variceal bleeding.
- ▶ TIPS = direct portocaval shunt; complication = encephalopathy in up to 20%; bridge to transplant.
- ▶ Sengstaken-Blakemore / Minnesota tube = balloon tamponade rescue; BRTO for splenorenal-shunt gastric varices.
- ▶ Ascites: spironolactone + furosemide, albumin after LVP ≥ 5 L; SBP = neutrophils >250/ μ L.
- ▶ HE: lactulose + rifaximin 550 mg BD; *caput medusae* with a hum = Cruveilhier-Baumgarten sign.

SOURCE & COVERAGE

Harrison 22e — Ch 355 “Cirrhosis and Its Complications” (Tables 355-2/355-3; Figs 355-3, 355-4, 355-5). **Coverage note:** Harrison Ch 355 covers the definition, HVPG thresholds, classification, pathophysiology and full management of portal hypertension and its complications, and names gastroesophageal varices, the splenorenal shunt, intra-abdominal collateral circulation and the TIPS portocaval shunt. The detailed *named anatomical sites of portosystemic anastomosis* (caput medusae / Cruveilhier-Baumgarten, anorectal varices, periumbilical and retroperitoneal veins of Retzius/Sappey, splenorenal shunt drainage) are universally accepted standard anatomy supplied to satisfy the “portocaval anastomosis” phrasing, as this anatomical detail is thin in the provided chapter.

Serologic and virologic markers of Hepatitis “B”

Asked in: Paper II Dec 2023 — RGUHS MD General Medicine

Definition / Introduction — Hepatitis B virus (HBV) is a 42-nm, enveloped, partially double-stranded DNA hepadnavirus with an outer **hepatitis B surface antigen (HBsAg)** coat, an inner **hepatitis B core antigen (HBcAg)**, secreted **hepatitis B e antigen (HBeAg)**, and circulating HBV DNA. Serologic and virologic markers diagnose acute HBV, distinguish natural recovery from vaccination, define chronic infection beyond 6 months, assess infectivity and replication, and identify clinically important mutant or occult infection.

Virologic basis and chronology

- ▶ **HBsAg** is the envelope protein of virions and abundant noninfectious spherical/tubular particles; routine assays detect all forms. It is the **first serum marker**, detectable **1-12 weeks after exposure**, usually **8-12 weeks**, and precedes ALT rise and symptoms by **2-6 weeks**.
- ▶ **HBcAg** remains intracellular or within HBsAg-coated nucleocapsids; naked core antigen does not circulate, so **HBcAg is not a routine serum diagnostic test**. Its antibody, **anti-HBc**, is therefore more useful clinically.
- ▶ **HBeAg** is a secreted nucleocapsid protein from the precore/core gene. It appears with or shortly after HBsAg and is a **qualitative marker of replication, intact virions, high infectivity, and usually detectable HBV DNA**.
- ▶ **HBV DNA** is the direct virologic marker of replication and is more sensitive and precise than HBeAg; it is essential in chronic HBV, pregnancy transmission risk, antiviral decisions, and follow-up.
- ▶ **Anti-HBc** appears **1-2 weeks after HBsAg**. **IgM anti-HBc** predominates for the first **6 months** after acute infection; **IgG anti-HBc** persists indefinitely after either recovery or chronicity.
- ▶ **Anti-HBs** appears after HBsAg clearance, usually weeks to months after anti-HBc, persists long-term, and is the **protective neutralizing antibody** after natural infection or vaccination.
- ▶ **Anti-HBe** appears after HBeAg loss and usually indicates lower replication and reduced infectivity, but it does not exclude HBeAg-negative chronic hepatitis due to precore or basal core promoter mutants.

Individual markers and interpretation

Marker	What it detects	High-yield interpretation
HBsAg	Surface/envelope antigen in virions and subviral particles	Current HBV infection; persistence >6 months = chronic HBV. In self-limited acute HBV it disappears 1-2 months after jaundice and rarely persists beyond 6 months.
Anti-HBs	Antibody to HBsAg	Recovery, noninfectivity, and immunity when it follows natural infection; isolated anti-HBs

Marker	What it detects	High-yield interpretation
		indicates vaccination. Protective vaccine response is commonly taken as ≥ 10 mIU/mL.
Total anti-HBc	IgM + IgG antibody to core antigen	Marker of natural exposure; not produced by vaccination . Persists after recovery and in chronic HBV.
IgM anti-HBc	Recent anti-core response	Best marker of acute/recent HBV; sole marker in the window period ; may reappear during severe flares/reactivation of chronic HBV.
IgG anti-HBc	Remote or chronic anti-core response	Past natural infection or chronic HBV; predominates beyond 6 months.
HBeAg	Secreted e antigen	High replication and infectivity; persistence >3 months after acute HBV suggests higher likelihood of chronic infection.
Anti-HBe	Antibody to e antigen	Seroconversion marker, usually lower infectivity; can coexist with active HBV DNA replication in precore/core promoter mutant disease.
HBV DNA by PCR	Viral nucleic acid	Quantitative replication marker; correlates with infectivity, liver injury, progression, cirrhosis, HCC risk, and treatment response.
Quantitative HBsAg	Serum HBsAg level	Specialist follow-up marker; serial use may help distinguish inactive carrier state from HBeAg-negative active disease.

Acute hepatitis B: serologic sequence

- ▶ **Early incubation:** HBV DNA and HBsAg appear before clinical hepatitis; HBeAg follows shortly and indicates high infectivity. ALT rises later, with symptoms and jaundice.
- ▶ **Symptomatic/icteric phase:** HBsAg remains detectable; **IgM anti-HBc** is present and confirms acute HBV. HBeAg usually disappears near peak ALT before HBsAg clearance.
- ▶ **Resolution:** HBsAg becomes negative, **anti-HBe** appears first, then **anti-HBs** appears and persists. Anti-HBc switches from predominantly IgM to predominantly IgG.

- ▶ **Window period:** HBsAg has disappeared but anti-HBs is not yet detectable; **IgM anti-HBc may be the only serologic evidence** of current or recent infection. More sensitive modern HBsAg and anti-HBs assays make this less common.
- ▶ **Rare HBsAg-negative acute HBV:** in up to 1-5% of acute infections, HBsAg may be below assay detection; **IgM anti-HBc establishes the diagnosis.**
- ▶ **Progression to chronicity:** persistence of HBsAg >6 months or HBeAg >3 months after acute illness suggests chronic HBV. Immunocompetent adults usually recover; chronicity is far more common after neonatal, childhood, or immunosuppressed infection.

Common serologic patterns

HBsAg	Anti-HBs	Anti-HBc	HBeAg / anti-HBe	HBV DNA	Interpretation
-	-	-	-	-	Susceptible, no evidence of prior infection or vaccination.
-	+	-	-	-	Vaccinated immune; anti-HBs alone.
-	+	IgG +	Usually anti-HBe + or -	Usually undetectable	Recovered natural infection; immune due to past HBV.
+	-	IgM +	HBeAg often + early	+	Acute hepatitis B.
-	-	IgM +	Variable	Variable	Window period or rare HBsAg-negative acute HBV.
+ >6 months	-	IgG +	HBeAg +	High	HBeAg-positive chronic HBV/chronic hepatitis; high replication and infectivity.
+ >6 months	-	IgG +	HBeAg -, anti-HBe +	Low or undetectable, usually <2000 IU/mL	Inactive carrier / HBeAg-negative chronic HBV infection, if ALT normal and stable over serial follow-up.
+ >6 months	-	IgG +	HBeAg -, anti-HBe +	Detectable/high, often fluctuating	HBeAg-negative chronic hepatitis B from precore/core promoter mutant or

HBsAg	Anti-HBs	Anti-HBc	HBeAg / anti-HBe	HBV DNA	Interpretation
					reactivation; ALT often elevated or fluctuating.
-	-	IgG +	-	Usually negative; occasionally low-level positive	Isolated anti-HBc: remote infection with lost anti-HBs, false-positive, window period if IgM, or occult/low-level infection.
+	+	IgG +	Variable	Variable	Chronic HBV with low-affinity/nonneutralizing anti-HBs or heterotypic anti-HBs; not proof of imminent clearance.

Chronic HBV phases and virologic classification

- ▶ **HBeAg-positive chronic HBV infection (*immune-tolerant phase*):** HBeAg positive, very high HBV DNA, commonly $\geq 10^7$ IU/mL, normal or low ALT, and minimal necroinflammation/fibrosis; typical after perinatal or early-childhood infection.
- ▶ **HBeAg-positive chronic hepatitis B (*immune-active/clearance phase*):** HBeAg positive, HBV DNA high or intermediate, ALT elevated, and active necroinflammation. Harrison emphasizes that DNA is often well above 10^3 - 10^4 IU/mL and may exceed 10^9 IU/mL.
- ▶ **HBeAg-negative chronic HBV infection (*inactive carrier state*):** HBsAg positive, IgG anti-HBc positive, HBeAg negative, anti-HBe positive, normal ALT, minimal histologic activity, and HBV DNA undetectable or low, usually < 2000 IU/mL.
- ▶ **HBeAg-negative chronic hepatitis B (*reactivation phase*):** HBeAg negative but HBV DNA detectable, ALT elevated or fluctuating, and active liver injury. It is usually due to **precore stop-codon** or **basal core promoter** mutations, so absence of HBeAg does not prove inactive disease.
- ▶ **HBsAg-negative phase / functional cure:** HBsAg negative, anti-HBc positive, anti-HBs present or absent, normal ALT, and serum HBV DNA usually undetectable; intrahepatic cccDNA may persist, so reactivation remains possible under intense immunosuppression.
- ▶ The distinction between inactive carrier state and HBeAg-negative chronic hepatitis requires **serial ALT and HBV DNA monitoring over months**, because both DNA and aminotransferases may fluctuate.

Special patterns, mutants, and pitfalls

- ▶ **Precore mutation:** classically G1896A creates a stop codon and prevents HBeAg synthesis; patients have **anti-HBe with detectable HBV DNA** and may have progressive HBeAg-negative chronic hepatitis.
- ▶ **Basal core promoter mutations:** reduce HBeAg production while maintaining replication; they are associated with HBeAg-negative active disease and have been linked with more severe infection and HCC risk in specialist texts.
- ▶ **Occult HBV infection:** HBsAg negative with **detectable HBV DNA**, often low level, and sometimes without anti-HBc; important in cryptogenic liver disease, blood/organ donation, and immunosuppression.
- ▶ **Isolated anti-HBc** should not be equated automatically with active replication; common explanations are remote resolved infection with loss of anti-HBs, false positivity, window-period acute HBV if IgM, or rarely low-level occult infection.
- ▶ **HBsAg escape mutants** may alter the surface antigen “a” determinant, causing failure of commercial HBsAg detection or reduced neutralization by vaccine/HBIG-derived anti-HBs.
- ▶ **IgM anti-HBc is not always de novo acute HBV:** it may reappear in severe flares or spontaneous/reactivation episodes of chronic HBV; clinical history, old records, HBsAg duration, and serial follow-up are essential.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Acute HBV timeline:** x-axis weeks after exposure; label HBV DNA/HBeAg early, HBsAg first antigen, ALT and jaundice peak, IgM anti-HBc, IgG anti-HBc, anti-HBe, anti-HBs, and the **window period** between HBsAg loss and anti-HBs appearance.
- ▶ **Chronic HBV phase chart:** label immune-tolerant HBeAg-positive infection, immune-active HBeAg-positive hepatitis, inactive carrier HBeAg-negative infection, HBeAg-negative chronic hepatitis/reactivation, and HBsAg-negative functional cure; show ALT and HBV DNA trends.

Clinical / Diagnostic significance

- ▶ **Acute HBV diagnosis:** HBsAg plus **IgM anti-HBc** confirms acute infection; IgM anti-HBc is decisive in the window period and in rare low-HBsAg acute disease.
- ▶ **Chronic HBV diagnosis:** HBsAg persistence beyond 6 months with IgG anti-HBc establishes chronic HBV; HBeAg, anti-HBe, HBV DNA, ALT, and fibrosis assessment classify activity.
- ▶ **Infectivity and transmission:** HBeAg-positive, high-DNA serum is highly infectious; HBeAg-positive mothers transmit HBV to offspring far more often than anti-HBe-positive mothers. Maternal HBV DNA $\geq 200,000$ IU/mL supports third-trimester antiviral prophylaxis in addition to neonatal HBIG plus vaccine.

- ▶ **Treatment and prognosis:** HBV DNA is the key quantitative marker for antiviral decisions and monitoring; persistent high replication predicts cirrhosis and HCC risk. Short-term treatment endpoints include HBV DNA suppression, HBeAg loss/seroconversion, ALT normalization, and ideally HBsAg loss.
- ▶ **Screening before immunosuppression:** HBsAg and anti-HBc, often with anti-HBs, should be checked before chemotherapy, B-cell-depleting agents, transplantation, or prolonged immunosuppression because resolved or inactive HBV can reactivate.
- ▶ **Vaccination and postexposure care:** isolated anti-HBs indicates vaccine immunity; postvaccination anti-HBs testing is useful in high-risk adults, dialysis, immunosuppression, and occupational exposure decisions. HBIG provides immediate anti-HBs, while vaccine provides durable active immunity.
- ▶ **Blood and organ safety:** screening of donated blood for HBsAg and anti-HBc has markedly reduced transfusion-associated HBV; isolated anti-HBc or occult HBV can still be clinically relevant in donors and immunosuppressed recipients.

High-yield exam pointers

- ▶ HBsAg first, anti-HBs last is the simplest acute HBV chronology.
- ▶ IgM anti-HBc = acute/recent HBV and is the marker of the **window period**.
- ▶ IgG anti-HBc = natural exposure, not vaccination.
- ▶ Anti-HBs alone = vaccination; anti-HBs plus IgG anti-HBc = recovered natural infection.
- ▶ HBsAg >6 months = chronic HBV; HBeAg >3 months after acute infection predicts chronicity.
- ▶ HBeAg = replication/infectivity, but HBV DNA is the best quantitative replication marker.
- ▶ HBeAg-negative does not mean inactive; check HBV DNA and ALT for precore/core promoter mutant disease.
- ▶ **Inactive carrier:** HBsAg positive, anti-HBe positive, normal ALT, low/undetectable HBV DNA, usually <2000 IU/mL.
- ▶ **Isolated anti-HBc** needs interpretation: remote infection, false-positive, window period, or occult/low-level HBV.

Tropical Sprue

Asked in: Paper II Nov 2020 — RGUHS MD General Medicine

Definition / Introduction — Tropical sprue (TS) is a **primary, acquired malabsorption syndrome** affecting residents of, or visitors to, endemic tropical regions, characterised by chronic diarrhoea, steatorrhoea, weight loss and multiple nutrient deficiencies (classically **both folate and vitamin B12**). The term “primary” implies that all other recognised causes of malabsorption have been excluded. By the **Baker–Klipstein definition (1970)**, diagnosis requires malabsorption of **at least two unrelated nutrient groups** (e.g. fat, carbohydrate, vitamins), an abnormal small-bowel mucosal biopsy, and exclusion of celiac disease, parasitic infection, SIBO and pancreatic insufficiency. It is regarded by many as a **post-infectious complication** of acute enteritis and responds to broad-spectrum antibiotics plus folic acid.

Historical note & epidemiology

- ▶ **History:** Malabsorption in the tropics is described in the *Charaka Samhita* as “**Grahani**” (loss of “digestive fire”). First English description by **William Hillary (1759, Barbados)** as *aphthoides chronica*; the word “sprue” derives from the Dutch *sprouw* (aphthous mouth ulceration); **Manson** coined “sprue” in 1880.
- ▶ **Geography:** Endemic in **South & South-East Asia** (southern India, Pakistan), **the Philippines**, **the Caribbean** (Puerto Rico, Haiti, Cuba), **Central/South America** and **parts of tropical Africa/Australia**. **Notably rare in Africa, Jamaica and parts of South-East Asia** — distribution is patchy, suggesting different aetiologies in different regions.
- ▶ **Burden:** Occurs in **8–20%** of people after an attack of infectious gastroenteritis in India. **Adults > children** (opposite to celiac disease). **Epidemic TS** occurred in WWII soldiers/POWs and in South India in the 1960s–70s (responsible for **30,000–40,000 deaths**); epidemic disease is **no longer reported**, but **sporadic TS** remains a leading cause of adult malabsorption in South Asia. Seasonal clustering was noted in Puerto Rico (first 3 months of the year).
- ▶ **Declining incidence** over recent decades — attributed to improved sanitation and wider antibiotic use in acute diarrhoea.

Aetiopathogenesis

- ▶ The aetiology is **uncertain**; no single causative agent has ever been isolated despite extensive search. Because TS **responds to antibiotics**, an **infectious/post-infectious basis** is favoured.
- ▶ **Post-infectious trigger:** In travellers/expatriates, an antecedent gastroenteritis (enteropathogenic *E. coli*, *Giardia*, *Cyclospora*) greatly raises risk — in US military personnel, prior infectious gastroenteritis increased the odds of TS **~36.6-fold** and of intestinal malabsorption **~3.9-fold**.
- ▶ **Small-intestinal bacterial overgrowth (SIBO):** Overgrowth of **enterotoxigenic coliforms** (*Klebsiella*, *Enterobacter cloacae*, *E. coli*) in the upper small bowel. Unabsorbed luminal fat activates the “**ileal brake**” (peptide YY, neurotensin) → slowed small-bowel transit → perpetuation of SIBO.

- ▶ **Other agents:** Coronavirus-like viral particles seen in jejunal enterocytes in some series (inconsistent).
- ▶ **Mucosal injury model:** Microbial toxins damage **intestinal crypt stem cells** → immature enterocytes, villous shortening and increased permeability → mucosal inflammation with a marked rise in **intraepithelial lymphocytes (IELs)** (predominantly CD8+ $\alpha\beta$ -T cells; innate signalling via NOD-2/TLR-2, IL-15, T-bet). The difference between symptomatic TS and asymptomatic tropical enteropathy may reflect host innate immune response.

Clinical features

- ▶ **Cardinal triad:** chronic diarrhoea, **sore red tongue (glossitis)** and weight loss; stools are **pale, bulky, frothy, foul-smelling (steatorrhoea)** with abdominal distension and borborygmi; nocturia.
- ▶ **Onset:** In southern India often follows an **acute enteritis**; in expatriates/epidemics begins with fever and watery (rarely bloody) diarrhoea, then lingering diarrhoea with weight loss. Course shows **exacerbations and remissions**.
- ▶ **Deficiency signs:** pallor (iron, folate, B12 anaemia); **angular stomatitis, cheilitis, glossitis** (B-complex); **hyperpigmentation of palms, knuckles and buccal mucosa** (attributed to B12 deficiency — may be the only presenting sign); pedal oedema, leukonychia, koilonychia and hair/skin changes (hypoproteinaemia/iron).
- ▶ **Late/severe:** gross emaciation with proximal muscle weakness; **night blindness, Bitot spots, corneal xerosis** (vitamin A); tetany/carpopedal spasm (Ca/Mg); haemorrhagic diathesis (vitamin K); metabolic bone disease (vitamin D); peripheral neuropathy. *Subacute combined degeneration of the cord* (historical) and “**sprue coma**” (apathy/listlessness from magnesium depletion) are now rare. A rare **Ogilvie-like colonic pseudo-obstruction** may occur.
- ▶ **Clubbing is NOT a feature** — its presence should suggest an alternative (e.g. IPSID/lymphoma).

Histopathology & pathophysiology

- ▶ Biopsy from distal duodenum/proximal jejunum (now standard at upper GI endoscopy) shows **partial villous atrophy with crypt elongation/hyperplasia**; villi may appear fused; lamina propria infiltrated by lymphocytes/plasma cells with **markedly increased IELs** (reported mean ~77 IELs/100 enterocytes); an eosinophilic infiltrate may be seen.
- ▶ The normal **villous-to-crypt ratio of 4:1–5:1 falls to ~2:1 or 1:1**. *Complete/flat (total) villous atrophy as in celiac disease is NOT seen in TS*.
- ▶ **Whole small-bowel involvement** (ileum often more affected than duodenum) — distinguishing it from the proximal-predominant celiac disease. Changes are of **similar severity throughout** the small bowel, and a **gluten-free diet does NOT improve TS**.

- ▶ **Electron microscopy:** degenerating/dead cells in the **basal crypt region** (a feature resembling radiation/chemotherapy enteritis) — supports a **primary stem-cell lesion**; *this differs from celiac disease*.
- ▶ **Functional consequences:** ↓ absorptive surface → ↓ **D-xylose** absorption; **fat malabsorption** with secondary *functional* pancreatic insufficiency (abnormal Lundh/pancreolauryl test, but **normal secretin response**); **B12 and bile-acid malabsorption** from terminal-ileal involvement; folate/iron malabsorption from proximal involvement → **combined folate + B12 deficiency** is characteristic.

Feature	Tropical sprue	Celiac disease
Distribution in small bowel	Entire small bowel (ileum ≥ duodenum)	Proximal (duodenum/jejunum) predominant
Villous atrophy	Partial; ratio 2:1–1:1; never totally flat	May be total/flat (Marsh III)
Vitamin pattern	Folate AND B12 both low	Folate low, B12 usually normal
Serology (anti-tTG/EMA)	Negative	Positive
Response to gluten-free diet	None	Clinical & histologic improvement
Response to antibiotics + folate	Curative	No response
EM crypt change	Degenerating basal crypt (stem-cell) cells	Absent

Diagnosis

- ▶ **No single diagnostic test** — diagnosis rests on **multiple nutrient deficiencies + abnormal small-bowel biopsy + exclusion** of other causes (Baker–Klipstein).
- ▶ **Mandatory exclusions:** *Giardia* and other parasites (≥3 stool samples with modified acid-fast stains — TS should not be entertained until cysts/trophozoites excluded), **celiac disease** (negative anti-tTG/EMA serology), SIBO and chronic pancreatitis.
- ▶ **Malabsorption tests (endemic-area data):** abnormal **D-xylose** ~99%, **steatorrhoea** ~90%, **B12 malabsorption** 60–90%; a 5-g (rather than 25-g) D-xylose dose is used in the tropics to avoid vomiting/diarrhoea. Serum **folate and B12 both low**; raised methylmalonic acid confirms B12 deficiency.
- ▶ **Endoscopy:** **scalloping** of duodenal folds and **mosaic/”mosaiform”** mucosa of the terminal ileum (better seen with narrow-band/magnification imaging); jejunal aspirate culture >10⁵ organisms/mL indicates SIBO.

- ▶ **Imaging:** barium follow-through shows **thickened mucosal folds, loss of the feathery jejunal pattern, dilated atonic loops and delayed transit**; CT mainly excludes mesenteric masses/lymphadenopathy (TB, lymphoma).

Treatment

- ▶ **Specific therapy:** Tetracycline 250 mg QID (or doxycycline 100 mg OD) for 3–6 months *plus* folic acid — usually **curative**, with clinical improvement often within 1–2 weeks; leaving the endemic area improves outcome.
- ▶ **Vitamin/mineral repletion:** parenteral **vitamin B12**, oral **folic acid** (alone induces haematologic remission, weight gain and partial histologic recovery), plus vitamin A (IM if night blindness/Bitot spots), vitamin K (if prolonged PT), vitamin D and calcium.
- ▶ **Supportive:** correct dehydration and electrolytes (**K, Mg, Ca, phosphate**) — severe hypokalaemia may need ECG-monitored replacement; high-protein, **fat-restricted, lactose-free** diet with **medium-chain triglycerides** to reduce steatorrhea; guard against **refeeding syndrome** in the severely malnourished (start ~10 kcal/kg/day, escalate over 4–7 days, give thiamine).
- ▶ **Prognosis:** relapses uncommon, especially if the patient leaves the tropics; **recurrent symptoms warrant re-investigation to exclude small-bowel lymphoma**.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Comparative small-intestinal villous histology (three panels):** label (A) *Normal* — tall finger-like villi, villous:crypt ratio 4–5:1; (B) *Tropical sprue* — partial villous atrophy/blunting + fusion, **crypt elongation**, ratio 2:1–1:1, **increased intraepithelial lymphocytes**, lamina-propria lymphocytic infiltrate (ileum ≥ duodenum); (C) *Celiac disease* — flat/total villous atrophy (Marsh III). Add an inset labelling **EM: degenerating basal crypt stem cells** (TS-specific).
- ▶ **Aetiopathogenesis flow diagram:** *Acute enteric infection / bacterial toxins* → *crypt stem-cell injury* → *villous atrophy & ↑ permeability* → *mucosal inflammation (↑ IELs)* → *fat malabsorption* → *ileal brake (↑ peptide YY)* → *slow transit* → *SIBO (coliform overgrowth)* → *perpetuation of malabsorption*.

Clinical / Diagnostic significance

- ▶ Suspect TS in any patient with **chronic diarrhoea + steatorrhea + macrocytic anaemia** who lives in or has travelled to the tropics, once Giardia and celiac disease are excluded.
- ▶ The **folate + B12 deficiency** combination is a key clinical clue — distinguishes TS (whole-bowel disease) from celiac disease (proximal, folate-deficient, B12-normal).
- ▶ A **therapeutic response to tetracycline + folate** is itself supportive of the diagnosis; **failure to respond** mandates a search for lymphoma, TB or other mimics.

- ▶ Differentiate from **tropical (environmental) enteropathy** — the *asymptomatic* subclinical mucosal abnormality of tropical residents (shorter villi, ↑ permeability, abnormal lactulose:mannitol ratio) which causes no overt malabsorption and is linked to childhood stunting and reduced oral-vaccine immunogenicity.

High-yield exam pointers

- ▶ **Baker–Klipstein criteria:** malabsorption of ≥ 2 unrelated nutrients + abnormal biopsy + exclusion of other causes.
- ▶ **TS = whole small bowel; celiac = proximal.** TS: **partial** villous atrophy (never totally flat); celiac: may be **total** flat mucosa.
- ▶ **Both folate and B12 deficient** in TS (combined megaloblastic anaemia); celiac usually B12-normal.
- ▶ **No response to gluten-free diet; responds to antibiotics + folate** (tetracycline/doxycycline 3–6 months).
- ▶ **Hyperpigmentation of palms/knuckles/buccal mucosa** and **glossitis** are classic; **clubbing** is **NOT** (suggests IPSID/lymphoma).
- ▶ **EM hallmark:** degenerating cells in basal crypts (stem-cell lesion) — absent in celiac.
- ▶ **Exclude Giardia** (≥ 3 stools) before diagnosing TS; D-xylose abnormal in ~99%.
- ▶ Epidemic TS (South India 1960s, tens of thousands of deaths) now extinct; **sporadic TS persists.**
- ▶ Watch for **refeeding syndrome** and **magnesium-related “sprue coma”**; recurrence → rule out lymphoma.

SOURCE & COVERAGE

- ▶ **Harrison’s Principles of Internal Medicine, 22e** — “Disorders of Absorption” (tropical sprue, environmental enteric dysfunction).
- ▶ **Sleisenger & Fordtran’s Gastrointestinal and Liver Disease, 11e** — “Tropical Diarrhea and Malabsorption” (definition, history, epidemiology, aetiopathogenesis, clinical features, Baker–Mathan histologic grading, pathophysiology, diagnosis and treatment) — primary depth source.
- ▶ **CMDT 2026** — Gastrointestinal Disorders (malabsorption/celiac differential) and Infectious Diseases (traveller’s diarrhoea, chronic watery diarrhoea) for current management context.
- ▶ Coverage note: CMDT 2026 mentions tropical sprue only briefly (within the celiac/traveller’s-diarrhoea differential), so management specifics (tetracycline/doxycycline ± folate) are grounded chiefly in Harrison and Sleisenger.

Autoimmune Hepatitis — Clinical Features, Extra-hepatic Associations and Autoantibodies

Asked in: Paper II 08 Apr 2026 — RGUHS MD General Medicine

Definition / Introduction — Autoimmune hepatitis (AIH) is a chronic, immune-mediated inflammatory disorder characterised by continuing hepatocellular necrosis and inflammation, usually with fibrosis, that can progress to cirrhosis and liver failure. It is defined serologically by circulating **autoantibodies**, biochemically by **polyclonal hypergammaglobulinaemia** (raised IgG), and histologically by **interface hepatitis** with a plasma-cell-rich infiltrate, in the absence of viral, drug, metabolic or alcoholic causes. The prominence of *extra-hepatic autoimmune features* and seroimmunological abnormalities — reflected in the old labels “**lupoid**” and “**plasma-cell**” hepatitis — underpins its autoimmune pathogenesis. It shows a strong female predominance (~75% of cases) and a characteristic responsiveness to glucocorticoid/immunosuppressive therapy.

Epidemiology & immunopathogenesis (context)

- ▶ **Incidence** 2–4/100,000 and **prevalence** 26–31/100,000 (rising); risk increased in first-degree relatives.
- ▶ **Female predominance** ~75%; **bimodal age distribution** — one peak in early decades (age <30) and a second in middle-to-late years (often >60).
- ▶ Injury is a **cell-mediated (cytotoxic T-cell) attack** on hepatocytes following loss of immune tolerance to self-liver antigens; predisposition is inherited and the trigger is environmental (drugs e.g. **minocycline**, viruses such as hepatitis A/B/C, EBV, measles; reported after **COVID-19** and **COVID-19 vaccination**).
- ▶ **HLA associations:** HLA-B1, B8, DR3, DR4; extended haplotypes *DRB1\0301 and DRB1\0401; *polymorphisms in CTLA-4 and TNFA\2*. **Histology shows cytotoxic T cells and plasma cells;** regulatory CD4+CD25+ T-cell **dysfunction** and molecular mimicry** are implicated.

Clinical features (Ask 1)

- ▶ **Onset is variable** — insidious or abrupt; may mimic and be confused with acute viral hepatitis; in its most severe form presents as **fulminant hepatitis** with multilobular collapse and high mortality.
- ▶ **Most common symptom is fatigue** (~85%); other constitutional features — malaise, anorexia, amenorrhoea, acne, arthralgias, low-grade fever and weight loss.
- ▶ **Jaundice** is present in severe disease (which accounts for ~20–25% of cases).
- ▶ **Asymptomatic presentation** in roughly a quarter to a third (Harrison ~25%; CMDT 34%; Sleisenger 29–45%) — discovered on abnormal liver enzymes; many later become symptomatic, so treatment is still warranted.
- ▶ **The classic “lupoid” subset:** young-to-middle-aged women with marked hyperglobulinaemia, high-titre ANA and a positive **LE-cell preparation**, in whom other autoimmune features cluster.

- ▶ **Examination:** a healthy-appearing young woman with **multiple spider telangiectasias**, **cutaneous striae**, **acne**, **hirsutism** and **hepatomegaly**; exacerbations may occur **post-partum**, and depression is more frequent.
- ▶ **Decompensated/cirrhotic presentation:** ascites and oedema (portal hypertension, hypoalbuminaemia), encephalopathy, hypersplenism, coagulopathy or variceal bleeding may be the first manifestation — **cirrhosis is present in 28–33% at diagnosis** (more common in older patients and in African-American/Black patients).
- ▶ **Course:** spontaneous remissions and exacerbations; untreated severe disease (AST/ALT >10× normal, marked hyperglobulinaemia, bridging/multilobular necrosis) carries a 6-month mortality up to ~40%. Treated 10-year survival 80–98% vs 67% untreated.
- ▶ **Laboratory:** AST/ALT typically 100–1000 U/L; in acute cases may exceed 1000 U/L. Bilirubin moderately raised in severe disease; **polyclonal hypergammaglobulinaemia** >2.5 g/dL and raised IgG; alkaline phosphatase usually near-normal (marked elevation suggests overlap with PBC/PSC); prothrombin time prolonged in advanced/active disease.

Associated extra-hepatic disorders (Ask 2)

Two mechanistically distinct groups occur: (a) **concurrent organ-specific/systemic autoimmune diseases** (clustering in the patient and relatives), and (b) **immune-complex-mediated extra-hepatic manifestations** of the disease itself (arthralgias, arthritis, cutaneous vasculitis and glomerulonephritis — due to deposition of circulating immune complexes with complement activation).

System	Associated disorders (faithful to source)
Endocrine	Autoimmune (Hashimoto) thyroiditis (~12% in type 1), Graves disease (~6%), type 1 / juvenile diabetes mellitus
Gastrointestinal	Ulcerative colitis (~6%; warrants MRCP/ERCP to exclude PSC), coeliac disease, pernicious anaemia
Haematological	Coombs-positive (autoimmune) haemolytic anaemia, autoimmune (idiopathic) thrombocytopenic purpura, symptomatic cryoglobulinaemia
Rheumatological	Rheumatoid arthritis, Sjögren's syndrome / sicca (keratoconjunctivitis, xerostomia), SLE, systemic sclerosis, synovitis
Renal	Membranoproliferative glomerulonephritis, nephritis, azotaemia
Cutaneous	Vitiligo, cutaneous (leukocytoclastic) vasculitis, erythema nodosum, maculopapular eruptions
Serosal / pulmonary	Pleuritis, pericarditis, fibrosing alveolitis

- ▶ **Type 1 AIH** is the type most associated with the broad systemic list above; concurrent autoimmune disease is found in ~18% overall. Older patients (≥ 60 y) carry **thyroid and rheumatic disease** more often (42% vs 13%), whereas younger adults (≤ 30 y) more often have **UC and autoimmune haemolysis**.
- ▶ **Type 2 AIH** characteristically co-occurs with **vitiligo, type 1 diabetes mellitus and SLE**, and may be part of **autoimmune polyglandular syndrome type 1 (APS-1 / APECED)**.
- ▶ Patients presenting with **autoimmune thyroid or skin disease** should be screened for subclinical AIH.

Autoantibodies & serological classification (Ask 3)

Circulating autoantibodies are diagnostic markers (not proven pathogenic). Their pattern defines **two serological types** (same management and similar outcome):

Autoantibody	Antigenic target	Diagnostic significance
ANA (antinuclear, homogeneous)	Multiple nuclear antigens	Present in ~80% of type 1 ; hallmark with SMA; low-titre also seen in MASLD/viral hepatitis (non-specific)
ASMA / SMA (anti-smooth-muscle)	Actin (F- and G-), vimentin, skeletin	Present in ~63%; high specificity when combined with ANA; anti-F-actin is the more specific component
Anti-SLA/LP (soluble liver antigen)	tRNP(ser)sec $\rightarrow$ SEPSECS	High specificity (~99%) ; HLA- <i>*DRB1\0301</i> ; nearly always with anti-Ro/SSA ; marks severe disease, relapse, worse prognosis*; <i>may be the sole*</i> marker
Atypical pANCA	β -tubulin isotype 5	In 50–92% of type 1 , absent in type 2 ; associated with UC and PSC ; useful when conventional antibodies absent
Anti-LKM1 (liver-kidney microsome 1)	Cytochrome P450 2D6 (CYP2D6)	Hallmark of type 2 (ANA/SMA usually absent); mainly children; HLA-DRB1 $\backslash$ *07; also seen in some hepatitis C
Anti-LC1 (liver cytosol 1)	Formiminotransferase cyclodeaminase	Marks type 2 (often with anti-LKM1, ~32%); young patients; rare in North American adults

- ▶ **Type 1 (classic) AIH**: ANA and/or ASMA positive; young women; marked hyperglobulinaemia; **HLA-DR3/DR4 (especially B8-DRB1\03)*; **commonest form in North America and northern Europe**; a subset is ANA/anti-LKM1–negative but anti-SLA**–positive.

- ▶ **Type 2 AIH:** defined by **anti-LKM1** ($\pm$ anti-LC1); typically **children/adolescents**, more common in Mediterranean/European populations; linked to HLA-DRB1 and DQB1 haplotypes; tends to present acutely and progress to cirrhosis early.
- ▶ **Other LKM antibodies:** **anti-LKM2** $\rightarrow$ drug-induced (tienilic acid) hepatitis; **anti-LKM3** (anti-UDP-glucuronyltransferase) $\rightarrow$ chronic hepatitis D and some type 2 AIH.
- ▶ Additional markers: **rheumatoid factor**, anti- α -actinin, antibodies to **asialoglycoprotein receptor (hepatic lectin)**. **Anti-mitochondrial antibody (AMA)** is normally *against* the diagnosis (suggests PBC) but occurs in up to $\sim 18\%$ without evolving to PBC. **IgG4-associated AIH** (≥ 10 IgG4+ plasma cells/HPF, serum IgG4 ≥ 135 mg/dL) defines $\sim 3.3\%$ of cases.

Diagnosis (brief)

- ▶ **Liver biopsy is imperative:** **interface hepatitis** (periportal “piecemeal” necrosis) is the hallmark, with **plasma-cell infiltrate**, **hepatocyte rosettes**, **emperipolesis** and **centrilobular (zone 3) perivenulitis**; bile-duct injury and granulomas are uncommon.
- ▶ **IAIHG simplified score (4 variables):** autoantibodies (ANA/SMA $\geq 1:40 = +1$, $\geq 1:80 = +2$; anti-LKM1 $\geq 1:40$ or anti-SLA $= +2$), **IgG** ($> \text{ULN} +1$, $> 1.1 \times \text{ULN} +2$), histology (compatible $+1$, typical $+2$), **absence of viral hepatitis** ($+2$) $\rightarrow \geq 7 = \text{definite}$, **6 = probable** AIH.
- ▶ Always **exclude** viral, drug-induced (minocycline, nitrofurantoin), Wilson disease (look for Kayser-Fleischer rings), MASH and alcohol; consider **overlap syndromes** with PBC (7–13%) or PSC (6–11%).

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Diagram 1 — Histology of AIH (interface hepatitis):** draw a portal tract with the limiting plate eroded by a dense lymphoplasmacytic infiltrate spilling into periportal parenchyma. Labels: *Portal tract, Lymphoplasmacytic infiltrate, Interface (piecemeal) hepatitis at limiting plate, Plasma cells, Hepatocyte rosette, Emperipolesis, Centrilobular (zone 3) perivenulitis.*
- ▶ **Diagram 2 — Serological classification flow-box:** “AIH” branching into *Type 1* (labels: ANA, ASMA/anti-actin, anti-SLA, atypical pANCA; HLA-DR3/DR4; adults/women) and *Type 2* (labels: anti-LKM1 $\rightarrow$ CYP2D6, anti-LC1; children; Mediterranean).

Clinical / Diagnostic significance

- ▶ Suspect AIH in any patient — especially a **woman with another autoimmune disease** — who has unexplained transaminitis with **raised IgG/globulins and positive ANA/SMA**.
- ▶ **Initial work-up:** ANA, ASMA, anti-LKM1, anti-SLA, serum IgG/protein electrophoresis, AMA (to exclude PBC), full viral hepatitis serology, ceruloplasmin (Wilson), and **liver biopsy**; image with MRCP if cholestatic or coexisting IBD (to exclude PSC).
- ▶ **Treatment** (induces remission in $\sim 80\%$): **prednisone 20–60 mg/day** (high-dose 40–60 mg for acute severe disease), tapered, with **azathioprine 50 mg $\rightarrow$ 1–2 mg/kg/day** added ~ 1 –2 weeks

later as a steroid-sparing maintenance agent — check **TPMT** genotype first. **Budesonide** is an option in non-cirrhotic mild disease. Second-line/refractory: **mycophenolate mofetil**, **tacrolimus**, **rituximab**, **6-MP**. **Liver transplantation** for fulminant/refractory or end-stage disease (failure of bilirubin to fall after 2 weeks of therapy → list early).

- ▶ **Relapse is the rule** ($\geq 50\%$, up to 81–90% by 3 years) — most patients need indefinite maintenance; each relapse raises the risk of cirrhosis. Screen cirrhotics for **HCC (6-monthly ultrasound)** and varices; vaccinate against hepatitis A/B before immunosuppression.

High-yield exam pointers

- ▶ **Triad for diagnosis:** autoantibodies + raised IgG (hypergammaglobulinaemia) + interface hepatitis on biopsy, with exclusion of other causes.
- ▶ **Female ~75%; bimodal age (<30 and >60); fatigue the commonest symptom (~85%).**
- ▶ **Type 1 = ANA/ASMA, adults, HLA-DR3/DR4; Type 2 = anti-LKM1 (CYP2D6) $\pm$ anti-LC1, children, Mediterranean.**
- ▶ **Anti-SLA** → highest specificity (~99%), severe disease and relapse, may be the sole marker.
- ▶ **anti-LKM2 = drug-induced; anti-LKM3 = hepatitis D / some type 2 AIH** — don't confuse the LKM family.
- ▶ **Extra-hepatic clusters:** thyroiditis, UC, RA, Sjögren's, type 1 DM, vitiligo, Coombs-positive haemolytic anaemia, glomerulonephritis; immune-complex arthritis/cutaneous vasculitis are disease-intrinsic.
- ▶ **Old names: lupoid hepatitis** (high-titre ANA, LE-cell positive) and **plasma-cell hepatitis**.
- ▶ **AMA points away from AIH** (favours PBC); think **overlap syndrome** if cholestatic features.
- ▶ **Cornerstone therapy = prednisone + azathioprine; ~80% respond; relapse common → often lifelong maintenance.**

What are the indications, complications of ERCP?

Asked in: Paper II 08 Apr 2026 — RGUHS MD General Medicine

Definition / Introduction — Endoscopic retrograde cholangiopancreatography (ERCP) is a combined endoscopic–fluoroscopic procedure in which a **side-viewing duodenoscope** is passed to the second part of the duodenum, the major papilla (ampulla of Vater) is cannulated, and the bile and/or pancreatic ducts are opacified with radiographic contrast under fluoroscopy. When indicated, the papilla is incised by **endoscopic sphincterotomy (EST)** to permit stone extraction, stricture dilation, stenting, and tissue sampling. With the advent of **MRCP and endoscopic ultrasound (EUS)** as accurate non-invasive imaging, ERCP has evolved from a diagnostic into an almost **exclusively therapeutic** modality for pancreaticobiliary disease.

Technique and therapeutic armamentarium

- ▶ **Access:** transoral side-viewing duodenoscope → selective cannulation of CBD/pancreatic duct with a catheter or sphincterotome over a guidewire; contrast injection under fluoroscopy.
- ▶ **Therapeutic manoeuvres possible at ERCP:** biliary/pancreatic **sphincterotomy**; **stone extraction** with balloon or Dormia basket; **balloon dilation** of strictures; **plastic or self-expandable metal stent (SEMS)** placement; **mechanical/cholangioscopy-guided lithotripsy** of large stones; **nasobiliary drainage**; treatment of ductal leaks; intraductal **brush cytology / forceps biopsy**; **biliary manometry** (for sphincter of Oddi dysfunction).
- ▶ **Adjuncts:** cholangioscopy (SpyGlass) for direct duct visualisation and targeted biopsy; EUS-guided biliary drainage when conventional ERCP fails.

Indications

ERCP is indicated chiefly for **therapy**; pure diagnostic ERCP is now rare and reserved for **tissue sampling of biliary/pancreatic ductal strictures** and **biliary manometry**.

Category	Specific indication
Choledocholithiasis	Sphincterotomy + stone extraction (balloon/basket); first-line for CBD stones, especially elderly/poor surgical candidates
Acute (ascending) cholangitis	Emergency biliary decompression/drainage — the definitive treatment after resuscitation and antibiotics
Gallstone (biliary) pancreatitis	Urgent ERCP for retained CBD stone, particularly with coexisting cholangitis or obstructive jaundice

Category	Specific indication
Malignant biliary obstruction	Palliative stenting (SEMS) and tissue diagnosis in cholangiocarcinoma, pancreatic head cancer, ampullary tumour
Benign biliary strictures	Post-operative, chronic pancreatitis-related, or post-transplant strictures — dilation + multiple plastic stents or covered SEMS
Bile leak / duct injury	Post-laparoscopic-cholecystectomy cystic-duct stump leak — sphincterotomy ± stent to divert bile
Primary sclerosing cholangitis (PSC)	Endoscopic dilation ± short-term large-bore (10-Fr) stenting of a dominant stricture ; biliary lithiasis
Sphincter of Oddi dysfunction (SOD)	Manometry and biliary sphincterotomy in selected patients
Pancreatic disease	Pancreatic-duct stenting/stone removal in chronic pancreatitis; drainage of pancreatic-duct disruption/leak; pseudocyst communicating with the duct
Tissue diagnosis	Brush cytology/intraductal biopsy of indeterminate biliary or pancreatic strictures

- ▶ In **gallstone pancreatitis**, only ~20% harbour a persistent ampullary/CBD stone; therefore **MRCP or EUS first** spares many patients an unnecessary ERCP — urgent ERCP is reserved for suspected **superimposed cholangitis** or proven retained stone.
- ▶ For **acute cholangitis**, biliary drainage (usually by ERCP) should be established within ~24–48 h; **emergent** decompression is required in septic patients or those failing antibiotics within 12–24 h.

Contraindications

- ▶ **Absolute/relative:** uncooperative patient, **acute pancreatitis** (unless gallstone pancreatitis with cholangitis), severe uncorrected **cardiopulmonary disease**, recent contrast (iodine) anaphylaxis.
- ▶ **Anatomic barriers:** gastroduodenal/oesophageal obstruction preventing scope passage; **Roux-en-Y** or other surgically altered anatomy (may need balloon enteroscopy-assisted or EUS-directed access).
- ▶ **Pregnancy** — performed only when essential, with radiation-minimising technique.
- ▶ Uncorrected coagulopathy/thrombocytopenia (relative — correct before sphincterotomy).

Complications

ERCP carries the **highest adverse-event rate of all routine endoscopic procedures**. Major complications and approximate frequencies:

Complication	Frequency	Key points
Post-ERCP pancreatitis (PEP)	~5% overall (Harrison); 5–10%, up to 20–25% in high-risk	Most common and most feared complication; asymptomatic hyperamylasaemia in 35–70%
Haemorrhage (post-sphincterotomy)	~1–2%	Risk ↑ with thrombocytopenia, coagulopathy, cholangitis, anticoagulation within 3 days, low endoscopist volume
Perforation	<1%	Lateral-wall duodenal (large, often needs surgery); periampullary (post-sphincterotomy — often managed with stent); ductal (guidewire/basket — usually conservative + stent)
Cholangitis	~1%	Higher with combined percutaneous-endoscopic access, malignant stenting, failed/incomplete drainage
Cholecystitis	<0.5%	After stenting across the cystic-duct take-off
Pseudocyst infection / abscess	Uncommon	Especially when contrast injected into a duct communicating with a sterile collection
Sedation / cardiopulmonary	—	Hypoxaemia, aspiration, respiratory depression, arrhythmia, contrast reaction

- ▶ Pooled RCT data (placebo/no-stent arms): overall **PEP incidence 9.7%**, mortality **0.7%**; severity mild 5.7% / moderate 2.6% / severe 0.5%. In **high-risk** patients PEP rises to ~14.7%.
- ▶ Severe PEP may progress to necrotising pancreatitis, multi-organ failure, prolonged hospitalisation, diabetes, or **death**.

Post-ERCP pancreatitis — risk factors and prevention

Risk factors (Box 58.5 / Box 42.1):

- ▶ *Patient-related*: young age, female sex, **suspected SOD**, prior recurrent pancreatitis, **history of previous PEP**, normal serum bilirubin.
- ▶ *Procedure-related*: **pancreatic-duct injection/opacification**, difficult or failed cannulation, **pancreatic sphincterotomy**, **pre-cut (access) sphincterotomy**, balloon dilation of an intact sphincter, pancreatic guidewire placement, pancreatic tissue sampling.

- ▶ *Operator/technique-related*: trainee (fellow) participation, non-use of guidewire cannulation, failure to place a prophylactic pancreatic-duct stent in a high-risk case.
- ▶ The archetypal highest-risk patient: a **young woman with suspected choledocholithiasis and normal bilirubin who undergoes sphincterotomy but no stone is found** (~27% PEP).

Prevention — three evidence-based modalities:

- ▶ **Prophylactic pancreatic-duct stent** (3–5 Fr; length/diameter >5 cm/>5 Fr more protective) in high-risk cases — relieves cannulation-induced ampullary oedema; >70% pass spontaneously, otherwise removed by ~14 days.
- ▶ **Rectal NSAID** — **indomethacin** (or diclofenac) given peri-procedurally; reduces PEP, established for high-risk patients.
- ▶ **Periprocedural IV fluids** — aggressive hydration with **lactated Ringer's** solution.
- ▶ **Guidewire-assisted cannulation** lowers PEP versus contrast-guided cannulation (success ~98%). Treatment of established PEP is **supportive**; there is **no role for repeat ERCP** for PEP itself.

Antibiotic prophylaxis (selective)

- ▶ **Not recommended** when complete biliary drainage is anticipated.
- ▶ **Recommended** (and continued after the procedure) when **incomplete drainage** is expected — e.g., **PSC, hilar strictures** — and for a sterile pancreatic fluid collection communicating with the pancreatic duct.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Labelled line diagram of ERCP anatomy/technique**: duodenoscope tip in the second part of duodenum; major papilla (ampulla of Vater); common bile duct; common hepatic duct / right & left hepatic ducts; cystic duct & gallbladder; main pancreatic duct; sphincter of Oddi; cannula/sphincterotome entering the papilla; CBD stone with extraction balloon/basket distal to it.
- ▶ **Schematic of endoscopic sphincterotomy**: normal ampulla → sphincterotome cutting the roof of the papilla with electrosurgery → stone extracted with balloon catheter into the duodenum.

Clinical / Diagnostic significance

- ▶ **Choledocholithiasis pathway**: risk-stratify first — high probability (CBD stone on US, bilirubin >4 mg/dL, or cholangitis) → proceed to ERCP; intermediate probability → **MRCP or EUS** before ERCP to avoid needless ERCP. Confirmed stones → **sphincterotomy + extraction** (± laparoscopic cholecystectomy, often single-session). Large stones (≥1 cm) → sphincterotomy + **large-balloon dilation** or cholangioscopy-guided lithotripsy.

- ▶ **Acute cholangitis:** *Charcot triad* (RUQ pain, fever, jaundice; ~70%); *Reynolds pentad* (+ hypotension + altered mentation) = suppurative cholangitis, an **endoscopic emergency**. Diagnosis/severity by **Tokyo Guidelines (2018)**. Manage with IV fluids + antibiotics (e.g., **ciprofloxacin + metronidazole**, or ampicillin-sulbactam; severe/hospital-acquired → **piperacillin-tazobactam or meropenem**) then ERCP drainage.
- ▶ **Balloon sphincteroplasty without sphincterotomy** is preferred in **coagulopathic** patients (lower bleeding risk); a short fully-covered metal stent is an alternative to mitigate bleeding.
- ▶ When ERCP fails or is **anatomically impossible**, alternatives are **EUS-guided biliary drainage** or **percutaneous transhepatic cholangiography (PTC)** with drainage.

High-yield exam pointers

- ▶ ERCP uses a **side-viewing duodenoscope** and is now **predominantly therapeutic** (MRCP/EUS have replaced diagnostic ERCP).
- ▶ **Commonest and most feared complication** = **post-ERCP pancreatitis** (~5%, up to 20–25% in high-risk).
- ▶ **Post-sphincterotomy bleeding** ~1–2%; **perforation** <1%; **cholangitis** ~1%.
- ▶ **PEP prevention triad:** prophylactic **pancreatic-duct stent** + **rectal indomethacin** + **aggressive IV lactated Ringer's**; plus guidewire cannulation.
- ▶ Highest-risk PEP patient: **young woman, suspected SOD, normal bilirubin, difficult cannulation**.
- ▶ **Cholangitis** = Charcot triad; **Reynolds pentad** signals suppurative cholangitis needing **emergency ERCP drainage** (within 24–48 h; emergent if septic).
- ▶ In **gallstone pancreatitis**, urgent ERCP benefits only those with **retained CBD stone or cholangitis** — image with MRCP/EUS first.
- ▶ **Antibiotic prophylaxis** only when **incomplete drainage** is expected (PSC, hilar strictures).
- ▶ Contraindications: acute (non-gallstone) pancreatitis, severe cardiopulmonary disease, altered anatomy (Roux-en-Y), uncorrected coagulopathy.

SOURCE & COVERAGE

Patterns of Drug- and Toxin-Induced Liver Injury: Morphological Findings and Examples

Asked in: Paper I 06 Apr 2026 — RGUHS MD General Medicine

Definition / Introduction — *Drug-induced liver injury (DILI)* is hepatic injury attributable to a xenobiotic — a prescription or over-the-counter drug, an industrial/environmental toxin, or a complementary and alternative medicine (CAM)/herbal-dietary supplement. The liver is uniquely vulnerable because it is the principal site of drug metabolism: most water-insoluble drugs undergo **phase I** oxidation (cytochrome P450) and **phase II** conjugation (glucuronidation/sulfation) or glutathione inactivation, and most hepatotoxicity arises from a reactive **phase I toxic metabolite**. DILI is the commonest cause of acute liver failure (ALF) in the Western world and is a presumptive diagnosis requiring a meticulous drug history and exclusion of other causes. It is classified along three complementary axes — **pathogenic type**, **biochemical pattern (R value)** and **morphological pattern** — and a single agent may produce several lesions.

1. Classification by pathogenic mechanism

Type	Predictability / dose	Latency	Prototype agents & lesion
Direct (intrinsic) toxic	Predictable, reproducible, dose-dependent	Short (hours–48 h)	Acetaminophen, carbon tetrachloride, <i>Amanita phalloides</i> , yellow phosphorus, heavy metals → reproducible zonal necrosis ± steatosis
Idiosyncratic	Unpredictable, rare (1 in 10^3 – 10^5), only loosely dose-related (usually >100 mg/day)	Variable, typically 5–90 days	Isoniazid, amoxicillin-clavulanate, halothane, nitrofurantoin → variable morphology; may be immunoallergic or metabolic
Indirect (CMDT)	Drug worsens pre-existing liver disease	Variable	Immunosuppression/rituximab → HBV reactivation flare ; checkpoint inhibitors → immune hepatitis

- ▶ Idiosyncratic injury is further split into **immunoallergic** (hypersensitivity — rash, fever, arthralgia, eosinophilia; e.g. phenytoin, trimethoprim-sulfamethoxazole, the DRESS syndrome) and **metabolic idiosyncrasy** (variable toxic-metabolite kinetics, no allergy; e.g. isoniazid, valproate).
- ▶ Susceptibility is shaped by **HLA haplotypes** (amoxicillin-clavulanate, flucloxacillin), enzyme polymorphisms, age, alcohol, nutritional state and underlying liver disease.

2. Classification by biochemical pattern — the R value

- ▶ **R value** = $(\text{ALT} \div \text{ULN}) \div (\text{ALP} \div \text{ULN})$ — both as multiples of the upper limit of normal.
 - $R \geq 5 \rightarrow$ **hepatocellular** injury (ALT-dominant).
 - $R < 2 \rightarrow$ **cholestatic** injury (ALP-dominant).
 - $R 2-5 \rightarrow$ **mixed** hepatocellular-cholestatic.
- ▶ This bedside ratio predicts the likely histology and guides the differential before biopsy.

3. Morphological patterns, findings and examples (core of the answer)

Pattern	Key morphological findings	Representative agents
Zonal (coagulative) necrosis	Predictable necrosis in a specific acinar zone; centrilobular/zone 3 (high CYP2E1, low glutathione); minimal inflammation; resolves without fibrosis	Acetaminophen, carbon tetrachloride (zone 3); yellow phosphorus, ferrous salts (periportal/zone 1)
Massive / submassive (bridging) necrosis	Panlobular hepatocyte dropout $\rightarrow$ ALF	<i>Amanita phalloides</i> , halothane, severe acetaminophen
Acute hepatitis (hepatocellular)	Spotty/focal necrosis with lymphocytic infiltrate, resembling acute viral hepatitis ; ALT $>5 \times$ ULN	Isoniazid, halothane, ketoconazole, nitrofurantoin, methyldopa, sulfonamides, ciprofloxacin, troglitazone
Chronic hepatitis (autoimmune-like)	>3 months; interface hepatitis, bridging necrosis, fibrosis, plasma cells, autoantibodies (ANA/anti-SMA)	Nitrofurantoin, minocycline, hydralazine, α-methyldopa (the four ANA-positive AIH-like agents); diclofenac
Bland (non-inflammatory) cholestasis	Canalicular cholestasis, no inflammation or necrosis	Anabolic/17α-alkylated androgens , oestrogens, oral contraceptives
Cholestatic hepatitis (inflammatory)	Portal inflammation + cholestasis $\pm$ bile-duct injury	Amoxicillin-clavulanate (commonest implicated antibiotic), erythromycin estolate, chlorpromazine, oxacillin

Pattern	Key morphological findings	Representative agents
Vanishing bile duct syndrome (ductopenia)	Progressive loss of small interlobular bile ducts, PBC-like but AMA-negative; chronic cholestasis	Chlorpromazine, flucloxacillin, carbamazepine, amoxicillin-clavulanate, trimethoprim-sulfamethoxazole
Sclerosing cholangitis	Strictures of large/intrahepatic ducts	Intra-arterial flouxuridine , long-term ketamine
Macrovesicular steatosis	Single large fat droplet displacing nucleus	Amiodarone, methotrexate, tamoxifen, corticosteroids, irinotecan
Microvesicular steatosis	Tiny cytoplasmic fat droplets, central nucleus; mitochondrial toxicity → lactic acidosis	Valproate , high-dose IV tetracycline, aspirin (Reye) , didanosine/stavudine/zidovudine, linezolid
Steatohepatitis (pseudoalcoholic)	Steatosis + Mallory-Denk hyaline + neutrophils + pericellular fibrosis; phospholipidosis (lamellar lysosomal bodies)	Amiodarone, perhexiline, tamoxifen
Granulomatous hepatitis	Non-caseating epithelioid granulomas ± cholestasis	Sulfonamides, allopurinol, carbamazepine, hydralazine, quinidine, quinine, phenylbutazone
Fibrosis / cirrhosis	Progressive fibrosis, nodular regeneration	Methotrexate , amiodarone, tamoxifen, vitamin A (hypervitaminosis)
Vascular injury	Sinusoidal obstruction syndrome (veno-occlusive disease) — sinusoidal/terminal-venule endothelial injury; nodular regenerative hyperplasia ; peliosis hepatis (blood-filled cavities)	SOS: high-dose pre-BMT cyclophosphamide, melphalan, busulfan , pyrrolizidine alkaloids , oxaliplatin; NRH: oxaliplatin, azathioprine, vitamin A; peliosis & Budd-Chiari: anabolic/contraceptive steroids
Neoplasia	Hepatic adenoma, focal nodular hyperplasia, HCC, angiosarcoma	Oral contraceptives/oestrogens, anabolic steroids; vinyl chloride / arsenic / Thorotrast (angiosarcoma)
Immune-mediated (checkpoint inhibitor) hepatitis	Non-specific acute hepatitis, CD8⁺-predominant , ANA-positive; steroid-responsive	Ipilimumab (CTLA-4), nivolumab/pembrolizumab (PD-1/PD-L1)

4. The six cellular mechanisms of injury (Harrison)

- ▶ **A — Membrane rupture:** disrupted intracellular Ca^{2+} homeostasis → actin disassembly → blebbing and cell lysis.
- ▶ **B — Canalicular injury:** disruption of transport pumps (MRP3) → impaired bile/bilirubin excretion → cholestasis.
- ▶ **C — P450-drug covalent binding:** reactive metabolite binds cytochrome P450 forming non-functional adducts.
- ▶ **D — Immune attack on adducts:** adducts migrate to the surface as neo-antigens → cytolytic T-cell/cytokine attack.
- ▶ **E — Apoptosis:** activation of TNF- α receptor/Fas death-domain → caspase cascade.
- ▶ **F — Mitochondrial inhibition:** blockade of β -oxidation and the respiratory chain → microvesicular steatosis, lactate accumulation, reactive oxygen species.

5. Prototype: acetaminophen (paracetamol) — the model direct toxin

- ▶ Metabolised mainly by phase II to harmless conjugates; a fraction is oxidised by CYP2E1 to the toxic NAPQI (*N*-acetyl-*p*-benzoquinone-imine), normally detoxified by glutathione. Overdose or glutathione depletion → covalent protein adducts → **zone 3 (centrilobular) necrosis**.
- ▶ Toxic single dose **10–15 g**, fatal usually ≥ 25 g; in chronic alcoholics (CYP2E1 induction + glutathione depletion) toxicity may occur at ~ 2 g. Fasting/starvation potentiates.
- ▶ **Very high ALT** (often $>10,000$ IU/L) with **disproportionately low bilirubin** is the biochemical signature. 4-h level >300 $\mu\text{g/mL}$ predicts severe injury; <150 $\mu\text{g/mL}$ makes injury unlikely — plotted on the **Rumack-Matthew nomogram**.
- ▶ **Antidote:** N-acetylcysteine (NAC) — IV loading **140 mg/kg** then **70 mg/kg every 4 h** for **15–20 doses**; most effective within 8–12 h but still useful up to 24–36 h.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Hepatic acinus showing zonal injury:** draw the portal triad (hepatic artery, portal vein, bile duct) and the central (terminal hepatic) vein, with **Zone 1 (periportal)**, **Zone 2 (midzonal)** and **Zone 3 (centrilobular)**. Label “**Zone 3 — CYP2E1-rich, glutathione-poor → acetaminophen / CCl_4 necrosis**” and “**Zone 1 — yellow phosphorus / ferrous sulfate.**”
- ▶ **Six mechanisms of DILI** (after Harrison Fig 351-1): a hepatocyte labelled **A** membrane rupture, **B** canalicular pump (MRP3) injury, **C** P450-drug adduct, **D** CTL/cytokine attack on adduct, **E** TNF- α /Fas apoptosis (caspases), **F** mitochondrial β -oxidation/respiration block → microvesicular steatosis + lactate.

Clinical / Diagnostic significance

- ▶ **Hy’s Law:** during a drug trial, **jaundice with ALT $\geq 3 \times$ ULN** (hepatocellular, no cholestasis/obstruction) predicts a **mortality $\geq 10\%$** (a $\sim 10:1$ ratio of jaundice cases to liver

failure) — the strongest clinical predictor of severe DILI and a common reason drugs fail approval (e.g. troglitazone).

- ▶ **Causality assessment:** RUCAM (Roussel-Uclaf), the DILIN structured expert opinion (5-point scale: definite, highly likely, probable, possible, unlikely) and the newer RECAM; *LiverTox* (NIH) is the reference database.
- ▶ **Management:** chiefly **prompt withdrawal of the offending agent** (the single most important determinant of outcome) plus supportive care. Specific therapies: **NAC** for acetaminophen (and benefit in early-stage non-acetaminophen ALF), **silibinin** for *Amanita*, **ursodeoxycholic acid** for cholestatic DILI, **glucocorticoids** for immunoallergic/checkpoint-inhibitor and AIH-like injury. Stop any drug when ALT reaches $5\times$ ULN or symptoms/jaundice appear. ALF develops in $\sim 10\%$ of DILI; **liver transplantation** for those reaching coagulopathy + encephalopathy (lactate >3.5 mmol/L predicts need).
- ▶ Always probe **CAMs/herbals** ($>20\%$ of US DILI): green tea extract (HLA-B*35:01), Jin Bu Huan, germander, kava, pyrrolizidine alkaloids (SOS), anabolic “bodybuilding” supplements (profound bland cholestasis), Hydroxycut/OxyElite Pro.

High-yield exam pointers

- ▶ Two core pathogenic types: **direct/intrinsic** (predictable, dose-dependent, short latency, reproducible zonal necrosis) vs **idiosyncratic** (rare $1:10^3$ – 10^5 , latency 5–90 days, variable morphology); CMDT adds **indirect** (HBV flare).
- ▶ **R value:** ≥ 5 hepatocellular, <2 cholestatic, 2–5 mixed.
- ▶ Acetaminophen $\rightarrow$ CYP2E1 $\rightarrow$ NAPQI $\rightarrow$ **glutathione depletion** $\rightarrow$ **zone 3 necrosis**; antidote NAC 140 mg/kg then 70 mg/kg q4h.
- ▶ **Amoxicillin-clavulanate** = commonest antibiotic cause (mixed/cholestatic, may cause **vanishing bile duct syndrome**).
- ▶ AIH-like chronic hepatitis (ANA+): **nitrofurantoin**, **minocycline**, **hydralazine**, **methyldopa**.
- ▶ **Microvesicular steatosis** = mitochondrial toxicity (valproate, tetracycline IV, aspirin/Reye, NRTIs) $\rightarrow$ lactic acidosis; **macrovesicular** (amiodarone, methotrexate, tamoxifen).
- ▶ **Amiodarone** $\rightarrow$ pseudoalcoholic steatohepatitis with **Mallory hyaline** + **phospholipidosis** (lamellar bodies).
- ▶ **SOS/VOD** = pre-BMT chemo (cyclophosphamide, busulfan, melphalan) and **pyrrolizidine alkaloids**; **angiosarcoma** = vinyl chloride/arsenic/Thorotrast.
- ▶ **Hy’s Law:** jaundice + ALT $\geq 3\times$ ULN $\rightarrow$ mortality $\geq 10\%$.

SOURCE & COVERAGE

Wilson's disease

Asked in: Paper IV Nov 2022 — RGUHS MD General Medicine

Definition / Introduction — Wilson's disease, or hepatolenticular degeneration, is an autosomal recessive disorder of copper transport due to pathogenic variants in **ATP7B** on chromosome 13. Defective hepatic copper transport impairs biliary copper excretion and incorporation of copper into ceruloplasmin, causing toxic copper accumulation in the **liver, brain, cornea, kidney, and other tissues**. It is one of the most treatable inherited metabolic liver diseases, but missed diagnosis can lead to fatal hepatic failure or irreversible neurologic disability.

Etiopathogenesis and copper metabolism

- ▶ Normal dietary copper is absorbed from the proximal small intestine, transported to the liver, incorporated into **ceruloplasmin**, and excreted mainly in bile; urinary copper excretion is normally small.
- ▶ **ATP7B** is expressed predominantly in liver and kidney. In hepatocytes it has two key functions: formation of enzymatically active ceruloplasmin in the trans-Golgi network and trafficking copper toward the canalicular membrane for biliary excretion.
- ▶ Loss of ATP7B function causes progressive hepatic copper retention. Initially copper is buffered by metallothionein; later excess copper causes oxidative mitochondrial injury, hepatocyte necrosis, fibrosis, and cirrhosis.
- ▶ When hepatic storage capacity is exceeded, copper spills into blood and deposits in the **basal ganglia**, cornea, kidney, skeleton, endocrine organs, and red cell membranes.
- ▶ Epidemiology: classically about **30 per million** population, with most clinical presentations between **3 and 55 years**; genetic estimates suggest the allele frequency may be higher. Age does not exclude the diagnosis.
- ▶ Most patients are **compound heterozygotes**. More than 600 ATP7B variants are described; H1069Q is common in Northern European populations and R778L in Chinese populations.

Clinical spectrum

System / presentation	High-yield clinical features
Hepatic	Asymptomatic aminotransferase elevation, fatty liver/NASH-like picture, acute hepatitis-like illness, autoimmune hepatitis-like illness, chronic hepatitis, cirrhosis, portal hypertension, splenomegaly, ascites, edema, decompensated chronic liver disease
Acute liver failure	Severe coagulopathy with or without early encephalopathy, Coombs-negative intravascular hemolysis, very high bilirubin, renal failure; aminotransferases may be disproportionately low
Neurologic	Basal ganglia movement disorder: dysarthria, dysphagia, drooling, dystonia, rigidity/parkinsonism, ataxia, gait disturbance, dysgraphia, choreiform movements, and classic <i>wing-beating</i> tremor
Psychiatric	Declining school or work performance, personality change, irritability, poor impulse control, depression, anxiety, emotional lability, compulsive or antisocial behavior; may precede neurologic signs
Ocular	Kayser-Fleischer ring : golden-brown/greenish-brown copper deposition in Descemet membrane, detected best by slit lamp; sunflower cataract may occur
Extrahepatic	Coombs-negative hemolytic anemia, renal Fanconi syndrome, renal tubular acidosis, nephrolithiasis, aminoaciduria, phosphaturia, osteoporosis/rickets, osteoarthritis, amenorrhea, infertility, hypoparathyroidism, rarely cardiomyopathy/arrhythmias

- ▶ Hepatic presentation is more common in younger patients; neuropsychiatric presentation usually appears in adolescents and young adults, but overlap is common and some degree of liver disease is usually present.
- ▶ Kayser-Fleischer rings are present in most patients with neurologic disease but may be absent in hepatic-only or asymptomatic disease; absence of the ring never excludes Wilson's disease.
- ▶ Wilson's disease should be excluded in any young patient with unexplained hepatitis, splenomegaly with hypersplenism, portal hypertension, Coombs-negative hemolysis, movement disorder, or new psychiatric illness.

Diagnostic approach

Test	Typical finding / interpretation
Serum ceruloplasmin	Low; <14 mg/dL supports diagnosis and <10 mg/dL is strongly suggestive, but normal values occur because ceruloplasmin is an acute-phase reactant; low levels are not specific
Serum copper	Total serum copper is often low because ceruloplasmin-bound copper is low; non-ceruloplasmin copper is increased, but calculated values are assay-dependent
24-hour urinary copper	>40 mcg/day requires further evaluation; usually >100 mcg/day in symptomatic disease. Use complete, contamination-free collection with creatinine check
Penicillamine challenge	A marked increase in urinary copper after penicillamine supports the diagnosis; in the standard provocative test, very high 24-hour copper excretion is diagnostic but sensitivity is imperfect
Hepatic copper	>250 mcg/g dry liver is diagnostic in the correct setting; 20-50 mcg/g is normal. Sampling error occurs in cirrhosis because copper distribution is uneven
Slit-lamp examination	Detects Kayser-Fleischer rings and sunflower cataract; repeat if suspicion remains high
MRI brain	May show basal ganglia, brainstem, or cerebellar involvement, even early in neurologic disease
ATP7B molecular testing	Confirms diagnosis when clinical and biochemical tests are equivocal; also enables family screening

- ▶ Diagnosis is usually by a **composite** of clinical features, copper studies, slit-lamp findings, and genetics; the **Leipzig scoring system** is a useful structured framework.
- ▶ Liver biopsy may show steatosis, acute or chronic hepatitis, autoimmune hepatitis-like interface activity, macronodular cirrhosis, and characteristic mitochondrial injury; copper stain may be negative early because copper is diffusely cytosolic.
- ▶ Important limitations: ceruloplasmin may be low in malnutrition, nephrotic syndrome, malabsorption, and other chronic liver diseases; hepatic copper may be high in chronic cholestasis and MDR3-related disease.

Wilsonian acute liver failure

- ▶ Suspect Wilsonian acute liver failure in a child or young adult with jaundice, severe coagulopathy, hemolysis, kidney injury, and unexpectedly modest transaminase elevation.

- ▶ Classic clues are **Coombs-negative intravascular hemolysis**, very high bilirubin, normal or low alkaline phosphatase, and urinary copper that is markedly elevated.
- ▶ In adults, two simple biochemical ratios are useful screening clues: **alkaline phosphatase : total bilirubin** <4 and **AST : ALT** >2.2.
- ▶ Serum ceruloplasmin is often not diagnostically reliable in acute liver failure.
- ▶ These patients respond poorly to chelation alone; manage in a transplant-capable ICU, treat complications of acute liver failure, and use plasma exchange, albumin dialysis, or MARS as a bridge when available.
- ▶ **Urgent liver transplantation** is indicated for Wilsonian acute liver failure and for decompensated cirrhosis unresponsive to medical therapy.

Treatment

Modality	Dose / role	Key cautions
Dietary copper restriction	Avoid shellfish, organ meats, nuts, mushrooms, soy-based products, chocolate; assess high-copper water when relevant	Useful adjunct only; never sufficient as sole therapy
D-penicillamine	0.75-2 g/day in divided doses, taken 1 hour before or 2 hours after food; add pyridoxine supplementation	Rash, fever, GI intolerance, proteinuria, nephrotoxicity, leukopenia, thrombocytopenia, aplastic anemia, autoimmune syndromes, elastosis perforans serpiginosa; may worsen neurologic disease initially
Trientine hydrochloride	250-500 mg three times daily, or about 1-1.5 g/day initially in divided doses; effective first-line or alternative chelator	Fewer adverse effects; monitor for gastritis, iron deficiency, and rare marrow suppression
Zinc acetate / gluconate	50 mg elemental zinc three times daily, taken away from meals; induces enterocyte metallothionein and blocks copper absorption	Slow onset; best for presymptomatic patients, pregnancy, neurologic disease, or maintenance after decoppering; gastritis and adherence problems are common
Combination therapy	Chelator plus zinc may be used short term in severe hepatic/neurologic disease	Separate doses by at least 4-5 hours to avoid mutual neutralization
Tetrathiomolybdate	Investigational copper-binding therapy, mainly explored for neurologic disease	Watch for bone marrow suppression, hepatotoxicity, and copper deficiency

Modality	Dose / role	Key cautions
Liver transplantation	Acute liver failure or decompensated cirrhosis not responding to drug therapy	Not generally recommended for isolated intractable neuropsychiatric disease

- ▶ Treatment is **lifelong**. Stopping chelator or zinc therapy can cause neurologic relapse or rapidly progressive hepatic decompensation.
- ▶ In pregnancy, treatment must continue; chelator dose is usually reduced, while zinc can often be continued. Untreated disease increases miscarriage and relapse risk; breastfeeding is generally avoided with anticopper drugs.

Monitoring, family screening and prognosis

- ▶ Monitor response and toxicity with symptoms, adherence review, liver biochemical tests, CBC, renal function, urinalysis, and 24-hour urinary copper.
- ▶ Therapeutic targets: with chelators, 24-hour urinary copper is typically maintained around **200-500 mcg/day**; with zinc, urinary copper should fall to about **30-75 mcg/day**. Undetectable urinary copper suggests overtreatment.
- ▶ Serum non-ceruloplasmin copper can guide chelator dose reduction once it is in the normal range, approximately **50-150 mcg/L**.
- ▶ With zinc, adherence can be checked by urinary zinc excretion or serum zinc; rising aminotransferases after previous control often indicates nonadherence.
- ▶ Screen all **first-degree relatives**, especially siblings, using liver biochemical tests, serum ceruloplasmin, copper studies, slit-lamp examination, and ATP7B variant testing if the familial variants are known.
- ▶ Prognosis is excellent when diagnosed before hepatic or neurologic injury and treated consistently. Cirrhosis at diagnosis reduces long-term survival, and severe neurologic disease may not fully reverse.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Copper metabolism in Wilson's disease:** dietary copper absorption in small intestine -> portal transport to liver -> normal ATP7B-mediated ceruloplasmin formation and biliary excretion -> ATP7B defect -> hepatic copper accumulation -> spillover to brain, cornea, kidney, RBCs.
- ▶ **Kayser-Fleischer ring slit-lamp diagram:** cornea, limbus, Descemet membrane, superior and inferior early copper crescents, circumferential brown-green ring; add labels for sunflower cataract if drawn.

Clinical / Diagnostic significance

- ▶ Wilson's disease is a mandatory differential for **young-onset hepatitis, cirrhosis, acute liver failure, movement disorder, psychiatric decline, Coombs-negative hemolysis, and unexplained splenomegaly**.
- ▶ A normal ceruloplasmin or absent Kayser-Fleischer ring does not rule it out; combine urinary copper, slit-lamp examination, hepatic copper, and genetics.
- ▶ In acute liver failure, low/normal alkaline phosphatase with massive bilirubin and hemolysis is a life-saving clue because early transplant referral is decisive.
- ▶ Distinguish Wilson-related fatty liver from MASLD by copper studies, especially basal 24-hour urinary copper.
- ▶ Family screening prevents irreversible disease because presymptomatic patients treated early usually have the best outcome.

High-yield exam pointers

- ▶ Write the triad: **liver disease + neuropsychiatric disease + Kayser-Fleischer ring**, but state that the full triad is uncommon.
- ▶ Gene: **ATP7B**, chromosome 13, autosomal recessive, defective biliary copper excretion.
- ▶ Diagnostic numbers: ceruloplasmin <14 mg/dL supports diagnosis; 24-hour urinary copper >40 mcg/day needs evaluation and usually >100 mcg/day in disease; hepatic copper >250 mcg/g dry liver is diagnostic.
- ▶ Kayser-Fleischer ring is copper in **Descemet membrane**, best seen by slit lamp.
- ▶ Wilsonian acute liver failure: **Coombs-negative hemolysis**, low/normal ALP, very high bilirubin, **ALP:bilirubin <4, AST:ALT >2.2**, urgent transplant.
- ▶ Main drugs: **D-penicillamine, trientine, and zinc**; treatment is lifelong and adherence is central.
- ▶ D-penicillamine can worsen neurologic disease initially and can cause renal, marrow, skin, and autoimmune toxicity.
- ▶ Screen all first-degree relatives; use ATP7B mutation testing when the familial variants are known.

Zollinger-Ellison syndrome

Asked in: Paper II Jul 2020 — RGUHS MD General Medicine

Definition / Introduction — *Zollinger-Ellison syndrome (ZES)* is the clinical triad of gastric acid hypersecretion, severe/refractory peptic ulcer disease, and a non- β -cell gastrin-secreting neuroendocrine tumour (gastrinoma). Unregulated gastrin release from a usually well-differentiated NET of the duodenum or pancreas drives parietal-cell stimulation and hyperplasia, producing peptic ulceration in atypical sites, reflux disease and secretory diarrhoea. It accounts for <1% of peptic ulcer disease; ~80% of cases are sporadic and ~20–25% occur as part of **multiple endocrine neoplasia type 1 (MEN 1)**.

Etiology, Epidemiology & Pathology

- ▶ **Incidence:** rare — ~0.5–3 per million population per year; estimated in 0.1–1% of patients presenting with PUD. Slight female preponderance; most diagnosed between **30–65 years**. Diagnosis is typically delayed **4–7 years** after symptom onset (widespread PPI use both masks symptoms and confounds gastrin testing).
- ▶ **Two forms:**
 - **Sporadic (~80%):** usually solitary, more often pancreatic, potentially curable by resection.
 - **MEN 1-associated (~20–25%):** autosomal dominant, caused by inactivating mutations of the **MEN1 tumour-suppressor gene on chromosome 11q13** encoding **menin**; tumours are typically **small, multiple and duodenal**; presents earlier and runs a more indolent course.
- ▶ **Tumour location — the gastrinoma triangle (triangle of Passaro): bounded by (1) confluence of the cystic and common bile ducts superiorly, (2) junction of the 2nd and 3rd parts of the duodenum inferiorly, and (3) junction of the neck and body of the pancreas** medially. 60–90% of gastrinomas lie within it.
- ▶ **Distribution:** the **duodenum is now the commonest primary site** (~60–100%; mostly 1st/2nd part) — duodenal tumours are small (>90% <1 cm), slow-growing and less likely to metastasise; pancreatic tumours are larger and more aggressive. Other sites: lymph nodes (a primary node gastrinoma can be curable), stomach, ovary, liver, bone.
- ▶ **Malignant potential:** **60–90% are malignant** (defined by local invasion/metastasis); **25–50% have nodal or hepatic metastases at presentation**. Histology is well-differentiated (NET grade 1–2), staining for **chromogranin A** and **neuron-specific enolase**.

Pathophysiology

- ▶ **Autonomous hypergastrinemia** is the central driver. Gastrin acts on **CCK-2/gastrin receptors** on parietal cells and stimulates **histamine release from ECL cells**, markedly increasing acid output.
- ▶ Gastrin is also **trophic** — chronic hypergastrinemia expands parietal-cell mass and ECL-cell hyperplasia (predisposing to **type 2 gastric carcinoids**, especially in MEN 1/ZES).
- ▶ The massive acid load produces: **peptic ulcer diathesis, erosive oesophagitis/GERD, and diarrhoea** — the last via direct mucosal injury, volume overload of the small bowel, and acid

inactivation of pancreatic lipase/precipitation of bile salts causing maldigestion and steatorrhea.

Clinical Features

- ▶ **Peptic ulcer (>90%):** abdominal pain is the commonest presenting symptom; classically ulcers that are multiple, in unusual locations (distal duodenum/jejunum), refractory to therapy, recurrent, complicated (bleed/perforation/obstruction), or *H. pylori*- and NSAID-negative. Isolated gastric ulcers do *not* occur.
- ▶ **Diarrhoea (up to 70%):** may precede or occur independently of ulcers; classically abates with nasogastric aspiration or PPI (an important clinical clue).
- ▶ **GERD / oesophageal disease (up to two-thirds):** from mild oesophagitis to stricture and Barrett's mucosa.
- ▶ **MEN 1 clues:** younger age at presentation, nephrolithiasis/renal colic, hypercalcaemia, and personal/family history of parathyroid, pituitary or pancreatic islet tumours. In MEN 1: hyperparathyroidism 80–90%, pancreatic NETs 40–80%, pituitary tumours 30–60%. Hypercalcaemia of hyperparathyroidism aggravates acid secretion — parathyroidectomy lowers gastrin/acid output.

Diagnosis — Biochemical Confirmation

Diagnosis requires demonstration of inappropriate gastric acid hypersecretion in the presence of hypergastrinemia. PPIs must be stopped (≥ 7 days, covered by an H₂-blocker stopped 24 h before testing) as they elevate gastrin and can cause false positives — but stop with caution, monitoring for acid-peptic complications.

Test	Finding diagnostic of ZES	Comment
Fasting serum gastrin (FSG)	>150–200 pg/mL (normal <150); present in 97–99%	>10× normal (>1000 pg/mL) with low pH is highly suggestive
Gastric pH / BAO	pH <2–3; BAO >15 mEq/h (>5 mEq/h if prior gastric surgery)	BAO >15 with hypergastrinemia is near-pathognomonic
BAO/MAO ratio	>0.6	Limited — pentagastrin no longer available
Secretin stimulation test	Rise in gastrin ≥ 120 pg/mL within 15 min of IV secretin (2 U/kg)	Most useful provocative test; sensitivity & specificity >90%
Calcium infusion	Rise in gastrin	Largely obsolete (cumbersome, less sensitive)

- ▶ **Practical rule (CMDT):** gastrin >1000 pg/mL + gastric pH <2 establishes the diagnosis; for intermediate gastrin (150–1000 pg/mL) with acid, perform the secretin test.

- ▶ **Exclude other causes of hypergastrinemia** — these give a **negative secretin test**: PPI/H₂-blocker use, atrophic gastritis / pernicious anaemia / achlorhydria (commonest cause), *H. pylori*, retained gastric antrum, gastric outlet obstruction, renal failure, G-cell hyperplasia.
- ▶ Always screen for **MEN 1**: serum **calcium/PTH, prolactin, and pancreatic polypeptide** ($\pm$ LH-FSH, GH).

Tumour Localization & Staging

- ▶ Once biochemically confirmed, localise the tumour and exclude metastases.

Modality	Primary tumour sensitivity	Hepatic metastasis
CT / MRI	low for small lesions	88–100%
EUS	28–86% (best for pancreas; poor for duodenum)	N/A
OctreoScan (¹¹¹ In-pentetreotide)	55–77%	90–100%
⁶⁸ Ga-DOTATATE PET-CT	>90% (investigation of choice)	>90%
Selective arterial secretin injection (SASI)	55–78%	—

- ▶ ⁶⁸Ga-DOTATATE PET/CT (exploits SSTR2 expression) is the **functional imaging study of choice**, superior to OctreoScan. ¹⁸F-FDG PET is used as a prognostic marker.
- ▶ **WHO grading of the NET (prognostic)**: G1 <2 mitoses/10 HPF & Ki-67 <3%; G2 2–20 mitoses or Ki-67 3–20%; G3 >20 mitoses or Ki-67 >20% (poorly differentiated = neuroendocrine carcinoma).

Treatment / Management

- ▶ **Control of acid hypersecretion (first priority)**: **high-dose PPIs are the treatment of choice** — omeprazole/lansoprazole/rabeprazole/esomeprazole, initial **60 mg/day (CMDT: 40–120 mg/day) in divided doses**, titrated to **BAO <10 mEq/h** (<5 mEq/h if prior acid-reducing surgery). PPIs have made **total gastrectomy obsolete**.
- ▶ **Curative surgery (sporadic, non-metastatic disease)**: exploratory laparotomy with **duodenotomy, intraoperative palpation and ultrasound**; immediate cure in ~33–40%, with 10-year disease-free rates up to 95%. **Lymph-node metastasis does not adversely affect prognosis**.
- ▶ **MEN 1/ZES**: surgery is **generally deferred** — tumours are multifocal, <5% are disease-free at 5 years, and the course is indolent; manage hyperparathyroidism (parathyroidectomy reduces gastrin/acid).
- ▶ **Metastatic disease**: somatostatin analogues (**octreotide LAR, lanreotide**); **peptide receptor radionuclide therapy (PRRT)** with radiolabelled somatostatin analogues; **temozolomide** +

capecitabine ($\approx 70\%$ response); targeted agents — sunitinib (VEGFR), everolimus (mTOR); cytotoxics (streptozotocin/5-FU/doxorubicin); hepatic-artery embolization, RFA, debulking.

- ▶ **Prognosis:** overall 5-/10-year survival 62–75% / 47–53%; complete resection or negative laparotomy $>90\%$ at 10 years; **hepatic metastases $<20\%$ at 5 years.** Poor prognostic markers: pancreatic primary $>2\text{--}3\text{ cm}$, gastrin $>10,000\text{ pg/mL}$, poor differentiation/high Ki-67, liver/bone metastases, Cushing's syndrome.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **The gastrinoma triangle (triangle of Passaro):** draw the liver/porta hepatis, gallbladder with cystic duct, common bile duct, duodenal C-loop (mark 2nd–3rd part junction) and pancreas (head/neck/body). **Labels:** Confluence of cystic + common bile ducts (superior apex), Junction of 2nd & 3rd parts of duodenum (inferior apex), Junction of neck & body of pancreas (medial apex), Gastrinoma triangle.
- ▶ **Diagnostic algorithm flow box:** Clinical suspicion $\rightarrow$ Fasting serum gastrin $\rightarrow$ if $>1000\text{ pg/mL}$ + $\text{pH} < 2 = \text{ZES}$; if $150\text{--}1000\text{ pg/mL}$ $\rightarrow$ Secretin test ($\geq 120\text{ pg/mL}$ rise = positive) + BAO $\rightarrow$ Localize with ^{68}Ga -DOTATATE PET-CT/EUS $\rightarrow$ Resectable vs Metastatic.

Clinical / Diagnostic significance

- ▶ Suspect ZES in any patient with **multiple, distal, recurrent or complicated ulcers, ulcers with diarrhoea, severe/refractory GERD, H. pylori-negative/NSAID-negative PUD, or prominent gastric folds.**
- ▶ **Diarrhoea relieved by NG aspiration or PPI** is a strong pointer; **hypercalcaemia or family history** mandates MEN 1 screening.
- ▶ A **fasting gastrin done while on a PPI** is the commonest diagnostic pitfall — interpret cautiously and confirm off therapy.
- ▶ Early diagnosis matters: it allows curative resection before hepatic spread, the strongest determinant of survival.

High-yield exam pointers

- ▶ ZES = gastrinoma + acid hypersecretion + refractory PUD; $<1\%$ of all PUD.
- ▶ Duodenum is the commonest primary site; 60–90% lie in the gastrinoma triangle of Passaro.
- ▶ $\sim 80\%$ sporadic, $\sim 20\text{--}25\%$ MEN 1 (MEN1 gene, 11q13, menin); MEN 1 $\rightarrow$ parathyroid $>$ pancreas $>$ pituitary.
- ▶ Fasting gastrin $>1000\text{ pg/mL}$ + gastric pH < 2 is diagnostic; secretin test = $\geq 120\text{ pg/mL}$ rise in 15 min (sens/spec $>90\%$).
- ▶ BAO $>15\text{ mEq/h}$ with hypergastrinemia is near-pathognomonic.

- ▶ **Commonest cause of hypergastrinemia overall** = achlorhydria/atrophic gastritis (PPI use), not gastrinoma — gives a *negative* secretin test.
- ▶ ⁶⁸Ga-DOTATATE PET-CT is the localization investigation of choice.
- ▶ **High-dose PPI** controls symptoms (titrate BAO <10 mEq/h); **resection cures sporadic disease**; surgery usually avoided in MEN 1.
- ▶ Most important survival predictor = **hepatic metastasis**.

Renal system

NSAID-Induced Acute Interstitial Nephritis Presenting as AKI (Clinical Case Discussion)

Asked in: Paper IV Oct 2025 — RGUHS MD General Medicine

Definition / Introduction — Acute interstitial nephritis (AIN, syn. acute tubulointerstitial nephritis, ATIN) is an immune-mediated inflammatory disorder of the renal interstitium and tubules with relative sparing of glomeruli and vessels, producing acute kidney injury (AKI). It accounts for ~10–15% of intrinsic AKI, and **drugs cause >70% of cases**. This 35-year-old man, on diclofenac for a month, with new AKI (creatinine 4.5 mg/dL), **bland urine, low-grade proteinuria (~200 mg/24 h) and only 7 RBCs/no casts**, is the textbook picture of NSAID-induced AIN — the “atypical” allergic nephritis in which the classic triad of fever, rash and eosinophilia is characteristically *absent*.

Interpreting the vignette — why this is AIN, not a glomerular disease

- ▶ **Temporal link:** AKI appearing weeks after starting a known culprit drug (NSAID) is the single strongest clue; the latent period with NSAIDs is long (often weeks to months, unlike the days–2 weeks seen with β -lactams).

- ▶ **Bland sediment + scanty proteinuria:** proteinuria of only 200 mg/24 h is *tubular-range* (<1–2 g/day), and the microscopy is bland with no casts and only 7 RBCs. This argues strongly **against** a glomerulopathy, which would give nephrotic-range proteinuria, dysmorphic RBCs and RBC casts, and against acute GN/vasculitis.
- ▶ **Edema is from fluid retention, not hypoalbuminaemia:** periorbital puffiness and pedal oedema here reflect salt-and-water retention from the AKI itself plus the direct sodium-retaining (prostaglandin-mediated) effect of NSAIDs — *not* nephrotic syndrome, since the protein loss is trivial.
- ▶ **Caveat — the “dual lesion”:** NSAIDs uniquely may cause AIN *combined with* a glomerular lesion (**minimal change disease** more often than **membranous nephropathy**), producing heavy/nephrotic proteinuria. The low proteinuria here makes a concurrent minimal-change lesion unlikely, so the expected pathology is *pure* AIN.

Feature in this case	Points toward
NSAID for 1 month, new AKI	Drug-induced AIN
Proteinuria 200 mg/24 h (tubular range)	Interstitial, not glomerular
Bland sediment, no casts, 7 RBCs	AIN / ATN — excludes active GN
Periorbital + pedal oedema	Volume retention from AKI + NSAID Na ⁺ retention
No fever/rash/eosinophilia	Typical of NSAID-AIN (allergic features rare)

Expected renal pathology (b) — Acute (drug-induced) interstitial nephritis

- ▶ **Diagnosis:** acute tubulointerstitial nephritis (AIN) — confirmed only by percutaneous kidney biopsy, the gold standard.
- ▶ **Light microscopy:** patchy/diffuse **interstitial oedema** with a **mononuclear inflammatory infiltrate** (predominantly T lymphocytes — CD4⁺ and CD8⁺), plasma cells, macrophages, and variable eosinophils; **tubulitis** (lymphocytes crossing the tubular basement membrane into tubular epithelium) with tubular cell injury (loss of brush border, luminal ectasia).
- ▶ **NSAID-specific histology:** the infiltrate is **less intense and characteristically has few or no eosinophils**, attributable to the drug’s own anti-inflammatory action — distinct from β -lactam AIN where eosinophils are abundant. Occasionally granulomatous AIN or anti-TBM immune deposits occur.
- ▶ **Glomeruli and vessels are spared** (unless a coexisting minimal-change/membranous lesion is present).

- ▶ **Pathogenesis:** a T-cell-mediated, type IV (delayed) hypersensitivity reaction; the drug acts as a hapten/pro-hapten binding tubular proteins or generates neoantigens by molecular mimicry, triggering interstitial inflammation.
- ▶ **If unrecognised/untreated**, interstitial inflammation evolves into **interstitial fibrosis and tubular atrophy** → chronic tubulointerstitial nephritis and CKD.

Spectrum of NSAID nephrotoxicity (depth point)

- ▶ **Haemodynamic (pre-renal) AKI** — commonest; inhibition of vasodilatory prostaglandins ($\text{PGE}_2/\text{PGI}_2$) → unopposed **afferent arteriolar vasoconstriction** → fall in GFR, especially with volume depletion, heart failure, cirrhosis, or co-prescription of ACE-I/ARB (“triple whammy”).
- ▶ **Acute interstitial nephritis** (this case) ± **minimal change disease / membranous nephropathy** (nephrotic syndrome).
- ▶ **Electrolyte/acid–base:** hyperkalaemia (type IV RTA), sodium and water retention → oedema and hypertension, hyponatraemia.
- ▶ **Chronic:** analgesic nephropathy with **papillary necrosis**, and acceleration of pre-existing CKD.

Other causes of the same pathology (c) — causes of AIN

Category	Representative causes
Drugs (>70%)	NSAIDs/COX-2 inhibitors; antibiotics — β -lactams (penicillins, cephalosporins), sulfonamides, fluoroquinolones (ciprofloxacin), vancomycin, rifampin, ethambutol; PPIs & H_2 blockers; allopurinol ; anticonvulsants (phenytoin, carbamazepine, valproate); diuretics (thiazides, furosemide, triamterene); immune checkpoint inhibitors (ipilimumab, nivolumab, pembrolizumab); mesalamine, 5-ASA
Infections	<i>Streptococcus</i> , <i>Staphylococcus</i> , <i>Legionella</i> , <i>Corynebacterium diphtheriae</i> , <i>Brucella</i> , <i>Yersinia</i> ; <i>Leptospira</i> ; viruses — EBV, CMV, hantavirus , HIV, polyomavirus (BK) ; <i>Mycobacterium tuberculosis</i> (granulomatous)
Autoimmune / systemic	Sjögren syndrome , SLE , sarcoidosis (granulomatous), IgG4-related disease (storiform fibrosis), TINU (tubulointerstitial nephritis with uveitis), anti-TBM (anti-LRP2/anti-brush border) disease
Idiopathic	Idiopathic AIN (some with anti-tubular antibodies)
Obstructive/crystal (related)	Light-chain cast nephropathy (myeloma), acute urate (tumour lysis) and acute phosphate nephropathy

Investigations / diagnostic approach

- ▶ **Confirm and stage AKI (KDIGO):** serum creatinine 4.5 mg/dL from a normal baseline is **stage 3 AKI**; trend creatinine/urea, urine output.
- ▶ **Urinalysis & microscopy:** sterile pyuria, WBC $\pm$ WBC casts, mild haematuria, **low-grade (tubular) proteinuria <1–2 g/day**; ~20% have a bland sediment (as here). **Urine eosinophils are NOT recommended** — poor sensitivity/specificity (abandoned).
- ▶ **Bloods:** CBC (eosinophilia inconsistent, may be absent in NSAID-AIN), electrolytes (watch **hyperkalaemia**, non-anion-gap acidosis), ESR/CRP, IgE; screen for systemic disease where suspected (ANA, anti-Ro/La, serum IgG4, ACE/calcium).
- ▶ **Imaging:** renal ultrasound — **normal-sized or enlarged, echogenic kidneys**; chiefly excludes obstruction.
- ▶ **Kidney biopsy** — definitive; indicated when diagnosis is uncertain, AKI is severe/progressive, or before committing to steroids.

Management (d)

- ▶ **Withdraw the offending drug immediately — stop diclofenac.** This is the single most important step; AKI often reverses after withdrawal alone. Avoid *all* nephrotoxins (NSAIDs, contrast, aminoglycosides, ACE-I/ARB during the acute phase).
- ▶ **Supportive AKI care (KDIGO):** optimise volume/haemodynamics, maintain MAP >65 mmHg, treat the oedema/volume overload with **salt and water restriction + loop diuretics**, correct hyperkalaemia (calcium gluconate, insulin-dextrose, β -agonist, K^+ binders), treat metabolic acidosis (NaHCO_3 if pH <7.2 / HCO_3^- <15), renal-dose all drugs, ensure 20–30 kcal/kg/day nutrition.
- ▶ **Corticosteroids** — consider if **kidney function does not improve within ~5–7 days of drug withdrawal**, or if biopsy shows florid inflammation without established fibrosis; benefit falls if started >1–2 weeks after onset. Regimens:

Regimen	Dose
IV methylprednisolone pulse	0.25–0.5 g/day IV for 1–4 days
Oral prednisone	1 mg/kg/day ($\approx$ 60 mg/day) for 4–6 weeks, then taper
Duration	Continue 4–8 weeks if responding; taper off by 3–4 weeks if no response

- ▶ **Renal replacement therapy (dialysis)** if refractory volume overload, hyperkalaemia or acidosis, or uraemic complications — AEIOU: Acidosis, Electrolytes (K^+), Ingestions/toxins, Overload, Uraemia. Up to one-third of AIN patients need temporary dialysis before recovery.

- ▶ **Prognosis:** generally good — most recover over weeks to months; progression to ESRD is rare. Worse outcomes with prolonged oliguria, older age, delayed drug withdrawal and established interstitial fibrosis. Counsel lifelong avoidance of the culprit class.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Diagram 1 — Histology of AIN (label):** interstitial *oedema* separating tubules; *mononuclear (lymphocytic) interstitial infiltrate*; *eosinophils* (note: sparse/absent in NSAID-AIN); *tubulitis* (lymphocytes crossing the *tubular basement membrane*); *normal glomerulus*; *normal vessel*.
- ▶ **Diagram 2 — NSAID renal effects flow chart (label):** NSAID → ↓ *vasodilatory prostaglandins (PGE₂/PGI₂)* → branch 1: *afferent arteriolar vasoconstriction* → ↓ *GFR (pre-renal AKI)*; branch 2: *hapten* → *T-cell (type IV) hypersensitivity* → AIN; branch 3: *Na⁺/water retention* → *oedema, hypertension, hyperkalaemia*; branch 4: ± *minimal change disease* → *nephrotic syndrome*.

Clinical / Diagnostic significance

- ▶ **Drug history is diagnostic:** any unexplained AKI with a temporally-related drug = suspect AIN; empirical drug withdrawal is both diagnostic and therapeutic.
- ▶ **A bland urine never excludes AIN** — ~20% of biopsy-proven cases have normal sediment, and NSAID-AIN classically lacks fever/rash/eosinophilia.
- ▶ **Distinguish from the commoner NSAID pre-renal AKI** (responds to volume) and from glomerular disease (active sediment, heavy proteinuria) — this changes management.
- ▶ **Early diagnosis prevents fibrosis:** delay → tubular atrophy/interstitial fibrosis → irreversible CKD.

High-yield exam pointers

- ▶ AIN = 10–15% of intrinsic AKI; **drugs cause >70%**; *Councilman* first described AIN (1897).
- ▶ NSAID-AIN is “atypical”: long latency, fever/rash/eosinophilia rare, **eosinophils often absent on biopsy**, low-grade proteinuria — may combine with **minimal change disease (>membranous)** to cause nephrotic syndrome.
- ▶ **Pathology:** interstitial oedema + **mononuclear (T-cell) infiltrate** + **tubulitis**, glomeruli/vessels spared; type IV hypersensitivity.
- ▶ **Urine eosinophils are NOT useful** — do not order.
- ▶ **Biopsy = gold standard;** ultrasound shows normal/enlarged echogenic kidneys.
- ▶ **Treatment = STOP the drug first;** **corticosteroids** (methylprednisolone 0.25–0.5 g/day IV ×1–4 days or prednisone 1 mg/kg ≈60 mg/day ×4–6 weeks) if no recovery in ~5–7 days.
- ▶ **Dialysis (AEIOU)** in up to one-third; overall **good prognosis**, ESRD rare.

- Other AIN causes to list: β -lactams, sulfonamides, PPIs, rifampin, allopurinol, **checkpoint inhibitors**; Sjögren, SLE, sarcoid, IgG4, TINU; *Legionella*, *Leptospira*, hantavirus, BK virus, TB.

Acute Interstitial Nephritis

Asked in: Paper IV Nov 2021 — RGUHS MD General Medicine

Definition / Introduction — **Acute interstitial nephritis (AIN)** is an acute tubulointerstitial disorder characterised by inflammation and oedema of the renal *interstitium* with secondary tubular injury, while the **glomeruli and renal vessels are relatively spared**. *Councilman* (1897) originally described it as “an acute inflammation of the kidney characterised by cellular and fluid exudation in the interstitial tissue, accompanied by, but not dependent on, degeneration of the epithelium; the exudation is not purulent in character, and the lesions may be both diffuse and focal.” Today AIN is most often an **allergic (immune-mediated) reaction to a drug** and is an important, frequently reversible cause of acute kidney injury (AKI).

Etiology / Classification

AIN is conveniently grouped into **drug-induced (allergic)**, **infection-associated**, and **autoimmune/systemic** causes (Harrison Table 328-1):

Category	Representative causes
Antibiotics	β -lactams, sulfonamides, quinolones, vancomycin, erythromycin, linezolid, minocycline, rifampin, ethambutol, acyclovir
NSAIDs / COX-2 inhibitors	All NSAIDs; selective COX-2 inhibitors
Diuretics	Rarely thiazides, loop diuretics, triamterene

Category	Representative causes
Anticonvulsants	Phenytoin, valproate, carbamazepine, phenobarbital
Immune modulators	Immune checkpoint inhibitors, vedolizumab, lenalidomide
Miscellaneous drugs	Proton pump inhibitors (PPIs), H2 blockers, captopril, mesalazine, indinavir, allopurinol
Infection	Bacteria (<i>Streptococcus</i> , <i>Staphylococcus</i> , <i>Legionella</i> , <i>Salmonella</i> , <i>Brucella</i> , <i>Yersinia</i> , <i>C. diphtheriae</i>); Viruses (EBV, CMV, hantavirus, polyomavirus/BK , HIV); <i>Leptospira</i> , <i>Rickettsia</i> , <i>Mycoplasma</i> , <i>Histoplasma</i>
Autoimmune / systemic	TINU, Sjögren's syndrome, SLE, granulomatous interstitial nephritis, IgG4-related disease , checkpoint-inhibitor-related TIN, anti-brush border (anti-LRP2) disease, idiopathic autoimmune IN

- ▶ **Drug-induced AIN is the commonest form** and the reaction is *idiosyncratic* (not dose-dependent) — it may recur on re-exposure. *Particularly severe, rapid-onset AIN follows reintroduction of rifampin after a drug-free period.*
- ▶ NSAIDs, PPIs, mesalazine/sulfasalazine and antiretrovirals characteristically cause a more *insidious* reaction that may progress to chronic tubulointerstitial damage.

Pathogenesis

- ▶ AIN represents an **immune-mediated (hypersensitivity) reaction** rather than direct dose-dependent toxicity; the drug or microbial antigen triggers an inflammatory infiltrate that produces interstitial oedema, tubular-cell injury and compromised tubular flow.
- ▶ In some idiopathic and autoimmune cases, **autoantibodies to a tubular antigen** (e.g. collecting-duct or proximal-tubule brush-border antigens, *anti-LRP2/anti-brush border disease*) have been demonstrated, supporting an autoimmune mechanism.
- ▶ The aggressive inflammatory infiltrate (with **eosinophils, lymphocytes and mononuclear cells**) leading to tissue oedema accounts for the *acute* nature and the occasional **flank pain from distension of the renal capsule**.

Clinical Features

- ▶ **Classic triad/tetrad** (the *exception, not the rule*): **fever, rash (maculopapular), peripheral eosinophilia, and oliguric AKI** occurring 7–10 days after starting methicillin or another β -lactam.
- ▶ More commonly, the patient is found **incidentally to have a rising serum creatinine** or presents with non-specific symptoms of AKI.

- ▶ **NSAID-induced AIN is atypical:** fever, rash and eosinophilia are *rare*, but AKI is often accompanied by **heavy (nephrotic-range) proteinuria** (from coexistent minimal-change disease/secondary FSGS).
- ▶ Features of associated tubular dysfunction may occur — *Fanconi's syndrome*, distal/proximal RTA, type IV RTA and nephrogenic diabetes insipidus, especially when injury is prolonged.

Investigations / Diagnosis

- ▶ **Clinical diagnosis** rests on otherwise-unexplained AKI ($\pm$ oliguria) with **temporally-related exposure to an offending agent**.
- ▶ **Urinalysis:** *pyuria (sterile) with white-blood-cell casts and haematuria*; modest proteinuria. Urinary eosinophils are **neither sensitive nor specific** — **testing is NOT recommended**.
- ▶ **Peripheral blood eosinophilia** supports the diagnosis but is present in only a minority.
- ▶ **Renal ultrasound** may show enlarged, echogenic kidneys (“medical renal disease”).
- ▶ **Kidney biopsy** is *generally not required* but is the gold standard when the diagnosis is uncertain or the course atypical — it shows **extensive interstitial and tubular infiltration by leukocytes, including eosinophils**, interstitial oedema separating tubules, with a *normal glomerulus*. Granulomas suggest granulomatous IN; dense IgG4-plasma-cell infiltrate suggests IgG4 disease.
- ▶ Biopsy-proven AIN accounts for **~15% of cases of unexplained AKI** (likely an underestimate, as drugs are often empirically stopped without biopsy).

Important Non-Drug / Systemic Forms

- ▶ **Tubulointerstitial nephritis with uveitis (TINU):** <5% of AIN; **females 3× > males**, median age **15 years**. Lymphocyte-predominant IN + **painful anterior uveitis** (often bilateral, with blurred vision/photophobia); ocular symptoms coincide with renal disease in only **one-third**. Sterile pyuria, mild proteinuria, Fanconi features, **raised ESR**; a diagnosis of exclusion. Self-limited in children, relapsing in adults.
- ▶ **Sjögren's syndrome:** lymphocytic TIN with distal RTA and nephrogenic DI; **anti-Ro (SS-A)/anti-La (SS-B)** positive, polyclonal hypergammaglobulinaemia.
- ▶ **SLE:** interstitial mononuclear infiltrate accompanies class III/IV lupus nephritis; may present with azotaemia and type IV RTA.
- ▶ **Granulomatous IN:** protracted/relapsing; biopsy shows granulomas and multinucleated giant cells (e.g. *sarcoidosis*); **rule out tuberculosis before steroids**.
- ▶ **IgG4-related systemic disease:** IgG4-plasma-cell infiltrate with autoimmune pancreatitis, sclerosing cholangitis, retroperitoneal fibrosis, sialadenitis; steroid-responsive.
- ▶ **Immune checkpoint-inhibitor AIN:** kidney involved in **2% (monotherapy) up to 5% (dual therapy)**; creatinine usually rises **within ~15 weeks**; treat by holding the drug + steroids.

- ▶ **Infection-associated AIN:** distinct from acute pyelonephritis; seen mainly in immunocompromised/transplant patients (**BK polyomavirus reactivation**); a rise in TIN/TINU in children has followed SARS-CoV-2.

Treatment

- ▶ **Prompt withdrawal of the offending drug** is the cornerstone and often leads to recovery of kidney function. Recovery may be **incomplete** if exposure was prolonged (tubular atrophy/interstitial fibrosis).
- ▶ **Supportive care:** management of AKI, fluid/electrolyte and acid-base correction, and **dialysis** when indicated. *Delay in initiating dialysis worsens long-term outcomes.*
- ▶ **Glucocorticoids** may accelerate recovery but are **not required in most cases**; reserve for severe injury when dialysis is imminent, and start promptly if function continues to deteriorate despite stopping the drug (Harrison Fig. 328-1 algorithm).
- ▶ **Relapsing/refractory or immune-mediated AIN** may need maintenance immunosuppression — azathioprine, mycophenolate mofetil or methotrexate.

Indications for corticosteroids / immunosuppressives (Table 328-2):

Absolute indications	Relative indications
Sjögren's syndrome	Drug-induced or idiopathic AIN with rapid progression of renal failure
Sarcoidosis	Diffuse infiltrates on biopsy
SLE interstitial nephritis	Impending need for dialysis
Adults with TINU	Delayed recovery
IgG4-related interstitial nephritis	Children with TINU
Idiopathic & other granulomatous IN	Post-infectious AIN with delayed recovery (?)

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Histology of AIN (PAS-stained section):** label — *interstitial mononuclear-cell infiltrate (eosinophils/lymphocytes), interstitial oedema separating the tubules (T), normal glomerulus (G), tubules with cellular debris.*
- ▶ **Treatment algorithm (Fig. 328-1):** boxes — *AKI with features of AIN → withdraw offending agent + supportive care/close observation → improvement (continue observation) OR no improvement in 1 week / rapid progression → classic allergic AIN (corticosteroids) vs atypical features (renal biopsy) → granulomatous/immune IN (immunosuppressive drugs) vs fibrosis (conservative).*

Clinical / Diagnostic significance

- ▶ AIN is a **potentially reversible cause of AKI** — early recognition and **drug withdrawal** are pivotal; missing it leads to progression to CKD via interstitial fibrosis and secondary FSGS.
- ▶ A **high index of suspicion** is needed because the classic allergic syndrome is uncommon; consider AIN in any unexplained creatinine rise with sterile pyuria/WBC casts and a recent new drug.
- ▶ **Recognise atypical NSAID-induced AIN** (nephrotic proteinuria, no allergic features) and **PPI-associated** insidious AIN, given how widely these drugs are used.
- ▶ Distinguish AIN from **acute pyelonephritis** (which causes AKI only if bilateral or with septic shock) and from **crystal/obstructive tubulopathies** (sulfadiazine, indinavir/atazanavir, acyclovir, urate, oxalate).

High-yield exam pointers

- ▶ **Most common cause = drugs**; classic offenders are β -lactams, NSAIDs, PPIs, rifampin, sulfonamides, allopurinol.
- ▶ **Reaction is idiosyncratic, not dose-related**; rifampin re-exposure causes severe rapid AIN.
- ▶ **Classic tetrad** — fever, rash, eosinophilia, AKI 7–10 days post- β -lactam — is the *exception*.
- ▶ **Urine**: sterile pyuria + **WBC casts** + haematuria; **urinary eosinophils not recommended** (poor sensitivity/specificity).
- ▶ **Biopsy** = interstitial leukocyte infiltrate with eosinophils, oedema, **normal glomeruli**.
- ▶ **TINU** = young female, anterior uveitis, raised ESR; **Sjögren's** = anti-Ro/anti-La, distal RTA.
- ▶ **Treatment** = stop the drug first; **steroids not routine**, reserved for severe/immune-mediated disease; maintenance with azathioprine/MMF for relapsers.
- ▶ AIN explains ~15% of unexplained AKI cases.

SOURCE & COVERAGE

Harrison's Principles of Internal Medicine, 22e — **Ch 328 "Tubulointerstitial Diseases of the Kidney"** (Beck & Salant), including Tables 328-1 (causes) and 328-2 (steroid indications) and Figs 328-1/328-2. *Coverage note:* The provided chapter frames AIN as an "allergic/immune-mediated" reaction with autoantibodies to tubular antigens but does not explicitly classify the mechanism as *type-IV (delayed/cell-mediated) hypersensitivity*; the dose-independent idiosyncratic framing in the Pathogenesis section is standard, universally-accepted internal medicine and is consistent with the chapter's wording.

Acute Kidney Injury

Asked in: Paper IV Jul 2020 — RGUHS MD General Medicine

Definition / Introduction — Acute kidney injury (AKI) is the abrupt impairment of kidney filtration and excretory function over hours to days (generally within 7 days), causing retention of nitrogenous and other waste products normally cleared by the kidney. The **KDIGO** definition is a rise in serum creatinine (SCr) of ≥ 0.3 mg/dL within 48 h, OR a rise to ≥ 1.5 times baseline known/presumed within 7 days, OR urine output < 0.5 mL/kg/h for > 6 h. AKI is a *clinical and not a structural* diagnosis — the kidney may have functional impairment with or without parenchymal injury — and ranges from asymptomatic biochemical change to life-threatening failure of volume, electrolyte and acid–base homeostasis. It complicates 5–7% of hospital admissions and up to 30% of ICU admissions, and is an independent risk factor for incident/progressive CKD, cardiovascular disease and death.

Classification and staging

- ▶ Three traditional anatomic-physiological categories: **prerenal azotemia** (commonest), **intrinsic renal disease**, and **postrenal (obstructive) AKI**.
- ▶ Severity is staged by the magnitude of SCr rise and the severity/duration of oliguria. Predecessor consensus systems were **RIFLE** (*Risk, Injury, Failure, Loss, End-stage*) and **AKIN** (Acute Kidney Injury Network); the current unifying system is **KDIGO**.

Stage	Serum creatinine	Urine output
1	1.5–1.9 × baseline OR ≥ 0.3 mg/dL (≥ 26.5 $\mu\text{mol/L}$) increase	< 0.5 mL/kg/h for 6–12 h
2	2.0–2.9 × baseline	< 0.5 mL/kg/h for ≥ 12 h
3	≥ 3.0 × baseline OR SCr ≥ 4.0 mg/dL OR initiation of RRT OR (age < 18 y) eGFR < 35 mL/min/1.73 m ²	< 0.3 mL/kg/h for ≥ 24 h OR anuria ≥ 12 h

Etiology and pathophysiology

- ▶ **Prerenal azotemia** (~40–80% of community AKI): inadequate renal plasma flow/intraglomerular pressure with *no parenchymal damage* — rapidly reversible once perfusion is restored. Causes: hypovolemia (haemorrhage, GI losses, diuresis, burns, third-spacing), low cardiac output, and reduced effective circulating volume (heart failure, cirrhosis, sepsis). Drugs impair autoregulation: **NSAIDs** block vasodilatory prostaglandins (afferent constriction) and **ACE-inhibitors/ARBs** block efferent constriction — combined use is especially high-risk, as is bilateral renal artery stenosis. *Hepatorenal syndrome* (splanchnic vasodilation in advanced cirrhosis) is a diagnosis of exclusion in this group. Prolonged prerenal ischaemia progresses to **acute tubular necrosis (ATN)**.
- ▶ **Intrinsic AKI** — by site:
 - *Tubular (ATN, ~85% of intrinsic AKI): ischaemia, sepsis, nephrotoxins.* The S3 segment of the proximal tubule in the outer medulla is most vulnerable (dependence on fatty-acid

oxidation/oxidative phosphorylation, venous-derived blood supply, hypoxic medulla).

Ischaemic ATN evolves through **initiation** → **extension (endothelial injury, medullary congestion)** → **maintenance** → **recovery** phases; mechanisms include vasoconstriction, loss of cell polarity (apical mislocalisation of Na^+/K^+ -ATPase → high FeNa), cytoskeletal breakdown, tubular obstruction by casts, and back-leak of filtrate.

- *Nephrotoxic — exogenous*: iodinated **contrast** (CI-AKI; SCr rises 24–48 h, peaks 3–5 d, recovers ~7 d), **aminoglycosides** (nonoliguric AKI in 10–30%, manifests after 5–7 d, hypomagnesaemia), **amphotericin B** (polyuria, hypomagnesaemia, hypocalcaemia, non-gap acidosis), **cisplatin**, vancomycin, tenofovir, **acyclovir/methotrexate/sulfadiazine** (intratubular crystals).
- *Nephrotoxic — endogenous*: **rhabdomyolysis** (myoglobin), haemolysis (haemoglobin), **tumour lysis syndrome** (uric acid often >15 mg/dL, hyperkalaemia, hyperphosphatemia), myeloma light chains, hypercalcaemia.
- *Glomerular (~5%)*: glomerulonephritis/vasculitis — important to recognise early as immunosuppression/plasma exchange may reverse it.
- *Interstitial*: allergic/acute interstitial nephritis (drugs ~75% — antibiotics, PPIs, NSAIDs, immune-checkpoint inhibitors), infection, infiltration.
- *Vascular*: thrombotic microangiopathies (**TTP/HUS**, scleroderma renal crisis, malignant hypertension), atheroembolic disease, renal artery/vein occlusion.
- ▶ **Postrenal AKI (~5–10%)**: obstruction anywhere from renal pelvis to urethra. For significant SCr rise, obstruction must be bilateral (or unilateral in a solitary/CKD kidney). Causes: bladder outlet obstruction (BPH, prostate cancer, neurogenic bladder, blocked catheter), bilateral ureteric stones/clots/papillae, retroperitoneal fibrosis or pelvic malignancy. Early relief usually reverses injury.

Diagnostic evaluation

- ▶ **First steps**: distinguish AKI from CKD (small echogenic kidneys, normocytic anaemia, renal osteodystrophy favour CKD; normal-sized kidneys favour AKI), then localise to prerenal/intrinsic/postrenal. Review every drug; exclude obstruction with bladder catheter and **renal ultrasound/CT** (hydronephrosis).
- ▶ **Urine output**: oliguria = <400 mL/24 h (denotes more severe AKI, worse prognosis). Complete anuria suggests complete obstruction, renal artery occlusion, overwhelming septic shock, cortical necrosis, or severe proliferative GN/vasculitis.
- ▶ **Urine sediment (Fig. 321-6)**: bland/hyaline casts → prerenal or postrenal; **pigmented “muddy-brown” granular and renal tubular epithelial cell casts** → ATN; dysmorphic RBCs/RBC casts → glomerulonephritis; WBC casts/eosinophiluria → interstitial nephritis; uric acid or oxalate crystalluria → tumour lysis or ethylene-glycol toxicity.

► Renal failure (differential) indices:

Index	Prerenal	Intrinsic (ATN)
BUN : creatinine ratio	>20 : 1	<20 : 1
$\text{FeNa} = (\text{UNa} \times \text{PCr}) / (\text{PNa} \times \text{UCr}) \times 100$	<1%	>1–2%
Urine Na^+ (mEq/L)	<20	>20
Urine osmolality (mOsm/kg)	>500	<350 (isosthenuria)
Urine specific gravity	>1.018	~1.010

Caveats: FeNa is most useful in **oliguric, diuretic-free, non-CKD** patients; it may be <1% even in intrinsic AKI from **sepsis (early), contrast, rhabdomyolysis** and glomerulonephritis. After diuretics, **fractional excretion of urea (FeUrea, <35% suggests prerenal)** is more reliable.

- **Blood tests:** hyperkalaemia, hyperphosphatemia, hypocalcaemia, high anion-gap metabolic acidosis; $\uparrow$ CK/uric acid (rhabdomyolysis), low anion gap (myeloma cationic proteins), schistocytes/ $\uparrow$ LDH/low haptoglobin/thrombocytopenia (TMA — check ADAMTS13, Shiga toxin, complement). Immunological panel where indicated: ANA, ANCA, **anti-GBM**, complement, ASO, cryoglobulins, serum free light chains.
- **Novel biomarkers:** NGAL (detectable within 2 h of cardiopulmonary bypass), KIM-1, cystatin C, suPAR, and the FDA-cleared cell-cycle-arrest pair TIMP-2 $\times$ IGFBP7 (**NephroCheck**) for risk of moderate–severe AKI in the critically ill. **Furosemide stress test** (1.0–1.5 mg/kg IV; urine <200 mL over 2 h) predicts progression/need for RRT.
- **Kidney biopsy:** reserved for when prerenal, postrenal and ischaemic/nephrotoxic ATN are unlikely and treatable diagnoses (GN, vasculitis, AIN, myeloma, TTP/HUS) are considered.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- **Classification flow-chart of AKI** — central box “Acute Kidney Injury” branching to three columns: *Prerenal* (hypovolemia, low cardiac output, low effective circulating volume — CHF/cirrhosis, impaired autoregulation — NSAIDs/ACE-I/ARB); *Intrinsic* (Glomerular: acute GN; Vascular: vasculitis, malignant HTN, TTP-HUS; Tubular/interstitial: ischaemia, sepsis, nephrotoxins — exogenous contrast/aminoglycoside/cisplatin, endogenous haemolysis/rhabdomyolysis/myeloma); *Postrenal* (bladder-outlet obstruction, bilateral pelviureteric obstruction). Label arrows.
- **Pathophysiology of ischaemic AKI** — interacting *Microvascular* limb (vasoconstriction: endothelin, adenosine, angiotensin II, thromboxane A_2 ; $\downarrow$ vasodilators: NO, PGE_2 ; endothelial damage; leukocyte–endothelial adhesion) and *Tubular* limb (cytoskeletal

breakdown, loss of polarity, apoptosis/necrosis, desquamation → **tubular obstruction + back-leak** → fall in GFR. Mark the vulnerable **S3 segment/outer medulla**.

Clinical / Diagnostic significance

- **Complications (mnemonic of the kidney's homeostatic roles):** volume overload/pulmonary oedema, **hyperkalaemia** (most dangerous — arrhythmia; worst in rhabdomyolysis/haemolysis/tumour lysis), high-anion-gap metabolic acidosis, hyperphosphatemia with hypocalcaemia, hyponatremia, **uremia** (encephalopathy, asterixis, pericarditis, platelet dysfunction/bleeding), anaemia, infection and malnutrition (hypercatabolic state).
- **General management (Table 321-3):** optimise systemic/renal haemodynamics with volume resuscitation (**crystalloids preferred**; 0.9% saline or balanced solutions; packed cells for haemorrhage) and judicious vasopressors to keep **MAP >65 mmHg**; **stop/avoid nephrotoxins** (NSAIDs, ACE-I/ARB, aminoglycosides, contrast, checkpoint inhibitors) and **renally dose all drugs**; nutrition **20–30 kcal/kg/day**, protein 0.8–1.0 g/kg/day (non-catabolic), 1.0–1.5 (on dialysis), up to 1.7 (hypercatabolic on CRRT).
- **Cause-specific:** *rhabdomyolysis* — aggressive IV fluids (may need up to 10 L/day), consider alkaline diuresis (risk hypocalcaemia); *tumour lysis* — IV fluids + **allopurinol or rasburicase**; *hepatorenal syndrome* — albumin + **terlipressin** (or noradrenaline, or octreotide + midodrine), definitive treatment **liver transplant**; *scleroderma renal crisis* — **ACE inhibitors**; *idiopathic TTP* — urgent plasma exchange; *atypical HUS* — complement blockade (eculizumab); *postrenal* — prompt catheter/stent/nephrostomy (watch for post-obstructive diuresis).
- **Hyperkalaemia ladder:** calcium gluconate (membrane stabilisation) → insulin–glucose and inhaled β -agonist (intracellular shift) → loop diuretic, K^+ -binders (sodium zirconium cyclosilicate, patiromer, SPS) → dialysis.
- **Renal replacement therapy — indications “AEIOU”:** Acid–base disturbance (refractory acidosis), Electrolyte disturbance (refractory hyperkalaemia), Intoxication (dialysable poison), Overload (volume, diuretic-unresponsive), Uremic complications (encephalopathy, pericarditis, bleeding). Modalities: intermittent haemodialysis; **CRRT** (CVVH/CVVHD/CVVHDF — preferred in haemodynamic instability, cerebral oedema, marked volume overload); SLED/EDD; peritoneal dialysis. Trials (e.g. **STARRT-AKI**) show no survival benefit from earlier/more-intensive RRT — initiate for indications, not arbitrary timing.

High-yield exam pointers

- KDIGO triad: $SCr \uparrow \geq 0.3 \text{ mg/dL/48 h}$ OR $\geq 1.5 \times$ baseline/7 d OR $UO < 0.5 \text{ mL/kg/h} > 6 \text{ h}$.
- Prerenal is commonest; $FeNa < 1\%$, $BUN:Cr > 20$, urine osm > 500 , bland/hyaline casts; ATN — $FeNa > 1\text{--}2\%$, **muddy-brown granular casts**.

- ▶ $\text{FeNa} = (\text{UNa} \times \text{PCr}) / (\text{PNa} \times \text{UCr}) \times 100$; unreliable on diuretics → use **FeUrea** (<35% = prerenal).
- ▶ **S3 proximal tubule / outer medulla** is the most ischaemia-susceptible segment; ATN phases = initiation–extension–maintenance–recovery.
- ▶ NSAID + ACE-I/ARB combination and bilateral renal artery stenosis are classic precipitants of prerenal AKI.
- ▶ Anuria differential: complete obstruction, renal artery occlusion, septic shock, cortical necrosis, severe proliferative GN/vasculitis.
- ▶ Most dangerous complication = **hyperkalaemia**; commonest dialysis indication categories = AEIOU.
- ▶ Low-dose dopamine, fenoldopam, ANP, loop diuretics do **not** prevent or hasten recovery from established ATN.
- ▶ Biomarkers: NGAL, KIM-1, cystatin C, **TIMP-2 × IGFBP7 (NephroCheck)**; furosemide stress test predicts progression.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Acute Kidney Injury” (Waikar & Bonventre): KDIGO definition/staging, etiologic classification, pathophysiology, diagnostic indices, complications, and management (Tables 321-1, 321-2, 321-3; Figs 321-1 to 321-6).
- ▶ **Brenner & Rector's The Kidney** — “Pathophysiology of Acute Kidney Injury”: RIFLE/AKIN/KDIGO context, S3-segment vulnerability, extension-phase microvascular/endothelial injury, Na^+/K^+ -ATPase mislocalisation and high FeNa in ATN.
- ▶ **CMDT 2026** — “Kidney Disease” (AKI / Acute Tubular Necrosis): prerenal/intrinsic/postrenal percentages, FeNa formula and caveats, FeUrea, furosemide stress test, AEIOU dialysis indications, three-phase ATN course and prognosis.

Acute renal failure in Tropics

Asked in: Paper IV May 2022 — RGUHS MD General Medicine

Definition / Introduction — Acute renal failure (now termed **acute kidney injury, AKI**) is an abrupt (hours–days) decline in glomerular filtration rate with retention of nitrogenous wastes and dysregulation of fluid, electrolyte and acid–base balance. *Tropical AKI* is not a separate disease but a distinct **epidemiological pattern**: in the developing world many etiologies are region-specific — **envenomations** (snakes, spiders, caterpillars, bees), **infections** such as **malaria** and **leptospirosis**, and **crush injury/rhabdomyolysis** — and resources to diagnose and treat AKI are often limited. It is typically

community-acquired, affects young previously healthy patients, is frequently single-cause and potentially fully reversible, but carries high mortality where dialysis is unavailable.

Why tropical AKI is distinct (epidemiology)

- ▶ AKI is a **major medical complication in the developing world**; its epidemiology differs from developed countries because of **differences in demographics, economics, environmental factors and the comorbid disease burden**.
- ▶ As urban centres of developing countries increasingly resemble those of the developed world, **hospital-acquired AKI** (sepsis, major surgery, critical illness, nephrotoxins) is rising and now coexists with the classic community-acquired tropical pattern.
- ▶ Region-specific etiologies explicitly named by Harrison: **envenomations from snakes, spiders, caterpillars and bees; infectious causes such as malaria and leptospirosis; and crush injuries with rhabdomyolysis** (e.g., after earthquakes).
- ▶ **Resources to diagnose and manage AKI are often limited**, so prevention, early recognition and timely renal replacement are the principal determinants of outcome.

Classification of causes (anatomical framework applied to the tropics)

The standard three-tier classification (Fig. 321-1) maps neatly onto tropical disease:

Category	General mechanism	Tropical examples (mapped)
Prerenal azotemia	Reduced renal perfusion, no parenchymal damage, rapidly reversible	Acute gastroenteritis/cholera, vomiting/diarrhoea, haemorrhage, sepsis, dehydration
Intrinsic (parenchymal)	Sepsis, ischaemia, endogenous/exogenous nephrotoxins	Sepsis-associated AKI , malaria, leptospirosis, snakebite, pigment nephropathy (rhabdomyolysis, haemolysis), viral infection, acute interstitial nephritis from traditional/herbal remedies
Postrenal (obstructive)	Obstruction to urine flow	Stone disease, schistosomal/genitourinary obstruction, retroperitoneal pathology

- ▶ **Prerenal azotemia is the commonest form of AKI overall**; prolonged hypoperfusion (common with diarrhoeal dehydration) progresses to **ischaemic acute tubular necrosis (ATN)**.
- ▶ **Sepsis complicates >50% of severe sepsis cases** and “is also a very important cause of AKI in the developing world”; reduced urine output is common and GFR can fall even without overt hypotension.

Major tropical syndromes and mechanisms

Syndrome	Renal injury mechanism	Renal lesion / clue
Severe malaria (<i>P. falciparum</i>)	Microvascular sequestration, intravascular haemolysis → haemoglobinuria (pigment nephropathy), volume depletion, sepsis-like cytokine state	ATN; <i>blackwater fever</i> with dark urine; often oliguric
Leptospirosis (<i>Weil's disease</i>)	Direct tubulointerstitial injury, hypovolaemia, jaundice-associated tubular toxicity	Classically non-oliguric , hypokalaemic AKI with jaundice
Snake/other envenomation	Haemolysis, DIC, rhabdomyolysis (myotoxic venom), hypotension, direct nephrotoxicity	ATN; severe cases → renal cortical necrosis
Rhabdomyolysis (crush, exertional, heatstroke, seizures, infections)	Myoglobin release → intrarenal vasoconstriction, direct tubular toxicity, intratubular cast obstruction	Pigmented granular casts; CK and myoglobin elevated ; urine heme-positive with few RBCs; FeNa may be <1%
Sepsis-associated AKI	Arterial vasodilation (inducible NO synthase), inflammation, mitochondrial dysfunction, interstitial oedema	Granular and renal tubular epithelial cell casts; positive cultures
Viral infections	Incompletely understood; pigment/haemodynamic/inflammatory injury	AKI complicates hantavirus, dengue virus, and SARS-CoV-2 ; “typical” diarrhoea-associated HUS from Shiga-toxin <i>E. coli</i>
Obstetric AKI	Septic abortion, haemorrhage, eclampsia, thrombotic microangiopathy	Pregnancy/postpartum TTP-HUS; severe cases → bilateral cortical necrosis

Pathophysiology of pigment (haem) nephropathy — a tropical mainstay

Pigment-induced AKI underlies malaria (haemoglobin), haemolysis (incl. G6PD-related, transfusion reaction) and rhabdomyolysis (myoglobin), and is grounded directly in the chapter:

- ▶ **Myoglobin** is released by injured muscle; **haemoglobin** is released during massive haemolysis — both produce **pigment nephropathy**.
- ▶ Three converging mechanisms: (1) **intrarenal vasoconstriction**; (2) **direct proximal tubular toxicity**; (3) **mechanical obstruction of the distal nephron** when myoglobin/haemoglobin precipitates with **Tamm-Horsfall protein (uromodulin)** — a process favoured by **acidic urine** (rationale for urinary alkalinisation).
- ▶ Causes of rhabdomyolysis listed: traumatic crush injuries, muscle ischaemia, compression during coma/immobilisation, prolonged seizures, excessive exercise, **heat stroke or malignant**

hyperthermia, infections, metabolic disorders and myopathies — many of which are common in tropical/field settings.

Clinical approach and investigations

- ▶ **History:** fluid loss (diarrhoea, vomiting, haemorrhage), fever, animal bite, dark/cola-coloured urine, drug/herbal exposure, recent pregnancy/abortion, oliguria/anuria.
- ▶ **Examination of volume status:** tachycardia, postural/absolute hypotension, low JVP, dry mucous membranes (prerenal); features of sepsis, jaundice, bleeding.
- ▶ **Urinalysis** is pivotal:
 - **Pigmented “muddy-brown” granular casts and tubular epithelial cell casts** → ATN/sepsis-associated AKI.
 - **Urine dipstick heme-positive with few RBCs** → rhabdomyolysis or haemolysis (pigment nephropathy).
 - Bland sediment with **FeNa <1%, urine osmolality >500 mOsm/kg, BUN/creatinine >20** → prerenal.
- ▶ **Blood:** serum creatinine/BUN, electrolytes (**hyperkalaemia is particularly common in rhabdomyolysis and haemolysis**), **creatinine kinase and myoglobin** (rhabdomyolysis), uric acid, LDH/haptoglobin (haemolysis), cultures, peripheral smear (malaria parasites, schistocytes).
- ▶ **Imaging/biopsy:** ultrasound to exclude obstruction and assess kidney size; kidney biopsy reserved for suspected glomerulonephritis/vasculitis/cortical necrosis or diagnostic uncertainty.

Management

General principles common to all AKI (Table 321-3): optimise haemodynamics, correct fluid/electrolyte/acid–base disturbances, **stop nephrotoxic drugs**, dose-adjust all renally-cleared drugs, ensure **20–30 kcal/kg per day** nutrition (protein 0.8–1.0 g/kg in non-catabolic, up to ~1.7 g/kg with hypercatabolism on CRRT), and start renal replacement therapy when indicated.

- ▶ **Prerenal / volume depletion (diarrhoeal AKI):** restore perfusion; **intravascular hypovolaemia is the only indication for fluids** (oliguria alone is not). Replace with crystalloid (commonly **0.9% saline**, or buffered solutions — Ringer’s lactate/Hartmann’s/Plasma-Lyte); transfuse **packed RBCs** for severe acute blood loss.
- ▶ **Rhabdomyolysis / pigment nephropathy:** **early and aggressive volume repletion is mandatory** — may require up to **10 L of fluid per day**; **alkaline fluids** (e.g., **75 mmol/L sodium bicarbonate in 0.45% saline**) may reduce tubular injury and cast formation (consider **forced alkaline diuresis**), but watch for **worsening hypocalcaemia**; diuretics only after adequate repletion, targeting urine flow **200–300 mL/h**. There is no specific therapy for established AKI other than supportive care/dialysis; monitor **calcium and phosphate** closely.

- ▶ **Sepsis-associated AKI:** source control, antimicrobials, restore perfusion with vasopressors as needed; no specific therapy once tubular injury is established — meticulous supportive care.
- ▶ **Electrolyte/acid–base emergencies:**
 - **Hyperkalaemia** — calcium gluconate/chloride (1 g) to stabilise the myocardium, **insulin–glucose** and inhaled β -agonist to shift K^+ intracellularly, loop diuretics, K^+ -binders (**sodium zirconium cyclosilicate, patiomer, polystyrene sulfonate**); stop ACEi/ARB/NSAIDs/ K^+ -sparing diuretics.
 - **Metabolic acidosis** — sodium bicarbonate if pH <7.2 / bicarbonate <15 mmol/L, avoiding overcorrection.
 - **Volume overload** — salt/water restriction, **furosemide bolus (200 mg) then 10–40 mg/h** $\pm$ thiazide, ultrafiltration if refractory.
- ▶ **Renal replacement therapy (RRT):** indicated for **refractory volume overload, hyperkalaemia or acidosis, certain toxic ingestions, and severe uraemic complications** (asterixis, pericardial rub/effusion, encephalopathy, uraemic bleeding). Many initiate empirically when **BUN exceeds ~100 mg/dL** without signs of recovery; early-vs-late initiation has not improved survival in RCTs but RRT should not await a life-threatening complication. Modalities: intermittent **haemodialysis** (3–4 h, 3–4 $\times$ /week), **continuous (CRRT)** for haemodynamically unstable patients, and **peritoneal dialysis** — the latter especially valuable in resource-limited tropical settings.
- ▶ **Postrenal:** prompt relief of obstruction (bladder catheter, ureteric stent or percutaneous nephrostomy); anticipate post-obstructive diuresis.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Diagram 1 — Classification of AKI mapped to tropical causes (flowchart).** Top box: *Acute Kidney Injury*. Three branches: **Prerenal** (labels: *Hypovolaemia — diarrhoea/cholera, haemorrhage; decreased effective circulating volume; sepsis*), **Intrinsic** (labels: *Sepsis/infection; Ischaemic ATN; Endogenous nephrotoxins — myoglobin, haemoglobin; Glomerular — GN/vasculitis; Vascular — TTP-HUS, cortical necrosis; Tropical: malaria, leptospirosis, snakebite, dengue/hantavirus*), **Postrenal** (labels: *Bladder outlet / bilateral ureteric obstruction*).
- ▶ **Diagram 2 — Pathophysiology of pigment nephropathy.** Labels: *Muscle injury / haemolysis $\rightarrow$ myoglobin / haemoglobin $\rightarrow$ (1) intrarenal vasoconstriction, (2) direct proximal tubular toxicity, (3) precipitation with Tamm-Horsfall protein (uromodulin) in acidic urine $\rightarrow$ distal tubular obstruction $\rightarrow$ ATN; arrow to “urinary alkalinisation + volume repletion” as the therapeutic interruption point.*

Clinical / Diagnostic significance

- ▶ **Reversibility:** community-acquired tropical AKI in young patients often recovers fully — the kidney has “remarkable capacity to repair itself” even after dialysis-requiring AKI — so aggressive early support is justified.
- ▶ **Urinary sediment + FeNa + CK/myoglobin** rapidly separate prerenal, ATN and pigment nephropathy at the bedside, guiding fluid and alkalinisation decisions.
- ▶ **Pregnancy/obstetric AKI and severe envenomation** carry a risk of **bilateral renal cortical necrosis**, which may leave permanent CKD/ESKD — a recognised tropical pattern.
- ▶ **AKI predisposes to CKD and to sepsis**, and superimposed AKI on CKD often heals by maladaptive repair — flag survivors for nephrology follow-up.
- ▶ **Peritoneal dialysis** is a practical, low-resource RRT modality central to tropical/rural practice.

High-yield exam pointers

- ▶ Tropical AKI = **community-acquired, young, single-cause, reversible, high mortality without dialysis**; Harrison’s named triad — **envenomation, malaria/leptospirosis, crush rhabdomyolysis**.
- ▶ **Prerenal azotaemia is the commonest AKI**; diarrhoeal dehydration is the prototypic tropical prerenal → ATN sequence.
- ▶ **Pigment nephropathy** trio of mechanisms: vasoconstriction, direct tubular toxicity, **Tamm-Horsfall (uromodulin) cast obstruction favoured by acidic urine** → treat with **volume + urinary alkalinisation**.
- ▶ **Leptospirosis** → classically **non-oliguric, hypokalaemic** AKI with jaundice (a favourite distinguishing point).
- ▶ **Rhabdomyolysis**: CK/myoglobin high, **heme-positive urine with few RBCs**, hyperkalaemia/hyperphosphataemia/hypocalcaemia; fluids up to **10 L/day**, alkaline fluid **75 mmol/L NaHCO₃ in 0.45% saline**, urine target **200–300 mL/h**.
- ▶ **Hyperkalaemia first move** = **IV calcium (1 g) to stabilise myocardium**, then insulin-glucose/β-agonist/binders.
- ▶ **Viral tropical AKI**: hantavirus, dengue, SARS-CoV-2; **Shiga-toxin (E. coli) typical HUS** after diarrhoeal prodrome.
- ▶ **Dialysis** for refractory volume/K⁺/acidosis or uraemic complications; empirical when **BUN >~100 mg/dL**; **peritoneal dialysis** is invaluable where resources are scarce.
- ▶ **No proven pharmacotherapy** reverses established ATN (dopamine, ANP, EPO etc. have all failed) — management is supportive + RRT.

SOURCE & COVERAGE

Harrison’s Principles of Internal Medicine, 22e (2025) — Ch 321 “Acute Kidney Injury” (AKI in the developing world; classification; sepsis-, ischaemia- and pigment-associated AKI;

prevention/treatment, supportive measures, RRT indications/modalities). *Coverage note (gap flagged)*: Ch 321 names the **tropical etiologies** (snake/insect envenomation, malaria, leptospirosis, crush rhabdomyolysis, dengue/hantavirus/SARS-CoV-2, diarrhoeal HUS) and grounds the **pathophysiology of pigment nephropathy and all management figures/doses** used above, but it does **not** detail the disease-specific mechanisms (e.g., *blackwater fever* of falciparum malaria, *Weil's disease* non-oliguric hypokalaemic AKI, snake-venom DIC/myotoxicity, obstetric cortical necrosis, G6PD-related haemolysis). Those points are standard, universally-accepted internal medicine drawn from the dedicated infectious-disease/toxicology chapters not provided in this task and should be cross-checked against Harrison's malaria, leptospirosis and envenomation chapters for full marks.

Autosomal Dominant Polycystic Kidney Disease

Asked in: Paper IV Nov 2022 — RGUHS MD General Medicine

Definition / Introduction — Autosomal dominant polycystic kidney disease (ADPKD) is a genetically heterogeneous, multisystem disorder characterised by progressive, bilateral formation of epithelial-lined cysts in the kidneys, leading to massive renal enlargement and a leading cause of kidney failure. It is the **most common life-threatening monogenic disease**, affecting an estimated **12 million people worldwide** (prevalence 1:1000 to 1:400). It is caused by germline mutations in **PKD1** (polycystin-1) or **PKD2** (polycystin-2), is inherited as an autosomal dominant trait with *complete penetrance but variable expressivity*, and belongs to the family of **ciliopathies**.

Genetics and Molecular Biology

- ▶ **PKD1** — chromosome **16p13** (localised 1985, near the alpha-globin gene); 46 exons, ~52 kb genomic DNA; ~14 kb transcript encoding **polycystin-1 (PC1)**, a large ~4300-amino-acid, **11-transmembrane** protein that behaves like a **G protein-coupled receptor (GPCR)**. Accounts for ~85% of cases; more severe phenotype, earlier ESRD.
- ▶ **PKD2** — chromosome **4q21-q23** (mapped 1993); single-copy gene, 15 exons; ~5.3 kb mRNA encoding **polycystin-2 (PC2)**, a 968-amino-acid, **six-transmembrane, calcium-permeable** protein of the **transient receptor potential (TRP)** cation channel family. Accounts for ~15% (probably more, as milder disease is under-diagnosed); later onset, slower progression.
- ▶ **Minor genes** — *GANAB* (encodes glucosidase IIα subunit) and *DNAJB11* (a BiP co-chaperone) cause milder, atypical disease and affect PC1 biogenesis/trafficking; found only in a small number of families.
- ▶ PC1 and PC2 bind via their **C-terminal tails** (proposed **1:3 PC1:PC2 stoichiometry**) to form a receptor-channel complex localised to the **primary cilium** (“9+0” axoneme), cell membrane and

cell–cell junctions, acting as a **mechano-/chemosensor** regulating calcium and G-protein signalling.

Feature	PKD1	PKD2
Chromosome locus	16p13	4q21–q23
Protein	Polycystin-1 (PC1)	Polycystin-2 (PC2)
Protein structure	11-TM, GPCR-like, ~4300 aa	6-TM, TRP Ca ²⁺ channel, 968 aa
Proportion of cases	~85%	~15% (often more)
Clinical severity	More severe, earlier ESRD	Milder, later ESRD

Pathogenesis (Cystogenesis)

- ▶ **Two-hit (“second-hit”) mechanism** — every cell carries a germline mutant allele, but cysts arise only from the small fraction of nephrons in which a **somatic mutation** inactivates the *normal* allele; cysts grow **clonally** from single cells. A **“third hit”** (additional genetic/epigenetic event or renal injury reactivating a developmental programme) may accelerate cyst formation.
- ▶ Loss of ciliary PC1/PC2 function → **aberrant calcium signalling** → increased **adenylyl cyclase** and decreased phosphodiesterase activity → raised **intracellular cAMP** → activation of **protein kinase A**, driving **cell proliferation and fluid secretion** via chloride (CFTR) and aquaporin channels into cysts.
- ▶ Implicated downstream pathways: **mTOR, Wnt, STAT3, cMET, PI3K/Akt, GPCR and EGFR** signalling. Cysts involve only ~5% of tubules, yet their enormous growth destroys surrounding parenchyma and renal function.
- ▶ Result: kidneys enlarge up to **fourfold in length** and weigh up to **20 times normal**; *hundreds to thousands* of cysts by the **fifth decade**.

Clinical Manifestations

- ▶ **Renal** — back/flank pain (~60%, from cyst infection, haemorrhage or stones); **gross haematuria** (~40%) from cyst rupture (recurrent); minor proteinuria; **nephrolithiasis** ~20% (>half **uric acid** stones, rest calcium oxalate — driven by low urine pH, hypocitraturia, distal acidification defects); **cyst infection/pyelonephritis** (gram-negatives) — the **second most common cause of death**; progressive enlargement → **ESRD** in late middle age.
- ▶ **Hypertension** — common, occurs **before any fall in GFR**; due to RAAS activation, increased sympathetic activity, and impaired endothelial cilium-dependent vasorelaxation; a major risk factor for cardiovascular and renal progression; LVH may occur even in normotensives.
- ▶ **Extrarenal:**

- **Polycystic liver disease** — most common extrarenal feature (biliary-epithelium-derived); massive disease **almost exclusively in women with multiple pregnancies**; does *not* cause liver failure. (Isolated ADPLD is a distinct disease from *PRKCSH/SEC63* mutations.)
- **Intracranial (berry) aneurysm** — 4–5× more frequent than general population; 20–50% have “warning headaches” before subarachnoid haemorrhage; CT is the first test, **lumbar puncture** confirms; **MR angiography** screening if positive family history.
- **Cardiac/vascular** — **mitral valve prolapse up to 30%**, tricuspid prolapse, aortic/mitral/tricuspid insufficiency; arterial dolichoectasia predisposing to dissection/stroke.
- **Others** — **colonic diverticulae** and **abdominal wall/inguinal hernias** are increased.
- ▶ **Risk factors for rapid progression** — early diagnosis, hypertension, gross haematuria, multiple pregnancies, **large kidney size**, *PKD1* (vs *PKD2*) and male sex.

Diagnosis

- ▶ Based on a **positive autosomal-dominant family history** plus **bilateral multiple renal cysts** on imaging; **renal ultrasonography** is first-line for presymptomatic screening of at-risk relatives and potential living-related donors.
- ▶ **Unified ultrasonographic (age-dependent) criteria** for at-risk individuals:

Age (years)	Cyst criterion for diagnosis	Performance
15–29	≥ 2 renal cysts (unilateral or bilateral)	Sensitivity 96%, specificity 100%
30–59	≥ 2 cysts in each kidney	Sensitivity 100%, specificity 100%
≥ 60	≥ 4 cysts in each kidney	Sensitivity 100%, specificity 100%

- ▶ In subjects aged 30–59, **absence of ≥2 cysts in each kidney** excludes disease (false-negative rate 0%); criteria are **less sensitive for PKD2** (late onset).
- ▶ **CT and T2-weighted MRI** (with/without contrast) are more sensitive and detect smaller cysts; **gadolinium T2-MRI** has minimal renal toxicity and detects cysts of only **2–3 mm**. CT carries radiation and contrast-nephrotoxicity risk.
- ▶ **Genetic testing** (linkage/mutational analysis, next-generation sequencing) for ambiguous cases; *PKD1* analysis is difficult/costly owing to its large size and multiple homologous pseudogenes.

Treatment

- ▶ **No FDA-approved therapy reverses cyst growth**; management slows progression and lowers cardiovascular risk.
- ▶ **Blood pressure control** — first-line by **inhibiting the RAAS** (ACE inhibitor/ARB); target **140/90 mmHg** (per JNC VIII). The **HALT-PKD** trial showed rigorous BP control slows cyst

growth, but a systolic target of 110 mmHg in moderate/advanced disease may *worsen* renal progression by reducing renal blood flow.

- ▶ **Tolvaptan** — a vasopressin V2-receptor (V2R) antagonist that lowers renal cAMP, slowing functional decline (TEMPO/"TAMPO" programme) and reducing renal pain; **FDA-restricted to patients at risk of rapidly progressing disease**; side effects include hepatotoxicity and polyuria/polydipsia.
- ▶ **Somatostatin analogues** (e.g. octreotide-LAR; ALADIN trial) lower cAMP and slow decline; side effect: cholecystitis. **mTOR inhibitors** (sirolimus, everolimus) have been trialed.
- ▶ **Cyst infection** — **lipid-soluble antibiotics** that penetrate cyst walls: **trimethoprim-sulfamethoxazole, fluoroquinolones, chloramphenicol**, often for 4–6 weeks.
- ▶ **Stones** — analgesia and hydration (standard measures). **Pain** — non-narcotic/narcotic analgesics, TENS, acupuncture, biofeedback, nerve block (DIPAK), occasionally surgical cyst decompression.
- ▶ **ESRD** — **>half eventually need dialysis or transplantation**; peritoneal dialysis may be limited by massively enlarged kidneys; **pre-transplant or bilateral nephrectomy** for very large kidneys or recurrent cyst infection.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Primary cilium and the polycystin complex** — label: *primary cilium* ("9+0" axoneme), *ciliary membrane*, *basal body*, *transition zone*, *Polycystin-1 (PC1)*, *Polycystin-2 (PC2/TRP Ca²⁺ channel)*, *kinesin-2 (anterograde)*, *dynein (retrograde)*, and downstream arrows $\text{Ca}^{2+} \rightarrow \uparrow \text{cAMP} \rightarrow \text{PKA} \rightarrow \text{proliferation} + \text{fluid secretion}$.
- ▶ **Cut-section of a polycystic kidney** — label: *grossly enlarged kidney*, *innumerable cortical and medullary cysts of varying size*, *compressed residual parenchyma*, *haemorrhagic cyst*.

Clinical / Diagnostic significance

- ▶ ADPKD is a **systemic disease** — always screen for **hypertension, hepatic cysts and intracranial aneurysm** (MRA if family history of SAH/ICA).
- ▶ Distinguishing a **complex cyst from renal cell carcinoma** needs CT/MRI; RCC is not more frequent but tends to be **bilateral, multicentric and sarcomatoid**.
- ▶ **Cardiovascular complications are the leading cause of mortality**; cyst infection is second — choose cyst-penetrating antibiotics.
- ▶ Pre-symptomatic screening of **potential living-related donors** is mandatory before transplantation.

High-yield exam pointers

- ▶ Most common **life-threatening monogenic** disease; **12 million** affected; prevalence **1:1000–1:400**.
- ▶ **PKD1 (16p13, ~85%, severe)** vs **PKD2 (4q21–q23, ~15%, mild)**; polycystin-1 = GPCR-like 11-TM; polycystin-2 = TRP Ca^{2+} channel.
- ▶ **Two-hit hypothesis**; central effector = **raised cAMP** → **PKA** → **proliferation + fluid secretion**; a **ciliopathy**.
- ▶ Triad to remember — **hypertension (before GFR fall), flank pain/haematuria, palpable enlarged kidneys**.
- ▶ **Berry aneurysm 4–5×**, **MVP up to 30%**, polycystic liver (worse in multiparous women), colonic diverticulae, hernias.
- ▶ **Stones ~20%, mostly uric acid**; gross haematuria ~40%; infection = 2nd commonest cause of death.
- ▶ **Ultrasound diagnostic criteria are age-dependent** (≥ 2 cysts at 15–29; ≥ 2 each kidney at 30–59; ≥ 4 each kidney at ≥ 60).
- ▶ **Tolvaptan (V2R antagonist)** for rapidly progressive disease; **RAAS blockade + BP target 140/90 (JNC VIII)**; **>50% reach ESRD** needing renal replacement.

SOURCE & COVERAGE

Harrison's Principles of Internal Medicine, 22e — Ch 327 "Polycystic Kidney Disease and Other Inherited Disorders of Tubule Growth and Development" (Zhou & Pollak). Coverage note: The chapter does not state the specific tolvaptan dosing regimen or named risk-stratification scores (Mayo imaging classification, PROPKD score); the ACE inhibitor/ARB drug names (lisinopril/telmisartan in HALT-PKD) and the "Pei/Ravine" eponym for the unified ultrasound criteria are standard internal-medicine additions — the criterion numbers themselves are verbatim from the chapter.

Bone Manifestations of Chronic Kidney Disease

Asked in: Paper IV Jul 2021 — RGUHS MD General Medicine

Definition / Introduction — The skeletal disturbances of CKD are the bone component of **CKD–Mineral and Bone Disorder (CKD-MBD)**, a *systemic* disorder of mineral metabolism defined by KDIGO (2006) as one or a combination of: (1) abnormalities of **calcium, phosphate, PTH or vitamin D** metabolism; (2) abnormalities of **bone turnover, mineralization, volume, linear growth or strength**; and (3) **vascular or soft-tissue calcification**. *Renal osteodystrophy* is the strictly histological term — an alteration of bone morphology quantifiable only by **bone histomorphometry** — and constitutes the

skeletal arm of CKD-MBD. These derangements begin early (detectable changes in mineral metabolism from CKD stage 2–3, with rising FGF-23) and are nearly universal once GFR falls below 30 mL/min.

Pathophysiology — how uraemia injures bone

- ▶ **Phosphate retention:** Falling GFR reduces phosphate excretion. Retained phosphate is the proximate driver — it stimulates osteocyte synthesis of **FGF-23**, directly stimulates **PTH** secretion, and promotes growth of parathyroid gland mass.
- ▶ **Calcitriol deficiency:** Phosphate retention and high FGF-23 suppress renal **CYP27B1** (1 α -hydroxylase) and accelerate calcitriol degradation (via CYP24), lowering **1,25(OH)₂D₃**. Low calcitriol causes hypocalcaemia (poor gut Ca absorption) and de-represses **PTH gene** transcription.
- ▶ **Hypocalcaemia:** From low calcitriol and phosphate complexing of calcium — a further stimulus to PTH.
- ▶ **FGF-23 / Klotho axis:** FGF-23 (a “phosphatonin”) rises *earliest*. Renal **Klotho** (its obligatory co-receptor) is down-regulated in CKD, so the normal Klotho-dependent inhibitory effect of FGF-23 on the parathyroid is *attenuated*, permitting PTH to climb. High FGF-23 is an independent risk factor for **left ventricular hypertrophy** and mortality.
- ▶ **Net result — secondary hyperparathyroidism:** Hyperphosphataemia + hypocalcaemia + calcitriol deficiency + Klotho loss → sustained PTH excess → high-turnover bone disease. Persistent stimulation can produce autonomous, hypercalcaemic **tertiary hyperparathyroidism**. PTH itself behaves as a uraemic toxin (muscle weakness, myocardial fibrosis, ESA-resistant anaemia from marrow fibrosis).

Spectrum of renal osteodystrophy (KDIGO TMV classification)

KDIGO classifies bone lesions on three histomorphometric axes — Turnover, Mineralization, Volume — replacing older eponymic categories.

Lesion	Turnover	PTH	Histology / hallmark
Osteitis fibrosa cystica (2° hyperparathyroidism)	High	High	Giant multinucleated osteoclasts in Howship’s lacunae , peritrabecular/marrow fibrosis, woven bone, cysts/ brown tumours
Adynamic (low-turnover) bone disease	Low	Low/normal	Absent osteoblast & osteoclast activity, little osteoid, no fibrosis; ↓bone volume & mineralization

Lesion	Turnover	PTH	Histology / hallmark
Osteomalacia	Low	Variable	Excess unmineralized osteoid , wide osteoid seams, markedly reduced mineralization rate
Mixed uraemic osteodystrophy	High + defect	High	Features of 2° HPT <i>plus</i> a mineralization defect on tetracycline labelling

- ▶ **Osteitis fibrosa cystica** is the *classic* high-turnover lesion of secondary hyperparathyroidism — bone pain, fragility, **brown tumours** (haemorrhagic cysts that appear brown) with compression syndromes, and ESA-resistant anaemia.
- ▶ **Adynamic bone disease** is now *increasingly prevalent*, especially in diabetics and older patients. It results from **over-suppression of PTH** — by vitamin D preparations, calcium-based binders or high-calcium dialysate — chronic inflammation, or both. Despite low turnover, patients suffer severe musculoskeletal pain (inability to repair microfractures), increased fractures, and a strong association with **vascular/cardiac calcification** (ingested calcium cannot enter low-turnover bone and is deposited ectopically).
- ▶ **Osteomalacia** is a distinct mineralization defect from reduced calcitriol; historically linked to **aluminium toxicity** (aluminium-containing binders, contaminated dialysate) — now rare. Aluminium deposits stain at the mineralization front.
- ▶ The historical predominance of osteitis fibrosa has shifted: osteomalacia has been largely “replaced” by adynamic bone disease, and mixed uraemic osteodystrophy has risen.

Extraskkeletal manifestations of CKD-MBD

- ▶ **Vascular calcification:** Hyperphosphataemia and hypercalcaemia drive **medial** calcification of coronaries and valves (orders of magnitude greater than in non-CKD), distinct from intimal atherosclerotic calcification. Phosphate induces an *osteoblast-like phenotypic switch* in vascular smooth-muscle cells (up-regulation of **RUNX-2 / MSX2**), with loss of inhibitors (fetuin-A, matrix Gla protein, pyrophosphate). Linked to LVH and cardiovascular mortality.
- ▶ **Calciphylaxis (calcific uraemic arteriopathy):** Devastating, near-exclusive to advanced CKD. Painful **livedo reticularis** and subcutaneous nodules progress to ischaemic skin necrosis/ulceration (legs, thighs, abdomen, breasts) from small-vessel medial calcification and thrombosis. **Warfarin** is a key risk factor (it blocks vitamin K-dependent activation of matrix Gla protein) and must be stopped.
- ▶ **Tumoral calcinosis:** Periarticular soft-tissue calcified masses in chronically, severely hyperphosphataemic, non-adherent dialysis patients.

Clinical / Diagnostic significance

- ▶ **Biochemistry** (serial trends matter more than single values): serum phosphate, corrected calcium, intact PTH, alkaline phosphatase (bone turnover surrogate), 25-OH vitamin D; FGF-23 and Klotho remain largely research tools.
- ▶ **Bone biopsy** (iliac crest) with **double tetracycline labelling** is the *gold standard* for renal osteodystrophy — tetracycline binds hydroxyapatite and fluoresces, allowing dynamic measurement of bone-formation rate (turnover) plus static mineralization and volume.
- ▶ **Radiology: subperiosteal resorption** (radial side of middle phalanges, distal clavicle), resorption of phalangeal tufts (acro-osteolysis), **brown tumours**, “salt-and-pepper” skull and the *rugger-jersey spine* of secondary hyperparathyroidism; pseudofractures (Looser’s zones) in osteomalacia. DEXA quantifies density but cannot distinguish lesion type.
- ▶ **Clinical clues**: bone pain, proximal myopathy/muscle weakness, fragility fractures, pruritus, periarticular masses, and ESA-hyporesponsive anaemia.
- ▶ **Caution: Bisphosphonates and denosumab** suppress turnover and can *precipitate adynamic bone disease* in CKD/ESKD — avoid unless a high-turnover state is confirmed.

Management (prevention-focused; KDIGO targets)

- ▶ **Control phosphate first** — the foundational step. Dietary phosphate restriction (avoid cola, processed/additive phosphate) + **phosphate binders taken with meals**:
 - *Calcium-based* (calcium acetate, calcium carbonate) — cheap but risk hypercalcaemia and positive calcium balance, especially in low-turnover bone; limit use.
 - *Non-calcium* — **sevelamer, lanthanum carbonate**; *iron-based* — **ferric citrate**, sucroferric oxyhydroxide; reduce vascular calcium loading.
 - **Tenapanor** (NHE3 inhibitor) reduces GI phosphate absorption; **aluminium hydroxide** only short-term (osteomalacia/neurotoxicity risk).
- ▶ **Active vitamin D** for secondary hyperparathyroidism once phosphate is controlled and 25-OH D repleted: **calcitriol** or analogues (**paricalcitol** — less hypercalcaemia). Dose-reduce/stop if hypercalcaemia or hyperphosphataemia develops.
- ▶ **Calcimimetics** — **cinacalcet** (oral), **etelcalcetide** (IV, at dialysis) — sensitize the parathyroid CaSR, lowering PTH *and* calcium; watch for hypocalcaemia. Useful when high Ca/PO₄ prohibit vitamin D analogues.
- ▶ **Target PTH**: KDIGO/KDOQI recommend 2–9 × **upper limit of normal** in ESKD (skeletal PTH resistance means normal levels risk adynamic bone); very low PTH predicts fracture and ectopic calcification.
- ▶ **Parathyroidectomy** for severe refractory/tertiary hyperparathyroidism with persistent hypercalcaemia, intractable pruritus, calciphylaxis or progressive disease.

- ▶ **Calciphylaxis:** stop warfarin, use IV **sodium thiosulfate**, correct Ca/PO_4 , wound care $\pm$ hyperbaric oxygen.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Diagram 1 — Pathophysiology cascade of CKD-MBD:** Box “ $\downarrow\text{GFR}$ ” $\rightarrow$ “Phosphate retention” branching to “ $\uparrow\text{FGF-23}$ (osteocytes)” and “ $\downarrow\text{Calcitriol}$ (CYP27B1 $\downarrow$)”; arrows converging through “Hypocalcaemia” and “ $\downarrow\text{Klotho}$ ” to a central box “**Secondary hyperparathyroidism** ($\uparrow\text{PTH}$)”, with downstream boxes “**Osteitis fibrosa cystica / high-turnover bone**”, “Vascular calcification”, “LVH/CV mortality”. Labels: *GFR, Phosphate, FGF-23, Klotho, Calcitriol, Calcium, PTH*.
- ▶ **Diagram 2 — Classification by bone turnover:** A horizontal axis “Bone turnover (low $\rightarrow$ high)”; left = **Adynamic bone disease & Osteomalacia** (low PTH); right = **Osteitis fibrosa cystica** (high PTH); centre = **Mixed uraemic osteodystrophy**. Annotate KDIGO TMV axes: *Turnover, Mineralization, Volume*.

High-yield exam pointers

- ▶ **CKD-MBD = triad:** biochemical ($\text{Ca}/\text{PO}_4/\text{PTH}/\text{vit D}$) + bone (renal osteodystrophy) + extraskeletal calcification (KDIGO 2006).
- ▶ **FGF-23 rises earliest**, before measurable $\text{PTH}/\text{Ca}/\text{PO}_4$ change; needs **Klotho** co-receptor (down-regulated in CKD).
- ▶ **Osteitis fibrosa cystica** = high-turnover, secondary HPT; *Howship’s lacunae, brown tumours, subperiosteal resorption, rugger-jersey spine*.
- ▶ **Adynamic bone disease** = low PTH, over-suppressed; commonest emerging lesion; linked to fractures + vascular calcification.
- ▶ **Bone biopsy with double tetracycline labelling** = gold standard; classify by TMV.
- ▶ **Target PTH** 2–9 $\times$ ULN in ESKD; avoid *over-suppression*.
- ▶ **Warfarin** $\rightarrow$ **calciphylaxis** (blocks matrix Gla protein); avoid in dialysis where possible.
- ▶ **Avoid bisphosphonates/denosumab** in CKD unless high-turnover confirmed.
- ▶ **Binder hierarchy:** phosphate control *first*, prefer non-calcium binders to limit vascular calcium loading.

SOURCE & COVERAGE

- ▶ **Harrison’s Principles of Internal Medicine, 22e** — “Chronic Kidney Disease” (Bone manifestations of CKD; disorders of calcium and phosphate metabolism; calciphylaxis; treatment) and “Disorders of the Parathyroid Gland and Calcium Homeostasis” (osteitis fibrosa cystica, Howship’s lacunae, subperiosteal resorption).

- ▶ **Brenner & Rector's The Kidney** — “Chronic Kidney Disease–Mineral Bone Disorder” (KDIGO CKD-MBD/renal osteodystrophy definitions, FGF-23/Klotho axis, TMV classification, histomorphometry, vascular calcification/RUNX-2).
- ▶ **CMDT 2026** — “Kidney Disease” (mineral bone disorders: binders, calcitriol/analogues, calcimimetics, PTH targets) and “Disorders of Parathyroid Glands & Bone Metabolism”.
- ▶ *Coverage note:* “Rugger-jersey spine,” “salt-and-pepper skull” and “Looser’s zones” are universally accepted standard radiographic eponyms included for completeness; the corpus explicitly documents subperiosteal resorption, phalangeal tuft resorption and brown tumours.

Counter current multiplier system of the Kidney. Write briefly on Gitelman Syndrome

Asked in: Paper I Nov 2022 — RGUHS MD General Medicine

Definition / Introduction — The **countercurrent multiplier** is the renal mechanism that generates and maintains a **hypertonic medullary interstitium**, enabling the kidney to produce urine far more concentrated than plasma. It exploits the hairpin (countercurrent) geometry of the **loop of Henle**, where active NaCl reabsorption by the water-impermeable thick ascending limb is “multiplied” along the cortico-medullary axis by the opposing flow in the two limbs. The medullary gradient, in concert with vasopressin-driven water reabsorption in the collecting duct, determines final urine concentration. **Gitelman syndrome** is a contrasting *distal* tubulopathy — an inherited salt-wasting disorder of the distal convoluted tubule (DCT) caused by loss of the thiazide-sensitive Na^+/Cl^- cotransporter.

Anatomical and functional basis of the countercurrent apparatus

- ▶ The loop of Henle has three segments: **descending thin limb**, **ascending thin limb**, and **ascending thick limb (TAL)**; the loop reabsorbs ~15–25% of filtered NaCl, mainly in the TAL.
- ▶ **Descending thin limb** — highly **water-permeable** owing to dense, constitutively active **aquaporin-1** channels; relatively solute-impermeable. Tubular fluid equilibrates osmotically with the interstitium and becomes progressively *concentrated* as it descends.
- ▶ **Ascending thin and thick limbs** — water permeability is **negligible** (“diluting segment”).
- ▶ **Thick ascending limb** — high-capacity secondary-active NaCl transport by the apical $\text{Na}^+/\text{K}^+/\text{2Cl}^-$ cotransporter (NKCC2) in series with basolateral Cl^- channels and the Na^+/K^+ -ATPase. Tubular K^+ (~4 meq/L) is the limiting substrate, so activity is sustained by K^+ **recycling** through an apical potassium channel (ROMK). NKCC2 is the molecular target of **loop diuretics**.
- ▶ K^+ recycling renders the lumen **electropositive**, driving **paracellular reabsorption** of Mg^{2+} and Ca^{2+} in the TAL.

Mechanism — the “single effect” and its multiplication

- ▶ **Step 1 — the single effect:** Active NaCl reabsorption by the *water-impermeable* TAL moves solute (without water) into the interstitium, **diluting tubular fluid** and **adding new osmoles** to medullary interstitial fluid. At any horizontal level this creates a modest osmotic gradient between lumen and interstitium (classically ~200 mOsm/kg).
- ▶ **Step 2 — countercurrent multiplication:** Because flow in the **descending and ascending limbs runs in opposite directions** (a hairpin), the small transverse single effect is repeatedly summed along the length of the loop, multiplying into a **large axial (cortico-medullary) gradient**.
- ▶ **Step 3 — solute trapping:** As water leaves the permeable descending limb to equilibrate with the hypertonic interstitium, solute is **progressively trapped** in the inner medulla, steepening the gradient from iso-osmotic at the cortex to maximally hypertonic at the papillary tip.
- ▶ **Net result:** A standing medullary osmotic gradient (in humans rising to ~1200 mOsm/kg at the papilla) against which the collecting duct can extract water. *NaCl reabsorption by the TAL is the primary initiating event of the whole process.*

Role of urea recycling and the vasa recta (countercurrent exchanger)

- ▶ **Urea recycling** — the **inner medullary collecting duct** transports urea (via urea transporters) out of the lumen into the interstitium, where it diffuses into the descending and ascending limbs and is recycled. Urea contributes substantially to **maximum medullary interstitial osmolality**.
- ▶ **Vasa recta** — the medullary peritubular capillaries that envelop the loop form the **second countercurrent system**. Their hairpin geometry allows passive **countercurrent exchange**: solutes and water are shunted between descending and ascending vessels so that blood flow nourishes the medulla **without washing out** the gradient. (The loop is an *active* countercurrent **multiplier**; the vasa recta is a *passive* countercurrent **exchanger** that preserves the gradient.)

Using the gradient — vasopressin and the collecting duct

- ▶ Collecting duct cells express vasopressin-regulated aquaporin-2 (apical) and aquaporin-3/-4 (basolateral) water channels.
- ▶ **Vasopressin (ADH)** binds the basolateral **V2 receptor** → G-protein activation of **adenylyl cyclase** → rise in **cyclic AMP** → insertion of aquaporin-2 into the apical membrane → water reabsorption and **concentrated urine**.
- ▶ Without vasopressin, the collecting duct is water-impermeable and urine stays **dilute**. *Vaptans* (nonpeptide V2 antagonists) block this effect to produce a water diuresis (e.g., for hyponatremia).

Feature	Countercurrent multiplier	Countercurrent exchanger
Structure	Loop of Henle (descending + ascending limbs)	Vasa recta (medullary capillaries)

Feature	Countercurrent multiplier	Countercurrent exchanger
Energy	Active (NKCC2 in TAL)	Passive (diffusion only)
Function	Generates the medullary gradient	Preserves the gradient (prevents washout)
Key requirement	Water-impermeable TAL + water-permeable thin descending limb	Hairpin geometry with slow blood flow

Gitelman syndrome

- **Definition / genetics:** An autosomal-recessive **salt-wasting tubulopathy** caused by **loss-of-function mutations of SLC12A3**, which encodes the apical thiazide-sensitive Na^+/Cl^- cotransporter (NCC) of the distal convoluted tubule** — effectively a lifelong “thiazide-like” state. The DCT normally reabsorbs ~5% of filtered NaCl.
- **Mechanism of electrolyte disturbance:**
 - Impaired distal NaCl reabsorption → mild **volume contraction** → activation of renin–angiotensin–aldosterone → enhanced distal Na^+ reabsorption with K^+ and H^+ secretion → **hypokalaemia and metabolic alkalosis**.
 - Blocking apical Na^+/Cl^- cotransport lowers intracellular Na^+ , favouring basolateral $\text{Na}^+/\text{Ca}^{2+}$ exchange and passive apical Ca^{2+} entry (TRPV5) → increased Ca^{2+} reabsorption → **hypocalciuria** (the hallmark distinguishing it from loop pathology).
 - **Hypomagnesaemia** — impaired Mg^{2+} handling in the DCT (the TRPM6/TRPM7 channel complex is critical for DCT Mg^{2+} reabsorption).
- **Clinical features (standard medicine):** Usually presents **later (adolescence/adulthood)** and is **milder** than Bartter syndrome — muscle cramps/weakness, tetany and carpopedal spasm (from hypomagnesaemia), fatigue, salt craving, **normal-to-low blood pressure**, and occasionally chondrocalcinosis.
- **Biochemistry:** Hypokalaemia, metabolic alkalosis, **hypomagnesaemia**, **hypocalciuria**, with high plasma renin/aldosterone and normal/low BP.
- **Management (standard medicine):** Liberal **sodium**, oral **potassium and magnesium** supplementation, and **potassium-sparing agents** (spironolactone/eplerenone or amiloride); magnesium repletion is central because it is needed to correct the hypokalaemia.

Feature	Bartter syndrome	Gitelman syndrome
Tubular site	Thick ascending limb	Distal convoluted tubule
Gene / transporter	NKCC2 (SLC12A2), ROMK (KCNJ1), CLCNKB/BSND, CASR	*NCC (SLC12A3)*

Feature	Bartter syndrome	Gitelman syndrome
Diuretic mimicked	Loop diuretic (furosemide)	Thiazide
K ⁺ / acid-base	Hypokalaemia + metabolic alkalosis	Hypokalaemia + metabolic alkalosis
Urinary calcium	Hypercalciuria ± nephrocalcinosis	Hypocalciuria
Magnesium	Usually normal	Hypomagnesaemia
Typical onset / severity	Neonatal/childhood, severe	Adolescent/adult, milder

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Nephron loop with the medullary gradient:** Draw the U-shaped loop in the medulla. Label *descending thin limb (aquaporin-1, water-permeable)*, *ascending thin limb, thick ascending limb (NKCC2 + ROMK + Na⁺/K⁺-ATPase, water-impermeable)*, *vasa recta (countercurrent exchanger)*, and the *inner medullary collecting duct (urea recycling, ADH/AQP2)*. Add a vertical osmolality scale on the right reading ~300 mOsm/kg (cortex) → ~1200 mOsm/kg (papilla) with horizontal arrows for the “single effect.”
- ▶ **DCT cell for Gitelman:** Apical *thiazide-sensitive Na⁺/Cl⁻ cotransporter (NCC, SLC12A3)* with a red cross (mutated), apical *TRPV5 (Ca²⁺)*, basolateral *Na⁺/K⁺-ATPase*, *Cl⁻ channel*, and *Na⁺/Ca²⁺ exchanger*.

Clinical / Diagnostic significance

- ▶ The medullary gradient is the physiological substrate for the **urine-concentrating/diluting** capacity; its disruption underlies **nephrogenic diabetes insipidus** (AQP2/V2 defects) and the polyuria of medullary disease.
- ▶ **Loop diuretics** abolish the single effect (block NKCC2) → impaired concentration and brisk natriuresis; **thiazides** act at the DCT NCC — the same target lost in Gitelman.
- ▶ **Differentiating hypokalaemic metabolic alkalosis with normal BP:** Gitelman (hypocalciuria + hypomagnesaemia, adult, thiazide-like) vs Bartter (hypercalciuria, neonatal, loop-like) vs surreptitious **vomiting/diuretic abuse** (check urine chloride/diuretic screen).
- ▶ Recognising the volume-contracted, **normal/low-BP** picture separates these salt-wasting tubulopathies from **Liddle syndrome** (ENaC gain-of-function: hypertension + hypokalaemic alkalosis with low renin/aldosterone).

High-yield exam pointers

- ▶ Two countercurrent systems: **loop of Henle = active multiplier**; **vasa recta = passive exchanger** (prevents washout).

- ▶ The **water-impermeable** TAL with NKCC2 is the engine (“single effect”); the **water-permeable descending limb** (AQP1) enables solute trapping.
- ▶ **Urea recycling** from the inner medullary collecting duct is essential for **maximal** medullary hypertonicity.
- ▶ ADH → V2 → cAMP → AQP2 insertion converts the gradient into concentrated urine.
- ▶ Gitelman = *DCT, SLC12A3/NCC, thiazide-like: hypokalaemic metabolic alkalosis + hypocalciuria + hypomagnesaemia*, normal/low BP.
- ▶ Mnemonic contrast — Gitelman = hypocalciuria (Goes low calcium in urine) vs Bartter = hypercalciuria.
- ▶ Treat Gitelman with Na, K, Mg replacement ± K⁺-sparing diuretic; correct Mg to fix the K⁺.

SOURCE & COVERAGE

Harrison 22e — Ch 320 “Cell Biology and Physiology of the Kidney” (countercurrent multiplication, loop/vasa recta, TAL/NKCC2, urea recycling, ADH/AQP2, DCT/NCC and the SLC12A3 Gitelman mention; Bartter genes). Ch 432 “Inherited Defects of Membrane Transport” was provided but covers cystinuria/lysine intolerance only and does **not** address Gitelman syndrome. *Coverage note:* The provided text grounds the countercurrent mechanism fully and names Gitelman syndrome with its core triad (salt-wasting, hypokalaemic alkalosis, hypocalciuria), the SLC12A3/NCC defect, and the DCT calcium/magnesium handling. The expanded Gitelman details — autosomal-recessive inheritance, secondary hyperaldosteronism, clinical presentation (age/severity, tetany, chondrocalcinosis), and treatment — plus the classic ~200 and ~1200 mOsm/kg figures and Bartter hypercalciuria are universally accepted standard internal medicine added for exam completeness, not verbatim from the supplied chapters.

Crescentic Glomerulonephritis

Asked in: Paper I Jul 2021 — RGUHS MD General Medicine

Definition / Introduction — *Crescentic glomerulonephritis* (CrGN) is the histological correlate of the clinical syndrome of **rapidly progressive glomerulonephritis (RPGN)** — a nephritic illness with loss of kidney function over days to weeks, accompanied by dysmorphic (glomerular) haematuria, red-cell casts and sub-nephrotic to nephritic-range proteinuria. It is defined pathologically by **extracapillary proliferation forming crescents in Bowman’s space in >50% of glomeruli**, and represents the most aggressive structural phenotype in the continuum of glomerular inflammatory injury. The terms RPGN (clinical) and crescentic GN (pathological) are used almost interchangeably because aggressive GN that causes RPGN nearly always shows extensive crescents. It is a nephrological emergency: untreated, it

progresses to irreversible scarring and end-stage kidney disease (ESKD), so urgent biopsy and immunosuppression are mandatory.

The crescent — morphology and pathogenesis

- ▶ A **crescent** is a collection of cells and matrix that fills part or all of Bowman's (urinary) space, compressing the glomerular tuft into a half-moon shape (*Fig. — cellular crescent, PAS ×500*).
- ▶ **Pathogenesis (final common pathway):** severe glomerular injury causes **focal rupture of glomerular capillary walls and breaks in the GBM/Bowman's capsule** → leakage of fibrin, plasma proteins and inflammatory mediators into Bowman's space → proliferation of parietal/visceral epithelial cells with influx and maturation of **macrophages**, producing the crescent. Fibrin (seen as *fibrin tactoids* on EM) is a potent stimulus.
- ▶ **Evolution:** *cellular* crescent → *fibrocellular* → *fibrous (fibrotic)* crescent. Cellular crescents are potentially reversible with treatment; fibrous crescents and Bowman's capsule rupture signify irreversibility.
- ▶ Associated features: **segmental fibrinoid necrosis** of the tuft, periglomerular inflammation, and in chronic stages, glomerulosclerosis, tubular atrophy and **interstitial fibrosis** (an ominous sign of irreversibility).
- ▶ Crescents are a marker of severity across many GNs — they are seen in ~97% of anti-GBM, ~90% of ANCA, ~56% of immune-complex and ~61% of proliferative lupus (class III/IV) biopsies (UNC Nephropathology data).

Immunopathologic classification (the three categories / Type I–III)

The precise category requires integrating immunofluorescence (IF) pattern, serology, light and electron microscopy. Three immunopathologic groups account for almost all cases:

Feature	Type I — Anti-GBM	Type II — Immune-complex	Type III — Pauci-immune (ANCA)
IF pattern	Linear IgG along GBM	Granular ("lumpy-bumpy") Ig + C3	Pauci-immune (little/no Ig or complement)
Antigen / serology	Anti-GBM Ab to $\alpha 3$ -NC1 domain of type IV collagen	Circulating/in-situ immune complexes; $\pm$ low complement	ANCA — PR3 (c-ANCA) or MPO (p-ANCA)
Frequency (all ages)	~15%	~24%	~60% (~90% ANCA-positive)
Typical age	Bimodal (20s; 60s–70s)	Children/young adults	Older adults (~79% of CrGN >60 yr)
Representative diseases	Goodpasture syndrome; renal-limited anti-GBM	Post-infectious GN, IgA nephropathy/IgA vasculitis, lupus	GPA, MPA, EGPA, renal-limited (ANCA) vasculitis

Feature	Type I — Anti-GBM	Type II — Immune-complex	Type III — Pauci-immune (ANCA)
		nephritis (III/IV), MPGN, cryoglobulinaemia, C3 glomerulopathy	

- ▶ **Type I (anti-GBM):** autoantibody against the *Goodpasture antigen* — the $\alpha 3$ chain NC1 domain of collagen IV (an autoimmune “conformeropathy”). Genetic link to *HLA-DR2 (DRB1\1501, DQB1\0602). *Bimodal age: young men (more often full Goodpasture syndrome with lung haemorrhage) and elderly (more often renal-limited, female predominance).* 25–33% are also ANCA (usually MPO)-positive* (“double-positive”).
- ▶ **Type II (immune-complex):** the underlying disease shapes the picture — e.g. mesangial IgA (IgA nephropathy), coarse granular capillary-wall deposits and sub-epithelial “humps” (post-streptococcal), C3-dominant with double contours (MPGN/C3GN), “full-house” with tubuloreticular inclusions (lupus). Intact glomeruli show **endocapillary hypercellularity and capillary-wall thickening**.
- ▶ **Type III (pauci-immune/ANCA):** most common cause of CrGN in adults; segmental necrotising GN with crescents but minimal deposits. Part of ANCA-associated small-vessel vasculitis (GPA = PR3 predominant; MPA/EGPA = MPO predominant) or renal-limited. A 4th category — **monoclonal Ig-mediated (MGRS)** — and rare “double/triple antibody-negative” cases are now also recognised.

Clinical features and investigations

- ▶ **Presentation:** rapidly rising serum creatinine over days–weeks, oliguria/anuria, **smoky/cola-coloured urine**, hypertension, oedema and uraemic symptoms (nausea, malaise, fatigue).
- ▶ **Urinalysis (the key bedside clue):** active nephritic sediment — **dysmorphic RBCs, red-cell casts**, pyuria, and proteinuria typically 1–3.5 g/day (rarely nephrotic).
- ▶ **Systemic clues:** haemoptysis/pulmonary haemorrhage (anti-GBM/Goodpasture, ANCA “pulmonary-renal syndrome”); sinusitis, nasal crusting, cavitating lung nodules, mononeuritis multiplex, palpable purpura (ANCA vasculitis); malar rash, arthralgia, serositis (lupus).
- ▶ **Serology panel (send before/at biopsy):** anti-GBM antibody; ANCA (anti-PR3, anti-MPO); ANA, anti-dsDNA, C3/C4 (low in lupus, post-infectious, MPGN, cryoglobulinaemia; normal in anti-GBM and ANCA); ASO/anti-DNase, cryoglobulins, hepatitis B/C and HIV serology, blood cultures.
- ▶ **Kidney biopsy = diagnostic cornerstone:** light microscopy (crescents, % involvement, necrosis, chronicity), **immunofluorescence** (linear vs granular vs pauci-immune — defines the category) and electron microscopy (location of deposits; linear staining has no deposits).

- **Mimics of RPGN to exclude:** thrombotic microangiopathy/HUS (MAHA, thrombocytopenia), atheroembolic disease, acute interstitial nephritis and ATN — these typically lack dysmorphic haematuria and RBC casts.

Management

- **Principle:** treat *urgently and empirically* — outcome depends on how early therapy is started relative to the degree of scarring; oliguria/dialysis-dependence at presentation predicts a poor renal outcome.
- **General:** supportive care — control BP (RAAS blockade once stable), manage volume, treat hyperkalaemia/uraemia, dialysis as needed.

Category	Induction	Adjunct / maintenance
Anti-GBM (Type I)	Daily plasma exchange × ~2 weeks (until antibody negative) + high-dose corticosteroids + cyclophosphamide	Rituximab in refractory cases; transplant deferred ~6 months until antibodies undetectable
ANCA / pauci-immune (Type III)	Corticosteroids + cyclophosphamide or rituximab (3–6 months)	Maintenance rituximab (preferred) or azathioprine 1–2 yr; avacopan (oral C5a-receptor inhibitor) can spare steroids; plasma exchange for Cr >3.4 mg/dL, diffuse alveolar haemorrhage, or double-positive disease
Immune-complex (Type II)	Treat the underlying disease; for severe/idiopathic — pulse methylprednisolone then prednisone 1 mg/kg/day, ± cyclophosphamide ± plasma exchange	Lupus: induction (steroid + MMF or cyclophosphamide ± belimumab) then MMF/azathioprine maintenance

- **Plasma exchange:** standard in anti-GBM and in pulmonary haemorrhage; in ANCA it is reserved (PEXIVAS-era) for severe renal failure or alveolar haemorrhage. It is **mandatory when anti-GBM and ANCA coexist**.
- **Outcomes:** ANCA — remission in 75–90%, but relapse in 25–50% (commonest in GPA). Post-infectious crescentic GN is usually supportive (no immunosuppression even with crescents).

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- **Labelled glomerulus with a cellular crescent:** label *Bowman's capsule, Bowman's (urinary) space, cellular crescent (proliferating parietal epithelial cells + macrophages), compressed glomerular tuft, segmental fibrinoid necrosis, break in GBM/capillary wall, fibrin in Bowman's space*.

- ▶ **Immunofluorescence comparison (three boxes):** *Linear* GBM IgG (anti-GBM / Type I) — *Granular* “lumpy-bumpy” IgG + C3 (immune-complex / Type II) — *Pauci-immune* / *negative IF with ANCA in serum* (Type III).

Clinical / Diagnostic significance

- ▶ **RPGN is a medical emergency** — the single most important determinant of renal recovery is *time to immunosuppression*; never wait for full results if anti-GBM/Goodpasture is strongly suspected.
- ▶ The IF pattern instantly triages therapy and prognosis: linear → plasma exchange + cyclophosphamide; pauci-immune → steroid + rituximab/cyclophosphamide ± avacopan; granular → treat the underlying immune-complex disease.
- ▶ **Percentage of crescents and degree of interstitial fibrosis** on biopsy are the strongest prognostic markers; >50% crescents, serum creatinine >5–6 mg/dL, oliguria or dialysis need at presentation portend a poor outcome.
- ▶ Always test **anti-GBM and ANCA together** — “double-positive” patients exist and require both plasma exchange and prolonged immunosuppression with closer relapse surveillance.

High-yield exam pointers

- ▶ **Crescentic GN = RPGN**; crescents in >50% of glomeruli defines it; crescent = extracapillary proliferation in Bowman’s space.
- ▶ **Three immunopathologic types:** Type I anti-GBM (linear IF), Type II immune-complex (granular IF), Type III pauci-immune/ANCA (negative IF) — remember frequencies ≈15% : 24% : 60%.
- ▶ **Pauci-immune/ANCA is the commonest** cause of CrGN overall and in older adults; **immune-complex** predominates in children.
- ▶ **Goodpasture antigen** = $\alpha 3$ chain NC1 domain of type IV collagen; HLA-DR2 association; lung + kidney = pulmonary-renal syndrome.
- ▶ **C3/C4 low** in lupus, post-infectious, MPGN, cryoglobulinaemia; **normal** in anti-GBM and ANCA vasculitis.
- ▶ **Anti-GBM treatment** = plasma exchange + steroids + cyclophosphamide; ANCA = steroids + rituximab/cyclophosphamide, maintenance rituximab/azathioprine, avacopan steroid-sparing.
- ▶ **Double-positive (anti-GBM + ANCA)** seen in 25–33% of anti-GBM cases — give both plasma exchange and full immunosuppression.
- ▶ **Crescent frequency hierarchy:** anti-GBM (97%) > ANCA (90%) > lupus III/IV (61%) > immune-complex (56%).

- ▶ Poor prognostic signs: oliguria, dialysis-dependence, creatinine >5–6 mg/dL, fibrous crescents and interstitial fibrosis.

SOURCE & COVERAGE

Diabetic nephropathy: pathological stages, investigations and management

Asked in: Paper IV May 2025 — RGUHS MD General Medicine

Definition / Introduction — **Diabetic nephropathy (DN)** is a chronic, progressive microvascular complication of diabetes mellitus characterised clinically by persistent **albuminuria**, a relentless **fall in GFR**, and rising blood pressure, and pathologically by **glomerular basement membrane (GBM) thickening**, **mesangial expansion** and **nodular (Kimmelstiel–Wilson) glomerulosclerosis**. It is the single most common cause of chronic kidney disease (CKD) and end-stage kidney disease (ESKD) worldwide. Approximately **20–40% of all diabetics develop nephropathy**; because type 2 DM is far commoner, most DN patients have type 2 disease. The term *diabetic kidney disease (DKD)* is preferred for the broader clinical entity (including normoalbuminuric GFR loss), reserving *diabetic nephropathy* for biopsy-proven classical glomerulopathy.

Pathogenesis (basis of the lesions)

- ▶ **Chronic hyperglycaemia** is the prime driver, acting through: non-enzymatic **advanced glycation end-products (AGEs)**, activation of **protein kinase C (PKC)** and the **hexosamine pathway**, and excess **reactive oxygen species**.
- ▶ **Haemodynamic injury** — hyperglycaemia activates the **renin–angiotensin–aldosterone system (RAAS)** and up-regulates proximal-tubular **SGLT1/SGLT2**, reducing distal Na^+ delivery to the *macula densa*, **inhibiting tubuloglomerular feedback** → afferent vasodilatation, **glomerular hyperfiltration** and **intraglomerular hypertension**.

- ▶ **Soluble mediators** — angiotensin II, **endothelin-1**, growth hormone, IGF-1, **connective tissue growth factor** and TGF- β , plus dyslipidaemia, drive matrix production and mesangial sclerosis.
- ▶ **Structural** — GBM thickening with **loss of heparan-sulfate (negative-charge) barrier** → increased filtration of albumin; mesangial matrix accumulation → mesangial sclerosis; **podocyte injury/depletion** (podocyturia, nephrinuria) precedes overt sclerosis.

Pathological (histological) stages — Renal Pathology Society (Tervaert) classification

DN evolves through reproducible glomerular lesions; the internationally used **RPS (Tervaert et al., 2010)** scheme grades glomerular damage I→IV with a separate tubulointerstitial/vascular score.

Class	Glomerular lesion	Defining (inclusion) criterion
I	Isolated GBM thickening; mild/non-specific light-microscopy change	EM-proven GBM >395 nm (female), >430 nm (male) ≥9 yrs; no class II–IV features
IIa	Mild mesangial expansion	Mild expansion in >25% of mesangium; not meeting III/IV
IIb	Severe mesangial expansion	Severe expansion in >25% of mesangium; not meeting III/IV
III	Nodular sclerosis (<i>Kimmelstiel-Wilson lesion</i>)	At least one convincing K–W nodule; not meeting IV
IV	Advanced diabetic glomerulosclerosis	Global glomerulosclerosis in >50% of glomeruli, with class I–III lesions

- ▶ **Interstitial / vascular score (separate):** IFTA (interstitial fibrosis & tubular atrophy, 0–3), interstitial inflammation (0–2), **arteriolar hyalinosis** (0–2) and arteriosclerosis (0–2). Higher cumulative scores (a “D-score”) predict worse renal outcome.
- ▶ **Key morphology:** GBM thickening is the earliest and most *sensitive* change but correlates poorly with clinical disease; **mesangial expansion correlates best with clinical DN**; K–W **nodules** are PAS-positive, eosinophilic acellular nodules and are essentially pathognomonic; **afferent and efferent arteriolar hyalinosis** is characteristic. Lesions of type 1 and type 2 DN with albuminuria are largely **indistinguishable**.

Clinical (functional) stages — Mogensen staging

The natural history was first defined in type 1 DM (similar in type 2) and is classically described in **five** Mogensen stages:

Stage	Designation	GFR / albuminuria	Approx. timing
1	Hyperfunction / hypertrophy	GFR ↑ (hyperfiltration), kidneys enlarged; normoalbuminuria	At diagnosis
2	Silent / latent	Structural change (GBM thickening, mesangial expansion); normoalbuminuria; GFR high-normal	First ~2–5 yrs
3	Incipient nephropathy	Microalbuminuria (UACR 30–300 mg/g); GFR begins to fall; BP rising	~5–10 yrs
4	Overt / clinical nephropathy	Macroalbuminuria (>300 mg/g), declining GFR, hypertension	~10–20 yrs
5	End-stage kidney disease	GFR <15; uraemia, requires KRT	~20–25 yrs

- Caveat (contemporary data): the classical sequence is now heterogeneous — **up to 24% of type 1 and ~50% of type 2 DKD are normoalbuminuric**, and microalbuminuria may regress.

Albuminuria remains the strongest single predictor of GFR decline; its regression on treatment is a good prognostic sign.

Investigations

- **Urinary albumin-to-creatinine ratio (UACR)** on an early-morning spot sample — screening/staging cornerstone. ADA/KDIGO categories: **A1 <30 mg/g (normal)**, **A2 30–300 mg/g (moderately increased)**, **A3 >300 mg/g (severely increased)**. Confirm on **2–3 samples over 3–6 months** (exclude transient causes: exercise, fever, UTI, heart failure, marked hyperglycaemia/hypertension).
- **Estimated GFR (eGFR)** from serum creatinine ($\pm$ cystatin C) — stage CKD G1–G5; assess both UACR *and* eGFR because GFR can fall without albuminuria.
- **Screening schedule:** type 1 DM — **5 years after diagnosis, then annually**; type 2 DM — **at diagnosis, then annually**.
- **Fundoscopy/retinal screening:** **>90% of type 1 (only ~60% of type 2) DN patients have diabetic retinopathy**; absence of retinopathy in a type 1 patient with proteinuria should prompt search for non-diabetic kidney disease. Retinopathy correlates with K–W nodules.
- **Supportive:** quantified proteinuria (24-h or PCR; ranges 0.5–25 g/day), serum K^+/HCO_3^- (type IV RTA / hyporeninaemic hypoaldosteronism $\rightarrow$ hyperkalaemia), lipids, HbA1c, renal ultrasound (kidneys remain enlarged even in advanced DN).

- **Renal biopsy** is *not* routinely required — diagnosis is clinical (long-standing DM + albuminuria + retinopathy). **Biopsy is indicated when non-diabetic disease is suspected:** proteinuria <5 yrs after type 1 onset, absence of retinopathy, active urinary sediment / haematuria / red-cell casts, rapid GFR decline or **acute kidney injury**, nephrotic syndrome of abrupt onset, or immunologic features.

Management

Modern care rests on **four to five pillars** of risk-factor and “renoprotective” therapy plus prevention.

Pillar	Agent / target	Key points
Glycaemic control	Individualised HbA1c ($\approx 7\%$)	Prevents/slows DN, strongest in type 1; reassess agents as GFR falls (avoid metformin & sulfonylureas in advanced CKD)
Blood pressure	<130/80 mmHg	Most patients need ≥ 3 drugs; lifestyle + DASH, Na ⁺ restriction, smoking cessation
RAAS blockade	ACE inhibitor or ARB (max tolerated dose)	First-line with albuminuria/HTN; slows progression at micro- and macro-albuminuric stages independent of BP. Do not combine ACEi + ARB. Accept creatinine rise up to 30%; aim to ↓UACR by 30%. Monitor K ⁺ /creatinine
SGLT2 inhibitor	e.g. empagliflozin, canagliflozin, dapagliflozin	Add to ACEi/ARB in type 2 DKD with eGFR >20; reduces ESKD, creatinine doubling and CV events; not effective <20 mL/min ; caution re euglycaemic DKA
Non-steroidal MRA	Finerenone	Added to ACEi/ARB improves renal & CV outcomes in type 2 DKD; monitor serum potassium
GLP-1 receptor agonist	Semaglutide (FLOW trial)	Improves kidney outcomes and lowers CV death in type 2 DM + CKD

- **Adjuncts:** treat dyslipidaemia (statins; LDL-C <55 mg/dL if established ASCVD), modest dietary protein ~ 0.8 g/kg/day, avoid nephrotoxins, hydrate around **iodinated contrast** (hold metformin peri-procedure), manage CKD–mineral bone disease, anaemia and acidosis.
- **End-stage care:** kidney transplantation gives better survival than dialysis (dialysis survival is worse in diabetics); **simultaneous pancreas–kidney transplant** in selected type 1 patients —

sustained normoglycaemia (≈ 10 yrs) can even reverse glomerular lesions including dissolution of K–W nodules.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Stage/natural-history graph:** x-axis *Years from onset of diabetes* (0→25); two curves — GFR (rising in hyperfiltration → returning to normal → progressive decline to <15) and Albuminuria (normo → micro 30–300 → macro >300). Label the five stages (Hyperfiltration, Silent, Incipient/microalbuminuria, Overt/macroalbuminuria, ESKD).
- ▶ **Glomerular histology schematic:** label *thickened GBM*, *mesangial matrix expansion*, *Kimmelstiel–Wilson nodule (PAS+)*, *afferent & efferent arteriolar hyalinosis*, *podocyte effacement*, *capillary microaneurysm*.

Clinical / Diagnostic significance

- ▶ Albuminuria and reduced GFR are potent independent predictors of cardiovascular death — many DN patients die of CVD before reaching ESKD.
- ▶ Retinopathy–nephropathy concordance is a practical bedside diagnostic tool: its absence in type 1 DM argues for an alternative renal diagnosis and biopsy.
- ▶ Distinguishing DN from **non-diabetic kidney disease** (FSGS, IgA nephropathy, membranous, hypertensive nephrosclerosis, acute tubular injury) changes treatment — hence the importance of the biopsy indications above.
- ▶ DN drives the global ESKD burden; **early UACR screening + the renoprotective pillars** measurably delay dialysis.

High-yield exam pointers

- ▶ Kimmelstiel–Wilson nodules = nodular glomerulosclerosis, PAS-positive, classic for DN; correlate with retinopathy.
- ▶ RPS/Tervaert classes I (GBM thickening) → IIa/IIb (mesangial expansion) → III (K–W nodule) → IV ($>50\%$ global sclerosis) + separate IFTA/vascular score.
- ▶ Mesangial expansion correlates best with clinical DN; GBM thickening is earliest/most sensitive.
- ▶ Microalbuminuria = UACR 30–300 mg/g (incipient); macroalbuminuria >300 mg/g (overt).
- ▶ Screen type 1 at 5 yrs, type 2 at diagnosis, then yearly; confirm on 2–3 samples.
- ▶ Kidneys stay enlarged even in advanced DN — a useful clue.
- ▶ Renoprotection pillars: glycaemia + BP $<130/80$ + ACEi/ARB + SGLT2i (eGFR >20) + finerenone ($\pm$ GLP-1 RA semaglutide).
- ▶ SGLT2 inhibitors cut ESKD/creatinine-doubling/renal death; ineffective below eGFR 20; risk of euglycaemic DKA.

- ▶ **Type IV RTA (hyporeninaemic hypoaldosteronism)** → hyperkalaemia, worsened by ACEi/ARB/MRA.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Glomerular Diseases” (diabetic nephropathy pathology, K–W nodules, hyperfiltration, albuminuria thresholds, RAAS/SGLT2/finerenone) and “Diabetes Mellitus: Complications” (natural history, UACR screening, treatment pillars).
- ▶ **Brenner & Rector's The Kidney** — “Epidemiology of Diabetic Kidney Disease” (RPS/Tervaert pathologic classification Tables 39.4/39.5, structure–function relationships, podocyte injury, reversibility, biopsy indications).
- ▶ **CMDT 2026** — “Diabetes Mellitus & Hypoglycemia” (albumin–creatinine cut-offs, ~0.8 g/kg/day protein, ACEi/SGLT2 sequencing, BP targets).

Coverage note: The **five-stage Mogensen functional staging** with approximate timings is standard internal medicine and is referenced in Brenner (Mogensen, *Diabetes* 1983) but the corpus does not tabulate stage-by-stage cut-offs verbatim; Harrison gives the equivalent natural-history sequence (hyperfiltration → silent structural change → albuminuria → GFR decline → ESKD), which is reproduced here.

Diabetic nephropathy

Asked in: Paper IV Dec 2023 · Paper IV Jul 2020 (2×) — RGUHS MD General Medicine

Definition / Introduction — Diabetic nephropathy, better termed **diabetic kidney disease (DKD)** in clinical practice, is chronic kidney disease attributable to diabetes mellitus, usually recognized by persistent albuminuria and/or falling eGFR in a patient with compatible diabetes duration and other microvascular disease. It is the commonest cause of CKD and ESKD worldwide. The lesion is a combined **metabolic, hemodynamic, glomerular, vascular, podocyte, and tubulointerstitial** injury pattern rather than isolated proteinuria.

Epidemiology and risk factors

- ▶ DKD develops in approximately **20–40%** of patients with diabetes; because type 2 diabetes is much more prevalent, most patients with DKD have type 2 diabetes.
- ▶ It is a major cause of **stage 5 CKD/ESKD** requiring dialysis or transplantation, and CKD in diabetes markedly increases cardiovascular morbidity and mortality.
- ▶ **Type 1 diabetes:** clinically significant DKD usually appears after several years of diabetes; CKD after **10 years or more** of type 1 diabetes is very likely to be DKD if the clinical picture is typical.

- ▶ **Type 2 diabetes:** onset of diabetes is often insidious, so albuminuria or low eGFR may already be present at diagnosis; lesions are more heterogeneous because hypertension, obesity, atherosclerosis, and aging often coexist.
- ▶ Important risk factors are **duration of diabetes, chronic hyperglycemia, hypertension, family history/genetic susceptibility, smoking, obesity, dyslipidemia, ethnicity**, and established cardiovascular disease.
- ▶ Diabetic retinopathy is strongly concordant with DKD, especially in type 1 diabetes; absence of retinopathy in type 1 diabetes with proteinuria should trigger a search for non-diabetic kidney disease.

Pathogenesis

- ▶ **Chronic hyperglycemia** drives advanced glycation end-products, oxidative stress, inflammatory and profibrotic signaling, epigenetic or “metabolic memory” changes, and activation of growth factors such as **TGF-beta** and VEGF.
- ▶ **Hemodynamic injury:** diabetes causes renal hypertrophy, glomerular hyperperfusion, increased intraglomerular pressure, and hyperfiltration. Upregulated proximal tubular **SGLT2** increases sodium-glucose reabsorption, lowers sodium delivery to the macula densa, and perpetuates glomerular hyperfiltration.
- ▶ **RAAS/endothelin axis:** angiotensin II, aldosterone, and endothelin promote efferent arteriolar tone, mesangial matrix production, podocyte injury, and interstitial fibrosis.
- ▶ **Structural glomerular injury:** glomerular basement membrane (GBM) thickening, mesangial matrix expansion, reduced filtration surface area, and later diffuse or nodular glomerulosclerosis.
- ▶ **Podocyte injury** begins early: foot-process widening, podocyte detachment, nephrin loss, and podocytopenia contribute to albuminuria and secondary focal segmental sclerosis.
- ▶ **Tubulointerstitial injury** with tubular basement membrane thickening, tubular dysfunction, inflammation, and fibrosis correlates with progressive eGFR decline.

Natural history and classification

- ▶ Classical sequence: **glomerular hyperfiltration and renal hypertrophy -> moderate albuminuria -> severe albuminuria/overt proteinuria -> declining GFR -> ESKD.**
- ▶ In type 1 diabetes, hyperfiltration and renal hypertrophy occur in the first years; GBM thickening and mesangial expansion appear early; albuminuria often appears after **5-10 years**. In type 2 diabetes, patients may present at any point in this sequence.
- ▶ Atypical but important pattern: DKD may present with **reduced eGFR without albuminuria**, particularly in type 2 diabetes and in contemporary treated cohorts.

Parameter	Category	Exam value
Urine albumin-creatinine ratio (UACR)	Normal	<30 mg/g
UACR	Moderate albuminuria, formerly microalbuminuria	30-299 mg/g
UACR	Severe albuminuria, overt nephropathy	≥300 mg/g
eGFR	G1/G2	≥90 / 60-89 mL/min/1.73 m ²
eGFR	G3a/G3b	45-59 / 30-44 mL/min/1.73 m ²
eGFR	G4/G5	15-29 / <15 mL/min/1.73 m ²

- ▶ Albuminuria is continuous risk: higher UACR predicts faster GFR loss, kidney failure, cardiovascular events, and all-cause mortality.
- ▶ Regression from moderate albuminuria to normoalbuminuria can occur, especially with early treatment; regression is a favorable prognostic sign.

Clinical evaluation and diagnosis

- ▶ Screen with **spot UACR plus serum creatinine-based eGFR**; routine urine dipstick misses low-grade albuminuria.
- ▶ Screening schedule: begin 5 years after onset of type 1 diabetes, and at diagnosis of type 2 diabetes; repeat annually if normal.
- ▶ Confirm an elevated UACR on **2-3 occasions over 3-6 months**, because transient albuminuria may follow strenuous exercise, infection, fever, congestive heart failure, marked hyperglycemia, marked hypertension, or prostate disease.
- ▶ Typical clinical picture: long-standing diabetes, persistent albuminuria, bland urine sediment, hypertension, diabetic retinopathy or neuropathy, and often enlarged kidneys until late disease.
- ▶ Kidney biopsy is usually unnecessary when the phenotype is typical, but is indicated or strongly considered for **sudden onset proteinuria, active urine sediment, RBC casts, nephritic features, rapid eGFR fall, massive proteinuria, refractory hypertension, systemic disease clues, absent retinopathy in type 1 diabetes, or >30% eGFR fall after ACE inhibitor/ARB initiation.**
- ▶ Differential diagnoses in a diabetic patient include hypertensive nephrosclerosis, IgA nephropathy, membranous nephropathy, amyloidosis, monoclonal/light-chain deposition disease, FSGS from obesity, renal artery stenosis, chronic interstitial nephritis, and drug/contrast-related kidney injury.

Renal pathology

- ▶ **Light microscopy:** diffuse mesangial expansion and diffuse glomerulosclerosis are common; advanced disease may show **nodular glomerulosclerosis (Kimmelstiel-Wilson nodules)**.

- ▶ **Kimmelstiel-Wilson nodules:** round, hypocellular mesangial matrix nodules, often PAS/silver positive, surrounded by patent capillaries; a classic exam lesion, but nodular glomerulosclerosis has mimics such as amyloid, light-chain deposition disease, and idiopathic nodular glomerulosclerosis.
- ▶ **Electron microscopy:** early and sensitive **GBM thickening**, mesangial matrix increase, podocyte foot-process widening or detachment, and thickened tubular basement membranes.
- ▶ **Immunofluorescence:** may show nonspecific linear IgG or complement accentuation along basement membranes, without immune-complex deposits on electron microscopy.
- ▶ **Vascular lesions:** afferent and efferent arteriolar hyalinosis is characteristic; exudative lesions include hyaline caps/fibrin caps and capsular drops.
- ▶ **Chronic damage:** global glomerulosclerosis, secondary FSGS, interstitial fibrosis, tubular atrophy, and arteriosclerosis determine irreversible kidney function loss.

Management

- ▶ Aim to slow albuminuria progression, preserve eGFR, reduce cardiovascular risk, avoid AKI, and prepare timely kidney replacement therapy when needed.
- ▶ **Glycemic control:** target HbA1c around 7% in many nonpregnant adults, individualized for age, comorbidity, hypoglycemia risk, and CKD stage. Intensive glycemic control clearly prevents or delays albuminuria in type 1 diabetes and helps early DKD; benefit is less dramatic once established albuminuria and GFR decline are present.
- ▶ As GFR falls, reassess diabetes drugs: insulin requirement may decline; sulfonylureas increase hypoglycemia risk; metformin should be stopped when **eGFR <30 mL/min/1.73 m²**.
- ▶ **Blood pressure:** a practical exam target is **<130/80 mm Hg** in diabetes with albuminuria or CKD, individualized lower if tolerated and cardiovascular/CKD risk is high. Use salt restriction, weight loss, exercise, DASH-style diet, and smoking cessation.
- ▶ **ACE inhibitor or ARB:** first-line antiproteinuric therapy in albuminuric DKD and/or hypertension; reduces intraglomerular pressure and fibrosis. Do not use ACE inhibitor plus ARB together, and do not prescribe RAAS blockade solely to prevent DKD in normotensive, normoalbuminuric diabetes.
- ▶ Check **serum creatinine/eGFR and potassium within 1-2 weeks** after starting or uptitrating ACE inhibitor/ARB/MRA. Review therapy if potassium rises significantly or creatinine rises/eGFR falls by **>30%**.
- ▶ **SGLT2 inhibitors:** in type 2 diabetes with CKD, canagliflozin, dapagliflozin, and empagliflozin slow GFR decline, reduce kidney failure risk, and reduce heart failure events; kidney benefit persists despite reduced glucose-lowering at low eGFR. They are generally useful down to about **20-25 mL/min/1.73 m²** depending on drug and guideline, and are stopped at dialysis initiation.

- ▶ **Mineralocorticoid receptor antagonism:** finerenone or other MRAs reduce albuminuria and improve kidney/cardiovascular outcomes in selected type 2 DKD patients already on ACE inhibitor/ARB; monitor carefully for hyperkalemia.
- ▶ **GLP-1 receptor agonists** such as dulaglutide or semaglutide are useful additional agents for glycemic, weight, cardiovascular, and kidney-risk reduction, especially when SGLT2 inhibitors are not tolerated or CKD is advanced.
- ▶ Treat dyslipidemia with statin-based therapy as indicated; manage obesity, avoid NSAIDs and unnecessary iodinated contrast, hydrate around contrast exposure, treat metabolic acidosis and anemia of CKD, vaccinate, and refer to nephrology for eGFR <30, rapid decline, or heavy albuminuria.
- ▶ ESKD management includes education for dialysis modalities and transplantation; **kidney transplantation improves survival**, and simultaneous pancreas-kidney transplantation may be considered in suitable type 1 diabetes patients.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Natural history graph:** x-axis = diabetes duration in years; y-axis left = UACR/albuminuria; y-axis right = GFR; labels = hyperfiltration, moderate albuminuria, severe albuminuria, falling GFR, ESKD, earlier presentation in type 2 diabetes.
- ▶ **Glomerular pathology diagram:** labels = thickened GBM, mesangial expansion, *Kimmelstiel-Wilson nodule*, podocyte foot-process effacement/detachment, afferent and efferent arteriolar hyalinosis, tubulointerstitial fibrosis.

Clinical / Diagnostic significance

- ▶ DKD is both a renal diagnosis and a **cardiovascular risk marker**; albuminuria independently predicts myocardial infarction, stroke, heart failure, and death.
- ▶ Retinopathy supports DKD, especially in type 1 diabetes; its absence, active sediment, or rapid loss of function should prevent blind attribution to diabetes.
- ▶ Diabetics are prone to **type 4 renal tubular acidosis** with hyperkalemia, especially with ACE inhibitors, ARBs, MRAs, NSAIDs, beta-blockers, or advanced CKD.
- ▶ Diabetes plus CKD is a high-risk setting for **contrast-associated AKI**; use the lowest necessary contrast dose, avoid volume depletion and NSAIDs, and monitor creatinine after exposure.
- ▶ Persistent albuminuria despite good BP and glycemic control should prompt adherence review, sodium intake assessment, optimized RAAS/SGLT2/MRA therapy, and exclusion of non-diabetic kidney disease.

High-yield exam pointers

- ▶ Write **UACR plus eGFR**; dipstick alone is inadequate for early disease.
- ▶ Screening: **type 1 after 5 years, type 2 at diagnosis, then annually.**

- ▶ Confirm albuminuria: 2-3 samples over 3-6 months.
- ▶ Albuminuria categories: 30-299 mg/g and ≥ 300 mg/g.
- ▶ Classical sequence: hyperfiltration $\rightarrow$ albuminuria $\rightarrow$ proteinuria $\rightarrow$ falling GFR.
- ▶ Pathology triad: GBM thickening, mesangial expansion, nodular glomerulosclerosis.
- ▶ Treatment triad for albuminuric DKD: BP control + ACE inhibitor/ARB + SGLT2 inhibitor; add finerenone when appropriate.
- ▶ Do **not** combine ACE inhibitor and ARB; monitor creatinine and potassium.
- ▶ Absence of retinopathy in type 1 diabetes with proteinuria means **look for another renal disease**.

Discuss clinical features and management of Nephrolithiasis

Asked in: Paper IV 17 Apr 2026 — RGUHS MD General Medicine

Definition / Introduction — Nephrolithiasis (kidney stone disease, urolithiasis) is the formation of crystalline concretions within the upper urinary tract due to supersaturation of lithogenic solutes in urine when the concentration product exceeds the solubility product, combined with deficient crystallisation inhibitors. It is a common, recurrent, costly **systemic disorder** — lifetime risk reaches ~20% in men and ~10% in women, with >50% of first-time formers recurring within 5–10 years. A stone may sit silently in the kidney for years, then migrate into the ureter to produce **renal colic**, often described by patients as the worst pain ever experienced. Identifying the stone type is central, as it dictates prognosis and the targeted, often life-long, preventive regimen.

Classification / Types of stones

Stone type	Approx. frequency	Key urinary risk factors	Radiology	Special features
Calcium oxalate	~75% (most common)	↑urine calcium, ↑oxalate, ↓citrate	Radiopaque	Insensitive to urine pH; grows on Randall’s plaque
Calcium phosphate	~15%	↑calcium, ↓citrate, ↑phosphate, urine pH ≥ 6.5	Radiopaque	Linked to distal RTA & primary hyperparathyroidism

Stone type	Approx. frequency	Key urinary risk factors	Radiology	Special features
Uric acid	~8%	High uric acid excretion, persistent urine pH ≤ 5.5	Radiolucent on KUB; visible on CT	Seen in gout, obesity, T2DM, tumour lysis
Struvite (Mg-ammonium-phosphate, “triple-phosphate”/infection stone)	~1%	Urease-producing UTI, urine pH > 8.0	Faintly opaque	Forms staghorn calculi ; <i>Proteus mirabilis</i> , <i>Klebsiella</i> , <i>Providencia</i>
Cystine	$< 1\%$	Autosomal-recessive cystinuria	Faintly opaque	Hexagonal crystals; staghorn / bilateral; childhood onset

- ▶ Calcium-containing stones together account for ~85% and are radiopaque, which is why most stones are seen on plain radiographs.
- ▶ Many stones are **mixtures** (e.g., calcium oxalate + calcium phosphate) and contain a protein matrix. Rarely stones are **drug-induced** (acyclovir, atazanavir/indinavir, triamterene, sulfadiazine, guaifenesin).

Pathogenesis and risk factors

- ▶ **Supersaturation–inhibition balance:** stones form when urine is supersaturated and protective inhibitors are deficient. **Citrate** is the most important inhibitor of calcium stones (complexes calcium, raising solubility); others include magnesium and pyrophosphate.
- ▶ **Randall’s plaque hypothesis:** interstitial **calcium-phosphate** deposits begin at the thin limb of the loop of Henle, extend to the papillary tip and erode through the urothelium, providing an anchored nidus on which calcium oxalate/phosphate crystals grow — explaining why stone formation begins years before a clinical stone.
- ▶ **Urinary risk factors:** low urine volume (< 1 L/day more than doubles risk), hypercalciuria (> 250 mg/day men, > 200 mg/day women, or > 4 mg/kg/day), hyperoxaluria (> 40 mg/day), hypocitraturia (< 450 mg/day), hyperuricosuria (> 800 mg/day men, > 750 mg/day women) and unfavourable urine pH.
- ▶ **Dietary risk factors:** high animal protein, oxalate, sodium, sucrose/fructose and high-dose vitamin C (raises oxalate). **Protective:** high dietary calcium (binds gut oxalate), potassium, phytate, citrus and high fluid intake. *Low* dietary calcium is harmful — it increases oxalate absorption and bone loss.
- ▶ **Associated/secondary conditions:** primary hyperparathyroidism, distal (type 1) renal tubular acidosis (urolithiasis in up to 75%), GI malabsorption (Crohn’s, gastric bypass → **enteric**

hyperoxaluria via fatty-acid sequestration of calcium), obesity, type 2 diabetes, gout, medullary sponge kidney, and recurrent UTI.

- ▶ **Genetic disorders:** **cystinuria** (AR defect in dibasic amino-acid reabsorption) and **primary hyperoxaluria** (AR hepatic overproduction of oxalate, types I–III) — both cause early, severe, recurrent stones.

Clinical features

- ▶ **Two classic acute presentations:** (1) **renal colic** and (2) painless gross haematuria.
- ▶ **Renal colic:** sudden-onset, severe **unilateral flank pain** that waxes and wanes (a misnomer — pain rarely fully subsides) with no relieving posture; patients are **restless and writhing** (cf. the still patient of peritonitis). Frequently accompanied by **nausea/vomiting** and visible or microscopic haematuria.
- ▶ **Radiation by stone site:** upper-ureteric stone → pain radiates anteriorly; lower-ureteric stone → radiates to ipsilateral **testis/labium**; ureterovesical-junction stone → urinary **urgency, frequency, dysuria** (mimics cystitis but culture-negative).
- ▶ **Differential diagnosis by location:** right UPJ stone mimics acute cholecystitis; right pelvic-brim stone mimics appendicitis; left pelvic-brim mimics diverticulitis. Also consider biliary colic, ectopic pregnancy/ovarian torsion, **leaking abdominal aortic aneurysm**, herpes zoster, musculoskeletal pain, and ureteric obstruction by clot or sloughed papilla.
- ▶ **Red-flag** — “**pus under pressure**”: an obstructing stone with proximal infection (fever, leucocytosis, sepsis) is an **obstructive pyonephrosis / urologic emergency** requiring emergent drainage; antibiotics alone are inadequate.
- ▶ Note: absence of haematuria does **not** exclude a stone (complete obstruction may give a normal urinalysis), and stone size does not correlate with pain severity.

Investigations

- ▶ **Urinalysis:** micro/gross haematuria in ~90%; sediment may show crystals — *bipyramidal (envelope)* calcium oxalate or *hexagonal* cystine crystals; pyuria with culture if infection suspected.
- ▶ **Imaging** — **non-contrast helical CT (KUB) is the gold standard:** highly sensitive, detects stones as small as 1 mm including “radiolucent” uric-acid stones, and shows hydroureteronephrosis and perinephric stranding. Hounsfield units estimate composition (pure uric acid = low HU).
Ultrasound (no radiation) is preferred first-line in pregnancy and for follow-up but is less sensitive and misses most ureteric stones. **KUB radiograph** misses radiolucent/small stones and gives no information on obstruction.
- ▶ **Blood:** serum electrolytes (for hypokalaemia/RTA), creatinine, calcium, phosphate, uric acid; PTH and 25-OH vitamin D if calcium is high/high-normal.

- ▶ **Metabolic work-up: stone analysis** is essential whenever a stone/fragment is retrieved (patients should strain urine). **Two 24-h urine collections** on the usual diet form the cornerstone of prevention — measure volume, calcium, oxalate, citrate, uric acid, sodium, potassium, phosphate, magnesium, pH, creatinine, and calculated supersaturation. Indicated after the first stone in interested/high-risk patients and in all recurrent formers.

Management — acute and surgical

- ▶ **Analgesia:** parenteral NSAIDs (e.g., ketorolac) are at least as effective as opioids with fewer side effects, and are first-line; opioids are adjuncts.
- ▶ **Fluids:** maintain euvolaemia — forced diuresis does not flush stones and worsens pain/obstruction.
- ▶ **Medical expulsive therapy (MET):** α -blocker (tamsulosin 0.4 mg OD) $\pm$ an NSAID (ibuprofen 600 mg TID) $\pm$ short low-dose prednisone increases spontaneous passage, most effective for distal ureteric stones >5 mm. Stones <5 – 6 mm usually pass spontaneously.
- ▶ **Indications for urologic intervention:** UTI/infection behind obstruction, low likelihood of passage (stone ≥ 6 mm, anatomic abnormality, solitary kidney), intractable pain/vomiting, or non-passage after a few weeks.
- ▶ **Emergency drainage** (ureteric stent or percutaneous nephrostomy) for the infected, obstructed kidney — *definitive stone removal is deferred until sepsis is treated.*
- ▶ **Definitive procedures** (chosen by stone size, site, composition, anatomy):
 - Ureteroscopy + laser/basket — mid/distal ureteric stones; outpatient, most reliable.
 - Extracorporeal shock-wave lithotripsy (ESWL) — least invasive; best for stones <1 cm in the lower pole or <2 cm elsewhere; poor for hard stones (cystine, brushite, >1000 – 1200 HU) and obese patients; contraindicated in pregnancy, untreated UTI, coagulopathy/anticoagulation, and discouraged for staghorn/infected stones.
 - Percutaneous nephrolithotomy (PCNL) — for large (>15 – 20 mm) and staghorn calculi; highest stone-free rate. Open ureterolithotomy/pyelolithotomy is now rarely needed.

Prevention by stone type

- ▶ **Universal measure (all types):** high fluid intake to keep urine volume ≥ 2 – 2.5 L/day — proven by RCT to halve recurrence; tailor advice to the measured 24-h volume.

Stone type	Targeted preventive measures
Calcium oxalate	Normal-to-high dietary calcium (~ 1000 – 1200 mg/d), restrict sodium (<2.5 – 3.5 g/d) & animal protein, reduce sucrose/fructose; thiazide (higher dose than for HTN — chlorthalidone/indapamide OD, HCTZ BD) for hypercalciuria; potassium citrate for hypocitraturia; allopurinol if

Stone type	Targeted preventive measures
	hyperuricosuric; avoid high-dose vitamin C; DASH / Mediterranean diet
Calcium phosphate	Thiazide + sodium restriction; potassium citrate (with urine-pH monitoring , as alkali can worsen phosphate stones); reduce dietary phosphate; exclude/treat distal RTA & hyperparathyroidism
Uric acid	Alkalinise urine to pH 6.5 (potassium citrate/bicarbonate) — <i>mainstay</i> ; reduce purine intake; add xanthine-oxidase inhibitor (allopurinol 300 mg/d or febuxostat) if alkalinisation insufficient (lowers urine uric acid 40–50%)
Struvite	Complete surgical clearance (PCNL) + prevent/treat UTI; acetohydroxamic acid (urease inhibitor) for refractory recurrent cases
Cystine	High urine volume (3–4 L/d), low sodium, alkalinise to pH 7.0–7.5 (potassium citrate); thiol drugs that solubilise cystine — tiopronin (preferred) or D-penicillamine
Primary hyperoxaluria (type I)	Pyridoxine (vitamin B6) in selected patients; siRNA agents lumasiran / nedosiran to cut hepatic oxalate production

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Labelled coronal nephron/urinary tract diagram of stone impaction sites:** label *Kidney (calyx, renal pelvis)*, *Randall's plaque at papillary tip*, and the **three ureteric narrowings** — *Pelvi-ureteric (UPJ) junction*, *crossing of iliac vessels / pelvic brim*, *Vesico-ureteric (UVJ) junction* — plus *bladder*; mark *hydronephrosis* proximal to an obstructing stone.
- ▶ **Urine-pH vs stone-type bar/line:** label axis pH 4.5 → 8.5; mark *uric acid* ≤ 5.5 , *calcium oxalate* (pH-independent), *calcium phosphate* ≥ 6.5 , *cystine* (more soluble at high pH), *struvite* > 8.0 .

Clinical / Diagnostic significance

- ▶ Nephrolithiasis is a **marker of systemic disease** — independently associated with hypertension, CKD/ESRD, reduced bone mineral density, gout, type 2 diabetes and cardiovascular disease; evaluate accordingly.
- ▶ A **culture-negative pyuria with haematuria** plus flank pain should prompt CT for an occult ureteric stone before labelling “cystitis”.

- ▶ Unexplained recurrent calcium stones mandate exclusion of **primary hyperparathyroidism** (serum Ca, PTH) and **distal RTA** (hyperchloraemic metabolic acidosis with inappropriately alkaline urine, hypocitraturia, hypokalaemia).
- ▶ **Stone composition and 24-h urine chemistry**, not symptoms, drive long-term prevention — preventive therapy is usually **life-long** with annual 24-h urine monitoring and radiation-sparing follow-up imaging (prefer ultrasound).

High-yield exam pointers

- ▶ Commonest stone = **calcium oxalate** (~75%); calcium-containing stones ~85% and radiopaque; **uric acid** stones are radiolucent on KUB but visible on CT.
- ▶ **Non-contrast helical CT** = investigation of choice (detects 1-mm stones); **ultrasound** in pregnancy/follow-up.
- ▶ Restless writhing patient with colicky flank-to-groin pain + haematuria = ureteric stone; **NSAIDs** first-line analgesia.
- ▶ **Obstructed + infected kidney** = **emergency drainage** (stent/nephrostomy) — “pus under pressure”.
- ▶ Stones <5 mm usually pass; offer **tamsulosin** MET; ≥6 mm or persistent → intervention; staghorn → PCNL.
- ▶ **Citrate** = key inhibitor; **hypocitraturia** → **potassium citrate**; **hypercalciuria** → **thiazide** + low sodium.
- ▶ Do **not** restrict dietary calcium — it raises oxalate absorption and stone risk; restrict **sodium**, **animal protein**, **oxalate**; fluids to ≥2–2.5 L urine/day.
- ▶ **Struvite** = infection stone (urease-positive *Proteus*); **cystine** = AR, hexagonal crystals, treat with tiopronin + alkali; **uric acid** stones managed primarily by **urinary alkalinisation to pH 6.5**.

Emphysematous Pyelonephritis: Clinical Presentation, Evaluation and Management

Asked in: Paper IV Oct 2025 — RGUHS MD General Medicine

Definition / Introduction — *Emphysematous pyelonephritis (EPN)* is an acute, severe, **necrotizing** infection of the renal and perinephric tissues characterized by the production of gas within the renal parenchyma, collecting system and/or perirenal space by gas-forming uropathogens. It is a **urological emergency** that occurs *almost exclusively in patients with poorly controlled diabetes mellitus*, frequently with co-existent urinary obstruction, and carries a high mortality if not promptly recognised and aggressively managed. It must be distinguished from the more benign *emphysematous pyelitis* (gas confined to the collecting system, parenchyma spared) and *emphysematous cystitis* (gas in the bladder wall/lumen).

Pathogenesis and predisposing factors

- ▶ **Diabetes mellitus** is the dominant risk factor — 62–100% of patients in case series are diabetic, and serum glucose is often very high at presentation; EPN occurs **almost exclusively in poorly controlled diabetics**.
- ▶ **Mechanism of gas formation:** high urinary and tissue glucose acts as a fermentable substrate for facultative anaerobes, generating large volumes of gas (CO₂, hydrogen, nitrogen) through *fermentation*. In the *non-diabetic minority*, **fermentation of tissue protein** is the proposed gas source.
- ▶ **Contributory factors:** *impaired host immunity and microvascular disease of diabetes*, **urinary tract obstruction** (calculus, papillary necrosis, stricture — a common predisposant), high tissue glucose, and locally **reduced perfusion**, which favours anaerobic metabolism and necrosis.
- ▶ A **female preponderance** is consistently reported (ascending infection, shorter urethra). Most infection is *ascending* from the lower tract.
- ▶ The end result is **acute suppurative necrosis** of parenchyma; a fulminant course is characterised by *tissue necrosis, intravascular thrombosis and microabscess formation*.

Microbiology

- ▶ ***Escherichia coli** is the single most common organism (~45–54% of episodes) — a gas-forming, facultative anaerobic uropathogen*.
- ▶ ***Klebsiella pneumoniae*** is the next most frequent isolate.
- ▶ Less common: *Proteus mirabilis*, *Enterobacter*, *Pseudomonas aeruginosa* and, rarely, *Candida* and *Clostridium* species.
- ▶ **Bacteraemia** is demonstrable in 20–50% of patients in whom blood cultures are obtained — reflecting the invasive, systemic nature of the disease.

Clinical presentation

- ▶ The presentation overlaps with severe acute pyelonephritis — the **classic triad of fever, vomiting and flank pain**.
- ▶ **Severe pyelonephritis** features: *high fever, rigors, nausea, vomiting, flank/costovertebral-angle (CVA) pain and marked CVA tenderness*; symptoms are usually acute in onset and may or may not be preceded by cystitis.
- ▶ **Systemic toxicity is common**: the patient is frequently *acutely ill, dehydrated, tachycardic and may present with septic shock*.
- ▶ **Crepitus** over the flank or a *palpable, tender renal mass* may rarely be appreciated when gas tracks into the retroperitoneum/subcutaneous tissue.
- ▶ **Frequent accompaniments / complications**: *acute kidney injury, diabetic ketoacidosis or hyperglycaemic crisis, thrombocytopenia, disturbance of consciousness, and shock* — these are also **adverse prognostic markers**.
- ▶ **Pneumaturia** suggests gas in the collecting system/bladder (more typical of emphysematous cystitis or pyelitis).
- ▶ A subset present with a **poor response to standard antibiotics for “pyelonephritis”**, or *persistent fever/bacteraemia*, which should prompt imaging to look for gas, abscess or obstruction.

Evaluation / Investigations

- ▶ **Urinalysis & urine culture**: pyuria, bacteriuria, haematuria; culture (with sensitivities) identifies the organism — *obtain before antibiotics where feasible*.
- ▶ **Blood culture**: positive in a substantial minority; identifies bacteraemia and guides therapy.
- ▶ **Blood investigations**: complete blood count (*leukocytosis with left shift; thrombocytopenia is a poor-prognosis marker*), **renal function (urea/creatinine — AKI is common)**, electrolytes, **blood glucose and HbA1c**, **arterial blood gas / serum lactate** (for acidosis and sepsis), and **CRP** (generally elevated). Screen for **DKA** (ketones, anion gap).
- ▶ **Plain abdominal radiograph (KUB)**: may show mottled/streaky or crescentic gas over the renal shadow — but **identifies renal gas in only ~50%** of EPN cases (more sensitive in emphysematous cystitis).
- ▶ **Ultrasonography**: usually shows renal abnormality with high-amplitude echoes and “dirty” shadowing from gas, but is **less accurate than CT** for defining extent.
- ▶ **Contrast-enhanced CT is the imaging modality of choice** — it confirms the diagnosis, maps the distribution and extent of gas, parenchymal destruction, fluid/abscess, obstruction and contralateral kidney, and underpins the radiological classification that drives management.

Radiological classification (CT-based — Huang & Tseng) — directs management & prognosis:

Class	CT findings	Implication
Class 1	Gas confined to the collecting system (emphysematous <i>pyelitis</i>)	Best prognosis
Class 2	Gas confined to the renal parenchyma alone	Good outcome with drainage
Class 3A	Extension of gas/abscess into the perinephric space	Higher risk
Class 3B	Extension of gas/abscess into the pararenal space (beyond Gerota's fascia)	Higher risk
Class 4	Bilateral EPN , or EPN in a solitary functioning kidney	Worst prognosis

An alternative morphological scheme (Wan) divides EPN into Type I — parenchymal destruction with streaky/mottled gas and no fluid (the “dry,” more necrotic, higher-mortality form) — and Type II — renal/perirenal fluid with bubbly/loculated gas (the “wet,” lower-mortality form).

Adverse prognostic factors (≥2 predict failure of conservative management): *thrombocytopenia, acute kidney injury (raised creatinine), disturbance of consciousness, and shock.*

Management

Management is **multidisciplinary** (physician/intensivist, nephrologist, urologist, interventional radiologist) and combines **resuscitation, source control and metabolic control**.

- ▶ **Resuscitation & supportive care:** IV fluids, correction of dehydration and electrolytes, management of sepsis/septic shock, and **aggressive glycaemic control** (treat DKA/hyperglycaemia with insulin).
- ▶ **Empirical broad-spectrum IV antibiotics**, started promptly after cultures and de-escalated by sensitivities:
 - For hospitalised/systemically ill patients, an IV **β-lactam** is preferred — *ceftriaxone* or *cefepime*, *piperacillin-tazobactam*, or a *carbapenem*; an **aminoglycoside** (e.g. with ampicillin) is an effective addition/alternative. **Carbapenems** are used for ESBL-producing organisms.
 - Treatment is *culture-guided*; switch to oral once stable, with a total course typically extending well beyond uncomplicated pyelonephritis given tissue-invasive necrotising disease.
- ▶ **Relief of obstruction:** *ureteric stenting* or *percutaneous nephrostomy* if there is obstructive uropathy (e.g. obstructing calculus, papillary necrosis) — essential for source control.
- ▶ **Percutaneous catheter drainage (PCD)** of gas/abscess, combined with antibiotics, is now the **recommended initial intervention** and the modern “kidney-sparing” standard; it has *similar or lower mortality* than emergency nephrectomy or medical therapy alone.

- ▶ **Nephrectomy** (emergency or delayed/elective) is reserved for **failure of PCD plus medical therapy**, fulminant/extensive disease, or a non-functioning kidney — typically in patients with **≥2 adverse prognostic factors** or extensive (Class 3B/4) disease.
- ▶ **Outcome:** mortality ranges from 7–20% in less severe disease to ~70% in a fulminant course (necrosis, intravascular thrombosis, microabscesses). Comparative case-series mortality: ~50% with medical therapy alone, ~25% with medical therapy plus emergency nephrectomy, and ~13.5% with medical therapy plus initial percutaneous drainage — underscoring the value of early drainage.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Labelled CT cross-section of EPN (axial):** label *renal parenchyma with destruction, intraparenchymal/streaky gas (mottled lucencies), gas tracking into perinephric space, Gerota's fascia, pararenal space, obstructing calculus/collecting-system gas, and normal contralateral kidney*. Annotate the **Huang-Tseng classes 1–4** alongside (gas in collecting system → parenchyma → perinephric → pararenal → bilateral/solitary).
- ▶ **Management flow-diagram:** *Suspected EPN → resuscitate + IV antibiotics + glycaemic control → CT (classify) → relieve obstruction (stent/nephrostomy) → Class 1–2 or <2 risk factors: percutaneous drainage; Class 3–4 with ≥2 risk factors / failure of PCD: nephrectomy.*

Clinical / Diagnostic significance

- ▶ EPN should be suspected in any diabetic with severe/septic pyelonephritis failing to respond promptly, or with gas seen on KUB/USG — CT is **mandatory** to confirm and stage.
- ▶ Early percutaneous drainage with relief of obstruction has shifted practice away from routine emergency nephrectomy, improving renal preservation and survival.
- ▶ **Glycaemic control and treatment of the underlying diabetes** are integral, not adjunctive — high tissue glucose perpetuates gas-forming infection.
- ▶ Differentiate from *xanthogranulomatous pyelonephritis* (chronic, staghorn-calculus-associated, lipid-laden foamy macrophages, usually needs nephrectomy) and from benign **post-instrumentation gas** in the collecting system (gas in *tissue* defines emphysematous infection).

High-yield exam pointers

- ▶ EPN = **gas-forming necrotising infection of renal/perinephric tissue**, *almost exclusively in poorly controlled diabetics*.
- ▶ ***E. coli (commonest) and Klebsiella pneumoniae are the leading pathogens;** bacteraemia in 20–50%*.
- ▶ **Pathogenesis** = fermentation of **high tissue/urinary glucose** by facultative anaerobes → gas; obstruction and impaired immunity contribute.
- ▶ **CT is the investigation of choice;** KUB detects renal gas in only ~50%.

- ▶ **Huang-Tseng Class 1→4** (collecting system → parenchyma → perinephric → pararenal → bilateral/solitary) classifies and prognosticates.
- ▶ **Four poor-prognosis factors:** *thrombocytopenia, AKI, altered sensorium, shock*; ≥ 2 predicts failure of conservative care.
- ▶ **Modern management** = antibiotics + glycaemic/sepsis control + percutaneous drainage + relief of obstruction; nephrectomy only if these fail.
- ▶ Mortality 7–20% (less severe) up to ~70% (fulminant); PCD-based therapy gives the lowest mortality (~13.5%).
- ▶ Distinguish from **emphysematous pyelitis** (collecting-system gas, parenchyma spared, benign) and **emphysematous cystitis** (bladder).

SOURCE & COVERAGE

Coverage note: The Huang & Tseng CT classification (Classes 1–4), the Wan Type I/II morphological types, and the four adverse prognostic factors are *universally accepted standard urological/nephrological references* used to stage and triage EPN but were **not present verbatim in the local corpus**; they are included as standard, accurate exam content. All organism frequencies, mortality percentages, imaging yields, pathogenesis and management principles are grounded in Brenner, Harrison and CMDT as cited above.

Focal Segmental Glomerulosclerosis

Asked in: Paper IV Nov 2019 — RGUHS MD General Medicine

Definition / Introduction — *Focal segmental glomerulosclerosis (FSGS)* is not a single disease but a **clinico-pathological pattern of podocyte injury** characterised by segmental (part of the tuft) scars in *some but not all* (focal) glomeruli, with **proteinuria** as its ubiquitous clinical hallmark. It is best regarded as a *podocytopathy* — a final common pathway of glomerular injury with multiple causes (primary/idiopathic, secondary/adaptive, viral and genetic). FSGS is now the **most common cause of**

primary glomerular disease leading to ESKD in the United States and an important cause of steroid-resistant nephrotic syndrome in both children and adults.

Etiological Classification (Primary, Secondary, Genetic)

- ▶ **Primary (idiopathic) FSGS** — driven by a presumed **circulating permeability factor** (yet to be definitively identified); typically presents with abrupt, *full nephrotic syndrome* and diffuse foot-process effacement; the form most likely to respond to immunosuppression and to recur after transplantation.
- ▶ **Secondary / adaptive FSGS** — maladaptive response to nephron loss, glomerular hypertrophy or hyperfiltration; usually sub-nephrotic proteinuria with *preserved serum albumin* and *segmental* foot-process effacement.

Category	Representative causes (from Harrison Table 326-4 / Brenner Box 31.6)
Adaptive (hyperfiltration / ↓ nephron mass)	Obesity, oligomeganephronia, unilateral renal agenesis/post-nephrectomy, reflux nephropathy, sickle cell disease, cyanotic congenital heart disease, hypoxic pulmonary disease, glomerulomegaly
Viral	HIV (collapsing), hepatitis B, parvovirus B19, SARS-CoV-2
Drug-associated	Heroin, analgesics, bisphosphonates (pamidronate) , interferon, anabolic steroids, ecstasy, lithium
Other secondary	Hypertensive nephrosclerosis, cholesterol emboli, radiation nephritis
Genetic / familial podocytopathies	<i>NPHS1</i> (nephrin), <i>NPHS2</i> (podocin), <i>ACTN4</i> (α-actinin-4), <i>TRPC6</i> , <i>INF2</i> (inverted formin 2), <i>WT1</i> , <i>PLCE1</i> , <i>CD2AP</i> ; Fabry disease (α-galactosidase A); nephrosialidosis
High-risk genetic background	APOL1 risk alleles (G1/G2) in those of sub-Saharan African ancestry

Pathology — Columbia Histological Variants

- ▶ **Light microscopy:** segmental glomerular **sclerosis/consolidation** with capillary collapse, hyalinosis (insudated plasma proteins), foam cells and adhesions to Bowman's capsule. Lesions are most prominent at the **cortico-medullary junction**, so a superficial biopsy may miss them and be mislabelled minimal change disease (MCD).
- ▶ **Immunofluorescence:** non-specific **IgM and C3** trapped *in the sclerotic segments only* (not pathogenic immune complexes).
- ▶ **Electron microscopy:** **foot-process effacement** — diffuse in primary, more *segmental/partial* in secondary FSGS; no immune-type dense deposits in non-sclerotic glomeruli.

- The **Columbia classification** recognises *five morphological variants* correlating with cause and prognosis:

Variant	Key features	Demographics / prognosis
NOS (classic)	Segmental sclerosis without distinctive features; commonest (~42%)	Primary or secondary; intermediate outcome
Perihilar	Sclerosis + hyalinosis at the vascular pole; glomerulomegaly	Typical of adaptive/secondary FSGS; often sub-nephrotic
Tip lesion	Consolidation at the tubular (urinary) pole opposite the hilum	Older Caucasian males; steroid-responsive, best prognosis
Cellular	Endocapillary hypercellularity, foam cells; heavy proteinuria	Intermediate remission/ESKD rates
Collapsing (collapsing glomerulopathy)	Global/segmental capillary collapse + podocyte hyperplasia (“pseudocrescents”)	African-American, HIV-associated; massive proteinuria; worst prognosis

Pathogenesis — Podocyte Injury as the Final Common Pathway

- **Circulating permeability factor (primary FSGS)**: plasma factor increasing glomerular albumin permeability; supported by **recurrence within hours–days of transplantation** and response to **plasmapheresis**. Candidate factors include **soluble urokinase receptor (suPAR)** (activates podocyte $\beta 3$ -integrin) and a galactose-binding factor — *neither yet conclusively proven*.
- **Genetic podocytopathies**: mutations disrupt the **slit diaphragm / actin cytoskeleton / GBM**. *NPHS2* (podocin) is the **most frequent genetic cause of steroid-resistant nephrotic syndrome** (the R138Q and R229Q variants are characteristic); *NPHS1* causes congenital (Finnish-type) nephrotic syndrome; *ACTN4*, *TRPC6* and *INF2* cause autosomal-dominant adult FSGS.
- **APOL1 risk variants (G1/G2, chromosome 22)**: explain the ~4-fold excess of FSGS and the 18–50-fold excess of HIV-associated collapsing FSGS in people of African ancestry (the same alleles that confer protection against *Trypanosoma brucei rhodesiense* — analogous to sickle trait and malaria).
- **Adaptive (maladaptive) hyperfiltration**: nephron loss $\rightarrow$ $\uparrow$ single-nephron GFR and intraglomerular hypertension $\rightarrow$ podocyte stretch, dropout and segmental sclerosis (mediated partly by TGF- $\beta 1$). Worsened by high dietary protein; ameliorated by RAAS blockade and protein restriction.
- **Direct injury**: viruses (HIV $\rightarrow$ collapsing variant with endothelial *tubuloreticular inclusions*), drugs (pamidronate, interferon, anabolic steroids).

Clinical Features and Natural History

- ▶ **Proteinuria is the hallmark** — ranges from sub-nephrotic (1–2 g/day) to >10 g/day with full nephrotic syndrome (oedema, hypoalbuminaemia <2 g/dL, hyperlipidaemia).
- ▶ **Microscopic (and frank) haematuria in >50%**, hypertension in ~⅓, and impaired GFR at presentation in ~25–50%.
- ▶ **Collapsing variant** — rapid onset, very heavy proteinuria, low albumin, high creatinine, rapid decline to ESKD; **tip lesion** — abrupt MCD-like nephrosis but favourable, often reversible AKI and good response.
- ▶ **Prognosis:** FSGS *rarely remits spontaneously*. Nephrotic-range proteinuria with kidney injury carries a poor outcome — ~50% **reach ESKD within 10 years**; proteinuria >10 g/day → most reach ESKD within ~3 years. **Achieving remission (spontaneous or treatment-induced) is the single best prognostic indicator**; entry serum creatinine >1.3 mg/dL also predicts poor renal survival.

Diagnosis and Investigations

- ▶ **Kidney biopsy is required** for diagnosis (LM + IF + EM); a deep/cortico-medullary sample is essential to avoid a false MCD label.
- ▶ **Quantify proteinuria** — spot urine protein:creatinine ratio or 24-h protein; urinalysis may show **oval fat bodies** / “Maltese crosses” under polarised light.
- ▶ **Exclude secondary and genetic causes before treating:** HIV serology (especially with collapsing pattern), hepatitis B/C, parvovirus; drug history (bisphosphonates, heroin, anabolic steroids, interferon); assessment for obesity, reflux, sickle cell, reduced nephron mass; **genetic testing** (increasingly in children and steroid-resistant cases).
- ▶ Supportive labs: hypoalbuminaemia, hyperlipidaemia, **normal complement** (helps distinguish from immune-complex GN).

Treatment

- ▶ **Supportive / antiproteinuric (all forms): RAAS blockade** (ACE inhibitor or ARB) ± mineralocorticoid-receptor antagonist; **SGLT2 inhibitor**; statin for dyslipidaemia; salt restriction and diuretics for oedema; anticoagulation for thrombotic complications of nephrotic syndrome.
- ▶ **Primary FSGS with nephrotic syndrome — immunosuppression:**
 - **Corticosteroids first-line** — prednisone 1 mg/kg/day (children 60 mg/m²/day) for 4–16 weeks followed by slow taper; response is *slower and less frequent than in MCD* — remission in only ~20–45%, median time to remission 3–4 months.
 - **Calcineurin inhibitors** for steroid-resistant or steroid-intolerant disease — cyclosporine 5 mg/kg/day (RCTs by Ponticelli and the North American Nephrotic Syndrome Study Group show induction of remission); relapse is common on withdrawal and chronic use risks nephrotoxicity / interstitial fibrosis.

- **Mycophenolate mofetil** and **rituximab** are second-/third-line/steroid-sparing options with limited evidence (FSGS Clinical Trial: MMF + pulse dexamethasone *not* superior to cyclosporine).
- ▶ **Secondary and genetic FSGS: no role for steroids/immunosuppression** — treat the underlying cause (weight loss, stop offending drug, antiretrovirals for HIV) and maximise antiproteinuric therapy.
- ▶ **Transplantation: FSGS recurs in ~30% of allografts** (more with primary, less with secondary, rarely with genetic disease); recurrent post-transplant FSGS from a presumed circulating factor often responds to **plasmapheresis**.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Diagram 1 — Glomerulus with a segmental sclerotic lesion:** label *Bowman's capsule, capillary tuft, segmental sclerosis/hyalinosis, foam cells, adhesion (synechia) to Bowman's capsule, afferent & efferent arterioles (vascular/hilar pole), tubular (urinary) pole, effaced podocyte foot processes*.
- ▶ **Diagram 2 — Columbia variant map (small glomerular line-drawings):** label *Perihilar (sclerosis at vascular pole), Tip lesion (consolidation at tubular pole), Collapsing (capillary collapse + podocyte hyperplasia), Cellular (endocapillary hypercellularity), NOS*.

Clinical / Diagnostic significance

- ▶ A **deep cortico-medullary biopsy** is mandatory — superficial sampling misses segmental lesions and causes mislabelling as MCD; steroid-resistant “MCD” on repeat biopsy is often FSGS.
- ▶ **Distinguishing primary from secondary FSGS is therapeutically decisive:** primary = full nephrosis + diffuse effacement → immunosuppress; secondary = sub-nephrotic + preserved albumin + segmental effacement → treat the cause, avoid steroids.
- ▶ **APOL1 genotyping** identifies high-risk African-ancestry patients (collapsing/HIV-associated disease) and informs transplant donor selection.
- ▶ **Remission of proteinuria** is the key modifiable determinant of long-term renal survival; **collapsing variant** flags aggressive disease and should prompt HIV testing.

High-yield exam pointers

- ▶ FSGS = podocytopathy; proteinuria is the hallmark; commonest cause of primary glomerular ESKD in the US.
- ▶ **Five Columbia variants:** NOS (commonest), Perihilar, **Tip (best prognosis, steroid-responsive)**, Cellular, **Collapsing (worst, HIV/African-American, APOL1)**.
- ▶ **IF:** segmental IgM + C3 (trapped, non-pathogenic); **EM:** foot-process effacement (diffuse in primary, segmental in secondary).

- ▶ **NPHS2/podocin** = commonest genetic cause of **steroid-resistant nephrotic syndrome**; key genes — *NPHS1*, *ACTN4*, *TRPC6*, *INF2*, *WT1*.
- ▶ **APOL1 G1/G2 alleles** → ↑ FSGS & HIV-associated collapsing FSGS in African ancestry.
- ▶ **Treatment:** RAAS blockade + SGLT2i for all; **prednisone 1 mg/kg/day** for primary nephrotic FSGS; CNI/rituximab/MMF for resistant disease; **no immunosuppression for secondary/genetic**.
- ▶ **Prognosis:** ~50% reach ESKD in 10 years; **remission of proteinuria = best prognostic sign**; rarely remits spontaneously.
- ▶ **Recurr in ~30% of kidney transplants** (primary > secondary); recurrent disease may respond to plasmapheresis.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Glomerular Diseases” (FSGS pattern of nephrotic syndrome; Table 326-4 causes; Columbia variants; APOL1; treatment).
- ▶ **Brenner & Rector's The Kidney** — “Primary Glomerular Disease” (Box 31.6 classification, Columbia variants, gene table including *NPHS1/NPHS2/ACTN4/TRPC6/INF2*, suPAR & permeability-factor pathogenesis, GDCN/Columbia outcome data, steroid/cyclosporine/MMF/rituximab trial evidence) and “Glomerular Cell Biology and Podocytopathies” for podocyte mechanisms.
- ▶ **CMDT 2026** — “Kidney Disease” (Nephrotic Spectrum: Focal Segmental Glomerulosclerosis) for current management (RAAS blockade, SGLT2i, prednisone 1 mg/kg/day 4–16 weeks, secondary/APOL1 immunosuppression caveats, transplant recurrence).

Goodpasture's syndrome

Asked in: Paper III Dec 2023 · Paper III Jul 2020 (2×) — RGUHS MD General Medicine

Definition / Introduction — Goodpasture's syndrome is the **pulmonary-renal form of anti-glomerular basement membrane (anti-GBM) disease**, classically defined by crescentic glomerulonephritis, pulmonary hemorrhage, and circulating or tissue-bound anti-GBM antibodies. Anti-GBM disease may be renal-limited; the term Goodpasture's syndrome is best reserved for cases with both glomerulonephritis and alveolar hemorrhage. It is a nephrology emergency because renal function can fall from normal to dialysis-requiring kidney failure within days to weeks, while pulmonary hemorrhage can cause fatal hypoxemia or airway flooding.

Etiopathogenesis and epidemiology

- ▶ The autoantibody is directed mainly against the **noncollagenous NC1 domain of the alpha-3 chain of type IV collagen** in the specialized alpha-3/alpha-4/alpha-5 collagen IV network of the GBM and alveolar capillary basement membrane.
- ▶ Harrison and Brenner describe anti-GBM disease as an autoimmune **conformeropathy**: normally sequestered epitopes in the collagen IV NC1 hexamer become exposed after infection, smoking, oxidant injury, or solvent exposure.
- ▶ The kidney and lung are selectively involved because the target antigen is concentrated in the **glomerular basement membrane and alveolar capillary basement membrane**.
- ▶ Lung hemorrhage usually requires an additional pulmonary injury that increases antibody access to alveolar basement membrane; important associations include **cigarette smoking**, pulmonary infection, hydrocarbon solvents, cocaine inhalation, metallic dust, and d-penicillamine. CMDT also lists alemtuzumab exposure.
- ▶ Anti-GBM glomerulonephritis accounts for about **10-20% of acute rapidly progressive glomerulonephritis (RPGN)**. Brenner describes anti-GBM disease as rare, about **1-2% of all glomerular diseases** in most estimates.
- ▶ Age distribution is **bimodal**: young men in the third decade often present with full pulmonary-renal disease, while older adults in the sixth to seventh decades more often have renal-limited disease and less sex specificity.
- ▶ Genetic predisposition is suggested by HLA associations; CMDT notes **HLA-DR2 and HLA-B7** as predisposing antigens.

Clinical presentation

- ▶ **True Goodpasture triad**: proliferative/crescentic glomerulonephritis + pulmonary hemorrhage + anti-GBM antibodies.
- ▶ Pulmonary hemorrhage may **precede, coincide with, or follow** renal disease. Symptoms include cough, dyspnea, hemoptysis, fever, sudden fall in hemoglobin, hypoxemia, and diffuse pulmonary infiltrates. Hemoptysis may be mild or absent despite diffuse alveolar hemorrhage.
- ▶ Renal disease is usually **acute nephritic syndrome or RPGN**: microscopic hematuria, dysmorphic RBCs, red cell casts, subnephrotic proteinuria, edema, hypertension, oliguria, and rapidly rising creatinine.
- ▶ Proteinuria is common but usually **not nephrotic range**; severe nephrotic-range proteinuria should widen the differential diagnosis or suggest overlap pathology.
- ▶ Constitutional symptoms may occur: fatigue, malaise, chills, fever, weight loss, nausea/vomiting, and arthralgia. Purpura, arthritis, or other systemic vasculitic features suggest **double-positive anti-GBM plus ANCA disease** rather than isolated Goodpasture's syndrome.

- ▶ Pulmonary-renal syndrome differential includes granulomatosis with polyangiitis, microscopic polyangiitis, eosinophilic granulomatosis with polyangiitis, SLE, cryoglobulinemia, IgA vasculitis, infection-related GN, and anticoagulant or coagulopathy-related alveolar hemorrhage.

Investigations and diagnosis

- ▶ Treat suspected disease as urgent. Send **CBC**, urea/creatinine/electrolytes, urinalysis with microscopy, urine protein quantification, ABG if hypoxemic, chest radiograph or HRCT, anti-GBM antibody, ANCA with MPO/PR3 specificity, ANA/anti-dsDNA, C3/C4, hepatitis/HIV tests where indicated, and coagulation profile.
- ▶ Urine microscopy shows **glomerular hematuria** with dysmorphic RBCs and red cell casts; creatinine may rise over days to weeks.
- ▶ Serology: circulating **anti-GBM antibodies are present in >90%** of typical cases; complement levels are usually **normal**. A minority are also ANCA-positive, most often MPO-ANCA.
- ▶ Chest imaging shows bilateral or patchy alveolar infiltrates when pulmonary hemorrhage is present, but imaging is not specific.
- ▶ Bronchoscopy is useful when the pulmonary diagnosis is uncertain; **sequential BAL aliquots becoming progressively bloodier** support diffuse alveolar hemorrhage, and hemosiderin-laden macrophages support recent or recurrent bleeding.
- ▶ **Kidney biopsy is the diagnostic and prognostic test** when feasible, but patients with pulmonary hemorrhage and strong clinical suspicion should receive emergency treatment before confirmation.

Pathology and diagnostic contrasts

Feature	Goodpasture / anti-GBM disease	ANCA-associated vasculitis	Immune-complex GN / SLE
Key serology	Anti-GBM antibody high; complement normal	MPO-ANCA or PR3-ANCA; complement usually normal	ANA/anti-dsDNA, cryoglobulins or infection markers; complement often low
Light microscopy	Focal necrosis early; commonly diffuse crescentic GN with circumferential crescents	Necrotizing crescentic GN	Endocapillary proliferation; immune-complex patterns
Immunofluorescence	Intense diffuse linear IgG along GBM; often fine C3; C1q usually absent	Pauci-immune or negative	Granular deposits; lupus may show “full house”
Electron microscopy	Usually no immune-type electron-dense	No immune deposits	Electron-dense deposits by location

Feature	Goodpasture / anti-GBM disease	ANCA-associated vasculitis	Immune-complex GN / SLE
	deposits; GBM gaps may be seen		
Relapse tendency	Rare once quiescent unless double-positive	Common, especially PR3/GPA	Depends on underlying disease

- ▶ The diagnostic biopsy phrase to write is: **crescentic necrotizing glomerulonephritis with linear IgG staining along the GBM.**
- ▶ Brenner notes that the common biopsy picture is diffuse crescentic GN involving more than half of glomeruli, with compressed tufts, focal necrosis, GBM breaks, and interstitial inflammation; chronic biopsies show glomerulosclerosis, tubular atrophy, and interstitial fibrosis.
- ▶ Similar **linear IgG deposition** can occur along alveolar capillary walls in the lung.

Management

- ▶ **Admit immediately;** ICU care is needed for hypoxemia, massive hemoptysis, respiratory failure, severe AKI, oliguria, or dialysis requirement.
- ▶ Supportive care: oxygen, ventilatory support if needed, transfuse for severe anemia, stop smoking/solvent exposure, treat intercurrent infection, manage fluid overload, control blood pressure, avoid unnecessary anticoagulation during active bleeding, and start dialysis for standard indications.
- ▶ Disease-specific therapy has three simultaneous goals: **remove circulating antibody, stop new antibody production, and control inflammatory injury.**
- ▶ **Therapeutic plasma exchange (plasmapheresis):** start urgently; daily exchanges are used in severe disease, often for **8-10 treatments** or up to about **2 weeks**, guided by pulmonary bleeding, renal course, and fall in anti-GBM titers. It is especially important for pulmonary hemorrhage because lung bleeding may respond dramatically.
- ▶ **Glucocorticoids:** IV pulse methylprednisolone may be used for several days in severe disease, followed by high-dose oral prednisone; Brenner gives oral prednisone **1 mg/kg/day** or IV methylprednisolone **30 mg/kg/day up to 1000 mg/day** as typical steroid dosing.
- ▶ **Cyclophosphamide:** used with steroids to suppress antibody formation; Brenner gives **2 mg/kg/day** as a typical oral dose. Adjust for renal function, monitor CBC, infection risk, hemorrhagic cystitis, fertility risk, and cumulative toxicity.
- ▶ Continue immunosuppression until anti-GBM antibodies are negative and disease is controlled; Brenner notes that immunosuppression is usually continued for about **6 months** with tapering. Azathioprine may be used as less toxic maintenance in selected patients after antibody disappearance.

- ▶ **Rituximab** has limited evidence and is reserved for refractory disease or cyclophosphamide-intolerant patients; it should not replace urgent plasma exchange in life-threatening pulmonary hemorrhage.

Prognosis and follow-up

- ▶ Outcome depends mainly on **renal status at presentation** and speed of treatment. Lung hemorrhage often improves with plasma exchange, whereas renal recovery is poor if irreversible crescentic scarring is already established.
- ▶ Poor renal prognostic markers: oliguria, dialysis requirement at presentation, serum creatinine around **>5-6 mg/dL** or severe renal failure, **>50% crescents**, advanced interstitial fibrosis/tubular atrophy, and delayed therapy.
- ▶ Untreated disease progresses to uremia and may be fatal from pulmonary hemorrhage or renal failure; modern rapid diagnosis, dialysis, ventilatory support, plasma exchange, and immunosuppression have markedly improved survival.
- ▶ Anti-GBM disease is typically a **one-shot disease** with rare relapse once antibodies disappear; persistent or recurrent disease should prompt evaluation for ANCA double positivity, infection triggers, and ongoing exposure.
- ▶ Follow anti-GBM titers until negative, serial creatinine/eGFR, urine sediment/proteinuria, hemoglobin, chest symptoms, and cyclophosphamide toxicity. ANCA-positive patients require longer relapse surveillance.
- ▶ Kidney transplantation is considered only after the acute illness is quiescent and anti-GBM antibodies are absent; recurrence in the allograft is uncommon when transplantation is delayed until seronegativity.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Pulmonary-renal syndrome flow diagram:** trigger (infection/smoking/solvent) -> exposed alpha-3 NC1 collagen IV epitope -> circulating anti-GBM IgG -> kidney GBM injury (hematuria, RBC casts, RPGN) + alveolar capillary injury (diffuse alveolar hemorrhage, hemoptysis, hypoxemia).
- ▶ **Renal biopsy sketch:** glomerular tuft, Bowman space, circumferential cellular crescent, compressed tuft, segmental necrosis, GBM break, and a side panel labelled “linear IgG on immunofluorescence”.

Clinical / Diagnostic significance

- ▶ In any patient with **hemoptysis plus hematuria or AKI**, send anti-GBM antibody and ANCA immediately; do not wait for classical hemoptysis because diffuse alveolar hemorrhage may be occult.

- ▶ Normal complement with RPGN narrows the diagnosis toward **anti-GBM disease** or **ANCA vasculitis** rather than lupus, cryoglobulinemia, or postinfectious GN.
- ▶ A positive anti-GBM antibody is highly useful, but biopsy remains important for prognosis because the percentage of crescents and fibrosis determines renal salvageability.
- ▶ Plasma exchange is controversial in isolated ANCA vasculitis but is standard in Goodpasture's syndrome and in ANCA disease with coexistent anti-GBM antibodies.
- ▶ In examination answers, separate **anti-GBM disease** from **Goodpasture's syndrome**: renal-limited anti-GBM GN is not true Goodpasture unless pulmonary hemorrhage is present.

High-yield exam pointers

- ▶ Write the triad: **crescentic GN + pulmonary hemorrhage + anti-GBM antibodies**.
- ▶ Target antigen: **NC1 domain of alpha-3 type IV collagen** in GBM and alveolar basement membrane.
- ▶ Risk/exposure clues: **young male smoker**, recent respiratory infection, hydrocarbon solvent exposure, and pulmonary-renal presentation.
- ▶ Urine: dysmorphic RBCs, **RBC casts**, subnephrotic proteinuria, rapidly rising creatinine.
- ▶ Complement is usually **normal**; anti-GBM antibody is positive in **>90%**.
- ▶ Biopsy hallmark: **linear IgG along GBM** with crescentic necrotizing GN.
- ▶ Treatment must be urgent: **plasmapheresis + high-dose corticosteroid + cyclophosphamide**.
- ▶ Poor renal prognosis: dialysis at presentation, oliguria, creatinine >5-6 mg/dL, >50% crescents, and interstitial fibrosis.
- ▶ Relapse is uncommon after antibody clearance; relapse suggests double-positive ANCA disease or renewed exposure.

Harrison 22e — “Glomerular Diseases”, “Hemoptysis”, “Bronchoscopy”; Brenner & Rector's The Kidney — “Secondary Glomerular Disease”, “Primary Glomerular Disease”, “Treatment of Glomerulonephritis”; CMTD 2026 — “Kidney Disease”, “Pulmonary Disorders”.

IgA Nephropathy

Asked in: Paper IV Nov 2020 — RGUHS MD General Medicine

Definition / Introduction — IgA nephropathy (IgAN, *Berger disease*) is an immune-complex glomerulonephritis defined by the **dominant or codominant deposition of IgA in the glomerular mesangium**, accompanied by mesangial proliferation. First described by *Berger and Hinglais* in the late 1960s, it is the **commonest primary glomerulonephritis worldwide**, classically presenting as

synpharyngitic macroscopic haematuria in a young male. Once thought benign, it is now recognised that up to 25–40% of patients progress to end-stage kidney disease (ESKD).

Epidemiology

- ▶ **Most common primary glomerular disease worldwide**, especially in **Asia/Pacific Rim (30–45% of glomerular biopsies)**; 20% in southern Europe, ~10% in northern Europe/North America. Higher Asian rates partly reflect routine school urinalysis prompting biopsy of asymptomatic haematuria.
- ▶ Peak incidence in the **2nd–3rd decades**; ~80% are aged 16–35 years at biopsy. Uncommon under 10 years.
- ▶ Strong **male preponderance** (M:F ratio ~2:1, quoted up to 6:1). Rare in African-Americans; common in Native American Zuni and Navajo tribes.
- ▶ Mostly **sporadic**; familial clustering in 4–14%, usually autosomal dominant with incomplete penetrance. *IGAN1* locus on chromosome **6q22-23**; GWAS implicate the **MHC region (6p21)**, *DEFA*, *TNFSF13*, *CFH/CFHR*, and *C1GALT1 / C1GALT1C1 (Cosmc)* glycosylation genes — pointing to innate/adaptive immunity and host–intestinal mucosal interactions.

Pathogenesis — the “four-hit” model

The central abnormality is *not* a quantitative excess of IgA but a **qualitative defect in O-glycosylation of the hinge region of polymeric IgA1**:

- ▶ **Hit 1 — Galactose-deficient IgA1 (Gd-IgA1)**: the 18-amino-acid, proline/serine/threonine-rich hinge region of IgA1 (absent in IgA2) carries O-linked sugars; premature sialylation and deficient β -1,3-galactosyltransferase (with reduced activity of its chaperone *Cosmc*) leave terminal **N-acetylgalactosamine exposed**, generating a neoepitope. This is an inherited trait (also raised in at-risk relatives).
- ▶ **Hit 2 — Anti-glycan autoantibodies**: circulating **IgG (and IgA1) autoantibodies** recognise the exposed Gd-IgA1 neoepitope.
- ▶ **Hit 3 — Immune-complex formation**: Gd-IgA1 and autoantibody form **circulating immune complexes** that escape hepatic clearance (defective asialoglycoprotein-receptor uptake) and via the asialoglycoprotein pathway.
- ▶ **Hit 4 — Mesangial deposition & injury**: complexes deposit in the mesangium (possibly via a transferrin receptor), activating **complement through the alternative and mannose-binding lectin pathways** (note: classical C1q pathway is *spared*), driving mesangial proliferation, cytokine/growth-factor release and secondary podocyte injury.
- ▶ The same Gd-IgA1 mechanism underlies **IgA vasculitis** (formerly Henoch-Schönlein purpura), the systemic counterpart of IgAN.

Pathology (kidney biopsy is mandatory for diagnosis)

Modality	Characteristic findings
Immunofluorescence (diagnostic)	Dominant/codominant mesangial IgA (100% by definition, mean ~3+), with C3 in nearly all; often IgM (~84%) and IgG (~62%) at low intensity. C1q rare/weak . Distinctively, λ (lambda) light chain staining > κ (kappa) . Deposits are <i>J-chain-containing polymeric IgA1</i> .
Light microscopy	Spectrum from normal glomeruli → focal/diffuse mesangioproliferative GN (commonest) → proliferative/necrotising → crescentic → sclerosing GN. Mesangial matrix expansion + hypercellularity.
Electron microscopy	Mesangial (paramesangial) electron-dense deposits , beneath the perimesangial basement membrane; foot-process effacement when proteinuria is heavy.

- ▶ *Oxford classification (MEST-C score)* — the validated histological prognostic tool reported on every IgAN biopsy:
 - **M — Mesangial hypercellularity:** $\leq 0.5 = 0$, $> 0.5 = 1$
 - **E — Endocapillary hypercellularity:** absent = 0, present = 1
 - **S — Segmental glomerulosclerosis:** absent = 0, present = 1
 - **T — Tubular atrophy / interstitial fibrosis:** $\leq 25\% = 0$, $26-50\% = 1$, $> 50\% = 2$
 - **C — Crescents** (added 2016/17): none = 0, in $< 25\% = 1$, $\geq 25\% = 2$

Clinical features and natural history

- ▶ **Synpharyngitic macroscopic haematuria** — recurrent gross haematuria appearing **1–2 days** after (concurrent with) an **upper-respiratory or GI mucosal infection** in 40–50% at onset; this short latency distinguishes it from the *longer 1–3 week latent period of post-streptococcal GN*. May be accompanied by loin pain/dysuria.
- ▶ **Asymptomatic microscopic haematuria ± proteinuria** (30–40%), frequently with hypertension — IgAN is the commonest cause of haematuria in hypertensive Caucasians.
- ▶ Less common: **nephrotic syndrome** (may signify coexistent minimal-change disease), malignant hypertension ($< 5\%$), and **RPGN/crescentic disease** with AKI ($< 10\%$).
- ▶ AKI accompanying an episode of gross haematuria is usually due to **tubular injury from haem pigment**, not true crescents, and typically recovers fully with a good long-term prognosis.
- ▶ Course is variable: spontaneous remission in some; **1–2% per year progress to ESKD**, with ~25–40% reaching ESKD over 20–25 years.

Laboratory and diagnosis

- ▶ **No diagnostic serology; serum C3 and C4 are characteristically normal** (a key contrast to post-streptococcal GN, lupus nephritis, MPGN where complement is low).
- ▶ **Serum IgA raised in only 20–50%** — neither sensitive nor specific; serum/urinary Gd-IgA1 assays remain investigational.
- ▶ Urinalysis: **dysmorphic RBCs / RBC casts**; proteinuria usually <1 g/day (heavier with worse lesions).
- ▶ Skin biopsy IgA deposits are not reliable — **kidney biopsy is required to confirm**.

Treatment

- ▶ **Optimised supportive care is the cornerstone (KDIGO)**: maximally-tolerated RAAS blockade (ACE inhibitor or ARB) titrated to **proteinuria <0.5–1 g/day** and BP control (~120/80 mmHg), plus dietary sodium restriction; treat for ~90 days before escalating. High-dose ARB (e.g. losartan 200 mg/day) is more antiproteinuric than standard dose.
- ▶ **SGLT2 inhibitors** (e.g. dapagliflozin) are now standard add-on in proteinuric CKD for renoprotection.
- ▶ **Sparsentan** — a dual endothelin-A and angiotensin-II receptor antagonist (PROTECT trial) — gives superior proteinuria reduction versus irbesartan; cost-limited.
- ▶ **Targeted-release (enteric) budesonide** (NeflgArd/NEFIGAN trials) targets gut mucosal (Peyer-patch) IgA production, reducing proteinuria with fewer systemic steroid effects.
- ▶ **Systemic corticosteroids** for persistent proteinuria >1 g/day despite supportive care, in patients with preserved GFR — efficacy weighed against infection risk (the TESTING trial was paused for excess serious infections; STOP-IgAN showed steroids cut proteinuria but did not preserve GFR).
- ▶ **Iptacopan**, an oral factor B inhibitor of the alternative complement pathway, reduces proteinuria without raising infection risk.
- ▶ **Crescentic/RPGN IgAN**: treat as for other crescentic GN — **pulse methylprednisolone + cyclophosphamide ± plasmapheresis**, then azathioprine maintenance.
- ▶ **Adjuncts of uncertain/limited benefit**: omega-3 fish oil; tonsillectomy (popular in Japan, *not* validated in the European VALIGA cohort); MMF (benefit largely in Asian cohorts only).
- ▶ **Transplantation** is excellent for ESKD, but **histological recurrence develops in ~30% by 5–10 years**.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Glomerular schematic (immunofluorescence)**: draw a glomerular lobule and label — *capillary loop, glomerular basement membrane (GBM), podocyte with foot processes, mesangial cell + matrix, granular mesangial IgA + C3 deposits (dominant/codominant), Bowman's capsule*. Caption: “Mesangial polymeric IgA1 deposition.”

- ▶ **Four-hit pathogenesis flow diagram:** Hit 1 *Galactose-deficient IgA1 (Gd-IgA1)* → Hit 2 *anti-glycan IgG/IgA autoantibody* → Hit 3 *circulating immune complex* → Hit 4 *mesangial deposition* → *alternative + lectin complement activation* → *mesangial proliferation & podocyte injury*.

Clinical / Diagnostic significance

- ▶ **Distinguish from post-streptococcal GN:** IgAN = short/synpharyngitic latency, **normal complement**, recurrent gross haematuria; PSGN = 1–3 week latency, **low C3**, single episode.
- ▶ **Distinguish from IgA vasculitis (HSP):** identical renal histology but with systemic features — palpable purpura (buttocks/legs), arthralgia, abdominal pain/GI bleed; typically <20 years after infection.
- ▶ **Exclude secondary IgAN:** chronic liver disease/cirrhosis, coeliac disease, HIV, Crohn disease, ankylosing spondylitis, dermatitis herpetiformis, and **IgA-dominant Staphylococcus-associated GN** (mimics post-infectious GN, often in diabetics).
- ▶ **Prognostic markers of progression:** hypertension, **persistent proteinuria >1 g/day** (sustained ≥6 months is the strongest predictor), reduced eGFR at diagnosis, *absence* of macroscopic haematuria, male sex, older age, and high MEST-C score (M, S, T, C lesions).

High-yield exam pointers

- ▶ IgAN = **Berger disease** = commonest primary GN worldwide; mesangial IgA deposition.
- ▶ **Synpharyngitic haematuria** (gross haematuria *with* a URI, 1–2 days) is the hallmark — contrast with post-strep latency.
- ▶ **Serum complement (C3/C4) is NORMAL** — a favourite exam discriminator.
- ▶ IF: **dominant mesangial IgA + C3, $\lambda > \kappa$, C1q absent**; EM: mesangial dense deposits.
- ▶ Pathogenesis = **galactose-deficient IgA1** + anti-glycan IgG, complement via **alternative + lectin** pathways.
- ▶ Prognosis scored by the **Oxford MEST-C** classification; **proteinuria >1 g/day = key adverse marker**.
- ▶ Treatment ladder: RAAS blockade + SGLT2i → sparsentan / TRF-budesonide / corticosteroids → cyclophosphamide for crescentic disease.
- ▶ ESKD in 25–40% over 20–25 years; recurs in ~30% of allografts.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — "Glomerular Diseases" (IgA nephropathy section).

- **Brenner & Rector's The Kidney** — “Primary Glomerular Disease” (IgA nephropathy: epidemiology, genetics, pathology, MEST-C/Oxford classification, pathogenesis, natural history, treatment trials — STOP-IgAN, TESTING, NEFIGAN, VALIGA).
- **CMDT 2026** — “Kidney Disease” (current management: RAAS blockade, SGLT2 inhibitors, sparsentan/PROTECT, targeted-release budesonide/NeflgArd, iptacopan).

Intrinsic Acute Kidney Injury (intrinsic AKI)

Asked in: Paper IV Jul 2021 — RGUHS MD General Medicine

Definition / Introduction — **Acute kidney injury (AKI)** is an abrupt fall in glomerular filtration over hours to days (within 7 days), with retention of nitrogenous wastes. By **KDIGO**, AKI = a rise in serum creatinine (SCr) ≥ 0.3 mg/dL within 48 h, OR SCr $\geq 1.5 \times$ baseline within 7 days, OR urine output < 0.5 mL/kg/h for > 6 h. The causes are partitioned into **prerenal**, **intrinsic**, and **postrenal**. **Intrinsic AKI** denotes structural damage to the renal parenchyma itself — the tubules, interstitium, glomeruli, or microvasculature — and accounts for up to 50% of all AKI. Its commonest forms are **acute tubular necrosis (ATN)** from sepsis, ischaemia, and nephrotoxins; unlike prerenal azotaemia it is *not* immediately reversible by restoring perfusion.

Classification — Where Intrinsic AKI Sits

Intrinsic AKI is best catalogued **anatomically** by the dominant compartment injured, although overlap is common (e.g. a glomerular lesion can reduce post-glomerular flow and injure tubules).

Compartment	Representative causes	Share of intrinsic AKI
Tubules (ATN)	Ischaemia, sepsis, nephrotoxins (endogenous + exogenous)	~85%
Interstitium	Acute interstitial nephritis (drugs ~70–75%), infection, infiltration	~10–15%
Glomeruli	Acute glomerulonephritis, vasculitis	~5%
Microvasculature	TTP-HUS, DIC, malignant hypertension, scleroderma crisis, atheroemboli	Variable

- ATN is the prototype and the majority of hospitalised intrinsic AKI; prolonged **prerenal** hypoperfusion progresses to ischaemic ATN — the two are a **continuum**.
- Early recognition of glomerular/vasculitic and interstitial causes is critical because they are **treatable** (immunosuppression, plasma exchange, drug withdrawal) and may reverse the AKI.

Etiology of Intrinsic AKI

- **Sepsis-associated AKI** — complicates >50% of severe sepsis; GFR can fall *without overt hypotension*. Mechanisms: generalised arterial vasodilation (inducible NO synthase, cytokines), efferent arteriolar vasodilation early, endothelial injury with microvascular leukocyte adhesion/thrombosis, interstitial oedema, mitochondrial dysfunction, and reactive oxygen species (ROS).
- **Ischaemia-associated AKI** — postoperative (cardiac surgery on bypass, aortic cross-clamp), haemorrhage with hypotension, burns (AKI in 25% with >10% BSA), pancreatitis, abdominal compartment syndrome (intra-abdominal pressure >20 mmHg → renal vein compression). The **S3 segment of the proximal tubule** and the **outer medullary thick ascending limb** are most vulnerable (hypoxic medulla, oxidative metabolism).
- **Nephrotoxin-associated AKI** (high renal perfusion + tubular concentration of solutes):

Agent	Mechanism / clinical clue
Iodinated contrast	Direct tubular toxicity + medullary ischaemia; SCr rises 24–48 h, peaks 3–5 d, resolves ~1 wk; risk ↑ in diabetic CKD, myeloma
Aminoglycosides	Cortical accumulation; non-oliguric AKI after 5–7 d, even at therapeutic levels; hypomagnesaemia
Amphotericin B	Vasoconstriction + membrane pores; polyuria, hypoMg, hypoCa, type 1 (distal) RTA , dose-dependent
Cisplatin / carboplatin	Proximal tubular necrosis/apoptosis; dose-limiting; prevent with hydration
Ifosfamide	Fanconi (type II RTA) , polyuria, hypokalaemia
Acyclovir, methotrexate, indinavir, sulfadiazine	Intratubular crystal obstruction
Calcineurin inhibitors	Dose-dependent vasoconstriction; type 4 RTA
PPIs, NSAIDs, β-lactams, rifampin, checkpoint inhibitors	Acute interstitial nephritis
Endogenous: myoglobin (rhabdomyolysis), haemoglobin	Pigment nephropathy — vasoconstriction, direct toxicity, cast obstruction with Tamm-Horsfall protein in acidic urine
Endogenous: uric acid (tumour lysis), myeloma light chains	Intratubular precipitation/casts; uric acid often >15 mg/dL

- **Glomerular / vascular**: post-streptococcal GN, anti-GBM disease, ANCA vasculitis, lupus nephritis, TTP-HUS, malignant hypertension, scleroderma renal crisis, cholesterol **atheroemboli** (livedo reticularis, eosinophilia, hypocomplementaemia, eosinophiluria).

Pathophysiology of Ischaemic / Septic ATN

The healthy kidney takes **20% of cardiac output** yet the medulla is one of the most hypoxic regions of the body. Injury results from **interacting microvascular and tubular events** (Bonventre):

- ▶ **Microvascular** — sustained pre-glomerular (afferent) vasoconstriction in response to **endothelin, adenosine, angiotensin II, thromboxane A₂, and sympathetic activity**, with reduced vasodilators (NO, PGE₂); enhanced **tubuloglomerular feedback** (injured proximal tubule delivers more solute to the macula densa); leukocyte–endothelial adhesion and congestion of the outer medulla.
- ▶ **Tubular** — ATP depletion → loss of apical brush border, **cytoskeletal (F-actin) breakdown**, and **redistribution of Na⁺/K⁺-ATPase from the basolateral to the apical membrane** (loss of cell polarity → impaired vectorial Na⁺ reabsorption → the **high FeNa** of ATN); loss of tight junctions causes **backleak** of filtrate; sloughed cells + Tamm-Horsfall protein form **muddy-brown granular casts** that cause **intratubular obstruction**; cell death by **apoptosis and necrosis**. Frank necrosis is actually inconspicuous and restricted to the outer medulla — hence “ATN” is partly a misnomer.

Clinical phases (Brenner four-phase model; CMDT groups them as three):

- ▶ **Initiation** — the ischaemic/toxic insult; GFR falls, potentially reversible.
- ▶ **Extension** — continued hypoxia + inflammation + endothelial injury in the corticomedullary junction.
- ▶ **Maintenance** — established injury; GFR nadir; oliguric or non-oliguric; lasts ~1–3 weeks. Complications (hyperkalaemia, acidosis, volume overload, uraemia) cluster here.
- ▶ **Recovery** — tubular regeneration; often a **polyuric/diuretic phase** from osmotic diuresis of retained solutes and delayed tubular reabsorption.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Anatomic classification box-diagram** (Fig. 321-1/321-3 style): three columns **Prerenal | Intrinsic | Postrenal**; under Intrinsic, four labelled boxes — **Tubules** (ATN — ischaemic, septic, toxic), **Interstitium** (allergic AIN), **Glomeruli/Small vessels** (GN, vasculitis, TTP-HUS), **Large vessels** (renal artery/vein). Label endogenous vs exogenous nephrotoxins.
- ▶ **Pathophysiology of ischaemic ATN** (Fig. 321-4): two interacting arms — **Microvascular** (label: vasoconstriction — endothelin, angiotensin II, thromboxane A₂; ↓NO/PGE₂; leukocyte–endothelial adhesion) and **Tubular** (label: ATP depletion, cytoskeletal breakdown, loss of polarity / Na⁺-K⁺-ATPase mislocation, apoptosis & necrosis, desquamation → **tubular obstruction + backleak**) → both converge on ↓ GFR.

Clinical / Diagnostic significance

- ▶ Differentiate prerenal vs intrinsic (ATN) — the cornerstone diagnostic step:

Index	Prerenal azotaemia	Intrinsic ATN
BUN : creatinine	>20 : 1	<20 : 1
Urine Na ⁺ (mmol/L)	<20	>20
FeNa (oliguric)	<1%	>1% (often >2%)
Urine osmolality (mOsm/kg)	>500	250–300
Sediment	Bland / hyaline casts	Muddy-brown granular & RTE-cell casts

- ▶ **Caveats:** FeNa may be <1% in sepsis (early), contrast, rhabdomyolysis, and pigment nephropathy, and is uninterpretable on diuretics or in CKD. **Fractional excretion of urea (FeUrea <35%)** helps when diuretics are used.
- ▶ **Urine sediment as a map** — RBC casts → GN/vasculitis; WBC casts → interstitial nephritis/pyelonephritis; oxalate crystals → ethylene glycol; uric acid crystals → tumour lysis.
- ▶ **Novel biomarkers** of tubular injury (rise earlier than SCr): **NGAL, KIM-1, suPAR**, and the FDA-cleared cell-cycle-arrest pair **TIMP-2 × IGFBP7** (NephroCheck) for risk-stratifying critically ill patients. The **furosemide stress test** (1.0–1.5 mg/kg; urine <200 mL over 2 h) predicts progression and need for dialysis.
- ▶ **Complications:** hyperkalaemia (worst in rhabdomyolysis/haemolysis/tumour lysis), high-anion-gap metabolic acidosis, hyperphosphataemia/hypocalcaemia, volume overload/pulmonary oedema, uraemia, anaemia and uraemic platelet dysfunction.
- ▶ **Management:** optimise haemodynamics (euvolaemia, **MAP >65 mmHg**, crystalloids over starch), **stop nephrotoxins**, renally dose drugs, treat hyperkalaemia/acidosis, nutrition **20–30 kcal/kg/day**. No proven specific drug reverses established ATN — **dopamine, fenoldopam, ANP, diuretics do not improve recovery**; diuretics only for volume control. Cause-specific: rhabdomyolysis → aggressive IV fluids (up to ~10 L/day) ± alkalinisation; tumour lysis → fluids + **rasburicase/allopurinol**; vasculitis/GN → immunosuppression ± plasma exchange; scleroderma crisis → **ACE inhibitors**; TTP → plasma exchange; atypical HUS → complement blockade.
- ▶ **Dialysis** — “**AEIOU**”: Acidosis, Electrolyte (refractory hyperkalaemia), Intoxications, Overload (volume) unresponsive to diuretics, Uraemic complications (encephalopathy, pericarditis, bleeding). Earlier vs later initiation shows no survival benefit (STARRT-AKI).

High-yield exam pointers

- ▶ **Intrinsic AKI ≈ 50% of AKI; ATN = 85% of intrinsic AKI; AIN 10–15%; GN ~5%.**
- ▶ **ATN triad of causes = ischaemia, sepsis, nephrotoxins**; prerenal azotaemia is the precursor of ischaemic ATN.
- ▶ **S3 proximal tubule + outer-medullary TAL** are the most ischaemia-vulnerable nephron segments.

- ▶ **High FeNa in ATN** is explained by **Na⁺/K⁺-ATPase mislocation** to the apical membrane + backleak.
- ▶ **Muddy-brown granular casts + RTE-cell casts** = ATN signature; their presence is highly predictive but absent in >20%.
- ▶ **Aminoglycoside** = non-oliguric AKI at day 5–7 with **hypomagnesaemia**; **contrast** = SCr peak day 3–5; **amphotericin** = distal RTA + hypoMg/hypoCa.
- ▶ Phases of ATN = **initiation** → **extension** → **maintenance** (1–3 wk) → **recovery** (polyuric).
- ▶ **Mortality** of AKI in hospital 20–50%, up to 70% in ICU patients requiring dialysis; AKI predisposes to subsequent CKD.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Acute Kidney Injury” (KDIGO definition/staging, prerenal–intrinsic–postrenal classification, sepsis/ischaemia/nephrotoxin mechanisms, urine sediment & FeNa, biomarkers, management, dialysis).
- ▶ **Brenner & Rector's The Kidney** — “Pathophysiology of Acute Kidney Injury” (S1/S2/S3 segment injury, cytoskeletal/F-actin breakdown, Na⁺-K⁺-ATPase redistribution → high FeNa, backleak, muddy-brown cast formation, extension phase) and “Prevention and Management of Acute Kidney Injury”.
- ▶ **CMDT 2026** — “Kidney Disease / Acute Tubular Necrosis” (urinary indices table, ATN clinical phases, “AEIOU” dialysis indications, contrast-AKI prophylaxis, prognosis).

Lupus nephritis: pathological classification and therapy for each class

Asked in: Paper III 15 Apr 2026 — RGUHS MD General Medicine

Definition / Introduction — *Lupus nephritis (LN)* is immune-complex-mediated glomerular injury complicating systemic lupus erythematosus (SLE), arising from glomerular deposition of nucleosome/anti-dsDNA immune complexes with complement activation. It is clinically silent to nephrotic/nephritic in presentation and is the single most important determinant of morbidity and mortality in SLE. The renal biopsy is central: the **2003 International Society of Nephrology/Renal Pathology Society (ISN/RPS) classification** (minor revision 2018) defines six histological classes that drive prognosis and class-specific therapy. Renal biopsy is recommended when urine protein:creatinine ratio (UPCr) exceeds ~0.5 g/g, to confirm active disease and assign class plus activity/chronicity.

Pathogenesis (basis of the lesions)

- ▶ Loss of self-tolerance → polyclonal B-cell activation and autoantibodies against nucleosomes, **dsDNA**, histones; high-avidity complement-fixing **anti-dsDNA IgG** correlates best with nephritis.
- ▶ Circulating and *in situ* immune complexes deposit in mesangium and capillary walls → **complement activation** (low C3/C4), leukocyte Fc-receptor engagement, cytokine release and proliferation.
- ▶ Deposit location dictates the histological pattern: **mesangial** (class I–II), **subendothelial** (class III–IV, inflammatory/proliferative), **subepithelial** (class V, membranous, non-inflammatory).
- ▶ Adjuncts to injury: neutrophil extracellular traps (NETs), type-1 interferon, APOL1 risk alleles (collapsing FSGS in patients of African descent), antiphospholipid antibody–related thrombotic microangiopathy, ANCA-associated necrotising lesions, and lupus podocytopathy.

ISN/RPS classification (2003; 2018 revision)

Class	Name	Light microscopy	Deposits (IF/EM)	Typical clinical picture
I	Minimal mesangial	Normal glomeruli	Mesangial deposits only (IF/EM)	No clinical renal disease
II	Mesangial proliferative	Mesangial hypercellularity (>3 cells/mesangial area)	Mesangial deposits	Microhaematuria/mild proteinuria <1 g/d; inactive sediment
III	Focal LN (<50% glomeruli)	Focal segmental/global endo- and/or extracapillary GN	Mesangial + segmental subendothelial	Active sediment, proteinuria >1 g/d, ~25–33% nephrotic
IV	Diffuse LN (≥50% glomeruli)	Diffuse endo-/extracapillary GN; wire loops, crescents	Mesangial + extensive subendothelial	Most active; active sediment, RBC casts, low C3/C4, high anti-dsDNA, ~50% nephrotic, HTN, ↓GFR
V	Membranous LN	GBM thickening, subepithelial “spikes”	Subepithelial (granular) ± mesangial	Nephrotic syndrome; ~40% subnephrotic; thrombotic risk
VI	Advanced sclerosing	≥90% globally sclerosed , no residual activity	Scant/residual	“Burned-out”; HTN, ↓GFR; serologies normalise

- ▶ **Class III & IV subscripts:** (A) active, (A/C) active + chronic, (C) chronic — guide reversibility. Class IV was sub-divided into IV-S (segmental) and IV-G (global) in 2003; the **2018 revision eliminated the S/G split**.
- ▶ **Combined classes:** Class V coexists with III or IV in many biopsies and **both are diagnosed** (e.g., III+V, IV+V) — these behave and are treated as proliferative disease.
- ▶ **2018 revision also:** redefined mesangial hypercellularity (>3 cells), clarified cellular/fibrocellular crescents, replaced “endocapillary proliferation” with “**endocapillary hypercellularity**”, and applied **modified NIH activity/chronicity indices to all classes**.

Diagnostic morphology and biopsy scoring

- ▶ **Light-microscopy clues:** *wire-loop* lesions = subendothelial deposits thickening the capillary wall; *hyaline thrombi* = large intraluminal deposits; *hematoxylin bodies* = swollen basophilic nuclear material (ambient ANA binding); fibrinoid necrosis, karyorrhexis and cellular crescents in active lesions.
- ▶ **Immunofluorescence:** IgG almost universal; “**full-house**” staining (IgG + IgA + IgM + C1q + C3) is highly suggestive of LN.
- ▶ **Electron microscopy:** electron-dense granular deposits; *fingerprint* substructure; **tubuloreticular inclusions** (“interferon footprints”) in endothelial cells.
- ▶ **Modified NIH Activity Index (0–24):** endocapillary hypercellularity, neutrophil infiltration/karyorrhexis, wire-loop deposits, fibrinoid necrosis, cellular/fibrocellular crescents, interstitial inflammation — *crescents and fibrinoid necrosis are double-weighted* (reversible disease).
- ▶ **Chronicity Index (0–12):** global/segmental glomerulosclerosis, fibrous crescents, tubular atrophy, interstitial fibrosis (irreversible). Combined **activity >7 plus chronicity >3** predicts poor long-term renal outcome.

General (adjunctive) measures for ALL classes

- ▶ **Hydroxychloroquine** for every SLE/LN patient (reduces flares, improves renal outcomes, lowers thrombosis).
- ▶ **RAAS blockade** — ACE inhibitor or ARB in all class III, IV and V disease to cut proteinuria and intraglomerular pressure; consider **SGLT2 inhibitor** when eGFR is reduced.
- ▶ BP target <130/80 mmHg, statin for dyslipidaemia, calcium/vitamin D ± bisphosphonate for steroid-induced osteoporosis, vaccination, smoking cessation.
- ▶ **Antiphospholipid (APS) nephropathy** on biopsy / thrombotic event → anticoagulate with vitamin K antagonist (warfarin), not a DOAC.
- ▶ Treatment targets (EULAR): **≥25% UPCr fall by 3 months; ≥50% fall to <3 g/d by 6 months; UPCr <0.5–0.7 g/d by 12–24 months** with eGFR within 10% of baseline.

Class-specific therapy

- ▶ **Class I & II (minimal mesangial / mesangial proliferative):** excellent prognosis — **no kidney-directed immunosuppression**; treat extra-renal lupus and use RAAS blockade. Rising proteinuria/active sediment heralds transformation → **repeat biopsy**.
- ▶ **Class III (mild focal, no necrosis/crescents):** good prognosis — short course of high-dose corticosteroids ± a brief immunosuppressive course. With many affected glomeruli, necrotising features or crescents → **treat as class IV**.
- ▶ **Class III & IV proliferative (± class V) — induction + maintenance:**
 - **Induction:** glucocorticoids (often IV **methylprednisolone 125–1000 mg/day × 1–3 days** then oral prednisone, rapidly tapered) **PLUS** either:
 - **Mycophenolate mofetil (MMF) 2–3 g/day** (preferred in Black/Hispanic patients), or
 - **Cyclophosphamide** — *Euro-Lupus low-dose 500 mg IV every 2 weeks × 6 doses*, or *NIH high-dose 0.5–1 g/m² IV monthly × 6*; high-dose/extended pulses favoured for crescentic/rapidly progressive GN.
 - **Modern triple regimens** (steroid-sparing, RCT-supported): **voclosporin + MMF + GC**, or **belimumab + (MMF or low-dose cyclophosphamide) + GC**. ACR guidance: add a calcineurin inhibitor (voclosporin/tacrolimus) to MMF when proteinuria ≥3 g/day, or add belimumab to MMF/CYC when proteinuria is lower.
 - **Maintenance:** MMF or azathioprine — MMF superior for relapse-free survival (ALMS); azathioprine preferred in pregnancy; total immunosuppression ≥36 months (KDIGO).
 - **Refractory disease:** rituximab (anti-CD20); obinutuzumab is emerging.
- ▶ **Class V (pure membranous):** RAAS blockade, antiproteinuric and statin therapy, individualised anticoagulation for nephrotic-range disease. **Immunosuppression** (CNI, MMF, cyclophosphamide or azathioprine + corticosteroids) reserved for significant/nephrotic proteinuria or progressive disease. **V combined with III/IV is treated as proliferative LN**.
- ▶ **Class VI (advanced sclerosing):** immunosuppression futile — supportive CKD care and **renal replacement therapy/transplantation**; allow 3–12 months of disease quiescence before transplant (recurrence in graft <4%).

Drug-safety / monitoring pearls

- ▶ Screen for homozygous **TPMT deficiency** before azathioprine (severe marrow suppression).
- ▶ **MMF and methotrexate are teratogenic** — avoid in pregnancy; **azathioprine and tacrolimus** are pregnancy-compatible.
- ▶ High-dose cyclophosphamide → premature ovarian failure; give a **GnRH agonist** for gonadal protection and **mesna** for bladder protection; *Pneumocystis* prophylaxis with cytotoxics/rituximab.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Glomerular capillary loop — deposit location by class** (schematic, after ISN/RPS): label *podocyte (epithelial cell)*, *GBM*, *endothelial cell*, *mesangial cell/mesangium*, *urinary space*, *capillary lumen*; mark Class I/II = mesangial deposits, Class III/IV = subendothelial deposits + leukocyte infiltration (wire loop), Class V = subepithelial deposits with GBM “spikes”, Class III/IV + V = combined subendothelial + subepithelial deposits.
- ▶ **Therapy algorithm flow-box:** *Renal biopsy* → *ISN/RPS class*; Class I/II → no renal immunosuppression + RAAS/Hcq; Class III/IV (±V) → Induction: GC + MMF or cyclophosphamide ± voclosporin/belimumab → Maintenance: MMF or azathioprine; Class V (pure) → antiproteinuric ± immunosuppression; Class VI → RRT/transplant (all classes share HCQ + ACEi/ARB ± SGLT2i).

Clinical / Diagnostic significance

- ▶ **Serology–biopsy correlation:** low C3/C4 with high anti-dsDNA flags active proliferative (III/IV) disease; serology does **not** reliably predict long-term renal prognosis or replace the biopsy.
- ▶ **Prognostic drivers:** ISN/RPS class, activity/chronicity indices, serum creatinine >3 mg/dL, Black race/socioeconomic factors, cellular crescents + interstitial fibrosis, and renal flares (relapse markedly raises risk of doubling creatinine).
- ▶ A **repeat (6-month) biopsy** can document conversion of active to chronic lesions and guide therapy switching when remission is not achieved.
- ▶ Class V predisposes to **renal-vein thrombosis/PE**; SLE carries accelerated atherosclerosis — aggressive cardiovascular risk reduction is essential.

High-yield exam pointers

- ▶ **Six ISN/RPS classes:** I minimal mesangial, II mesangial proliferative, III focal (<50%), IV diffuse (≥50%), V membranous, VI advanced sclerosing (≥90% sclerosed).
- ▶ **Class IV = most severe/common** for clinical nephritis; **wire-loops**, **hyaline thrombi**, **hematoxylin bodies** = active proliferative lesions.
- ▶ “Full-house” IF (IgG+IgA+IgM+C1q+C3) + **tubuloreticular inclusions** on EM ≈ lupus nephritis.
- ▶ **2018 revision:** dropped IV-S/IV-G, redefined mesangial hypercellularity (>3 cells), “endocapillary hypercellularity,” NIH activity/chronicity to all classes.
- ▶ *Class I/II → no renal immunosuppression; III/IV → induction (GC + MMF or cyclophosphamide) then maintenance (MMF or azathioprine).*
- ▶ **Euro-Lupus cyclophosphamide** = 500 mg IV q2-weekly × 6 = as effective as high-dose with less toxicity.

- ▶ **Voclosporin and belimumab** are the newer add-on agents approved for active LN; **rituximab** for refractory disease.
- ▶ **HCQ + ACEi/ARB** in essentially every patient; **azathioprine/tacrolimus** safe in pregnancy, **MMF/cyclophosphamide** teratogenic.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Systemic Lupus Erythematosus” (ISN/RPS classes, Figure 368-3 ultrastructure, Figure 368-5 lupus nephritis treatment algorithm, EULAR targets, voclosporin/belimumab).

Lupus nephritis

Asked in: Paper IV 17 Apr 2026 · Paper III 09/2025 · Paper IV Dec 2023 · Paper III Nov 2020 · Paper IV Jul 2020 (5×) — RGUHS MD General Medicine

Definition / Introduction — **Lupus nephritis (LN)** is immune-complex–mediated glomerulonephritis occurring as a complication of **systemic lupus erythematosus (SLE)**, the human prototype of chronic immune-complex glomerular disease. It results from glomerular deposition (and *in situ* formation) of immune complexes — principally **DNA/anti-dsDNA** — with complement activation, leukocyte infiltration and cytokine release. Clinically apparent renal disease is present in ~25–50% of patients at SLE onset and develops in up to 60% during the course; it is a major determinant of morbidity and mortality, and ~5–20% progress to **end-stage kidney disease (ESKD)**.

Pathogenesis

- ▶ **Loss of self-tolerance:** defective clearance of apoptotic material, polyclonal B-cell activation and defective B-/T-cell tolerance generate autoantibodies to **nucleosomes, dsDNA, histones and ribonucleoproteins**.
- ▶ **Immune-complex deposition:** circulating and *in situ*-formed complexes localise in the **mesangium, subendothelium and/or subepithelium** (site determines histologic class and clinical picture).

- ▶ **Effector amplification:** complement cascade activation (classical pathway), Fc-receptor-mediated leukocyte recruitment, procoagulant activation and cytokine release; **type I interferon (IFN-α)** signature is prominent.
- ▶ **Neutrophil extracellular traps (NETs):** poorly degraded in SLE — a source of autoantigen and IFN-α induction by plasmacytoid dendritic cells.
- ▶ **Genetic/host factors:** HLA-DR3/DR13, homozygous **C1q/C2/C4 deficiency**, Fcγ-receptor and **APOL1** risk alleles (markedly raise ESKD risk in patients of African descent); female:male ≈ 10:1, peak onset 15–45 yr.
- ▶ **Modifiers:** antiphospholipid antibodies (thrombotic microangiopathy), ANCA-associated pauci-immune necrotising lesions, and a podocytopathy (MCD/FSGS/collapsing) pattern.

ISN/RPS classification (2003, modified 2004; 2018 revision)

Biopsy is the cornerstone — it defines class and **guides therapy**. The International Society of Nephrology / Renal Pathology Society (ISN/RPS) system integrates light microscopy (LM), immunofluorescence (IF) and electron microscopy (EM).

Class	Name	Defining histology	Typical clinical picture
I	Minimal mesangial	Normal LM; mesangial deposits only on IF/EM	Inactive sediment; normal function
II	Mesangial proliferative	Mesangial hypercellularity (>3 cells/mesangial area) + mesangial deposits	Mild; proteinuria <1 g/d; nephrotic syndrome rare
III	Focal	Endocapillary ± extracapillary GN in <50% of glomeruli; focal subendothelial deposits ± fibrinoid necrosis	Haematuria, proteinuria, active sediment; ~25–33% nephrotic
IV	Diffuse	Same lesions in ≥50% of glomeruli; diffuse subendothelial deposits; subdivided IV-S (segmental) / IV-G (global)*	Most active; high anti-dsDNA, low complement, RBC casts; ~50% nephrotic
V	Membranous	Diffuse subepithelial deposits + GBM thickening; may coexist as III+V or IV+V	Nephrotic syndrome; thrombotic risk (RVT, PE)
VI	Advanced sclerosing	≥90% globally sclerosed glomeruli, no residual activity	ESKD, hypertension; serologies often normalise

Indices appended: (A) active, (A/C) active+chronic, (C) chronic. The 2018 revision raised the mesangial cutoff to >3 cells, refined crescent definitions, replaced “endocapillary proliferation” with endocapillary hypercellularity, and applies modified NIH activity/chronicity indices to all classes (eliminating the IV-S/IV-G split).*

Histopathology, immunofluorescence and indices

- ▶ **LM hallmarks of proliferative LN:** endocapillary hypercellularity, leukocyte infiltration, fibrinoid necrosis, karyorrhexis, **cellular/fibrocellular crescents**; “**wire-loop**” lesions (subendothelial deposits thickening capillary walls); “**hyaline thrombi**” (large intraluminal deposits); **hematoxylin bodies** (ANA-bound nuclear debris).
- ▶ **IF — “full-house” staining: IgG + IgA + IgM + C1q + C3** — highly suggestive of LN (IgG near-universal). “Tissue ANA” nuclear staining may be seen.
- ▶ **EM:** electron-dense granular deposits; “**fingerprint**” **substructure** (curvilinear arrays); **tubuloreticular inclusions** (24-nm “interferon footprints” in endothelial cells).
- ▶ **Activity index (0–24):** graded 0–3+ on six features — endocapillary hypercellularity, neutrophils/karyorrhexis, wire-loop deposits, **fibrinoid necrosis** and **crescents** (latter two **double-weighted**), interstitial inflammation; identifies *reversible* lesions.
- ▶ **Chronicity index (0–12):** glomerulosclerosis, **fibrous crescents**, tubular atrophy, interstitial fibrosis (each 0–3+); identifies *irreversible* damage. High activity (>7) **plus** chronicity (>3) predicts poor long-term renal survival.
- ▶ Tubulointerstitial disease, vasculopathy (non-inflammatory necrotising vasculopathy, thrombotic microangiopathy) and lupus podocytopathy carry independent prognostic weight.

Clinical features and investigations

- ▶ **Presentation:** proteinuria (most common), microscopic haematuria, **dysmorphic RBCs and RBC casts**, hypertension, oedema, nephrotic syndrome (esp. class IV/V) and varying GFR loss; rapidly progressive GN with crescents.
- ▶ **Serology:** anti-dsDNA (high-avidity, complement-fixing IgG) correlates best with renal activity; **hypocomplementaemia (C3, C4) in 70–90%** of acute LN — falling C3/C4 and rising anti-dsDNA often **herald a flare**. Anti-Sm is specific but insensitive; ANA is a sensitive screen.
- ▶ **Indication for biopsy:** new/unexplained proteinuria (UPCR >0.5 g/g), active sediment or rising creatinine — to establish class, activity/chronicity and guide/withdraw therapy. **Repeat biopsy** is valuable because classes can **transform** and the 6-month biopsy predicts outcome.
- ▶ **Monitoring:** serial UA, UPCR, eGFR, C3/C4 and anti-dsDNA; quarterly urinary biomarkers where available.

Management

General principle: vigorous **induction** (~6 months) to attain remission, then prolonged **maintenance** (≥3 years) — per KDIGO 2024 and EULAR 2023/24 recommendations.

- ▶ **Background for all classes:** hydroxychloroquine (unless contraindicated); ACE inhibitor / ARB for class III/IV/V to cut proteinuria and intraglomerular pressure; consider SGLT2 inhibitor if eGFR reduced; BP, lipid, bone and infection prophylaxis; VKA/heparin if concomitant antiphospholipid nephropathy.
- ▶ **Class I / II:** no class-specific immunosuppression; antiproteinuric therapy and monitor for transformation.
- ▶ **Class III / IV (proliferative — aggressive Rx):** glucocorticoids (pulse IV methylprednisolone 125–1000 mg/d ×1–3 days for severe disease, then oral GC tapered rapidly to ≤5 mg/day) PLUS one of:
 - Mycophenolate mofetil (MMF) 2–3 g/day — first-line, especially in Black/Hispanic patients;
 - Low-dose IV cyclophosphamide — Euro-Lupus regimen: 500 mg every 2 weeks ×6 doses (then AZA/MMF), as effective as and safer than high-dose;
 - High-dose (“NIH”) IV cyclophosphamide 0.5–1 g/m² monthly ×6 — reserved for crescentic/RPGN, fibrinoid necrosis or reduced eGFR;
 - Triple therapy: add belimumab (anti-BAFF; FDA-approved 2020) or voclosporin (calcineurin inhibitor; FDA-approved 2021, given with MMF) for more severe presentations.
- ▶ **Class V (membranous):** treat if significant nephrotic-range proteinuria or superimposed proliferative lesions (V+III / V+IV → treat as class IV); CNIs especially effective; ACEi/ARB + anticoagulation prophylaxis for thrombotic risk.
- ▶ **Maintenance:** MMF (preferred) or azathioprine for ≥3 years; AZA preferred in pregnancy (cyclophosphamide and MMF are contraindicated/teratogenic). Screen TPMT before azathioprine.
- ▶ **Treatment targets:** ≥25% reduction in UPCR by 3 months; ≥50% reduction (to <3 g/day) by 6 months; UPCR <0.5–0.7 g/day by 12–24 months, with eGFR within 10% of baseline.
- ▶ **Refractory/relapsing:** rituximab (anti-CD20), obinutuzumab + MMF (steroid-sparing) or multi-target regimens; GnRH agonist before cyclophosphamide to preserve ovarian function.
- ▶ **ESKD:** dialysis (lupus activity often quiesces); transplant after ~3–12 months of inactive disease — allograft survival comparable to non-lupus recipients, recurrence low.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Glomerulus showing deposit sites by class:** draw a capillary loop + mesangium and label — *mesangial deposits* (class I/II), *subendothelial deposits* = “wire-loop” (class III/IV),

subepithelial deposits + GBM “spikes” (class V), fibrinoid necrosis + cellular crescent (active class III/IV), and “full-house” IF (IgG, IgA, IgM, C1q, C3).

- ▶ **Induction–maintenance algorithm:** boxes for *Biopsy* → *ISN/RPS class*; *Class III/IV* → *GC + (MMF or low-dose CYC) ± belimumab/voclosporin (induction 6 mo) → MMF/AZA maintenance ≥3 yr*; *Class V* → *CNI/MMF if nephrotic*; with the adjunct rail labelled *HCQ + ACEi/ARB ± SGLT2i*.

Clinical / Diagnostic significance

- ▶ **Biopsy is decisive:** class, activity and chronicity directly determine immunosuppression intensity and prognosis; clinical/serologic activity alone under-stages disease (“silent LN”).
- ▶ **Serologic surveillance** (anti-dsDNA ↑, C3/C4 ↓) gives early warning of flares before creatinine rises.
- ▶ **Prognostic markers of poor outcome:** raised serum creatinine, **crescents/fibrinoid necrosis**, high combined activity+chronicity index, interstitial fibrosis, nephrotic-range proteinuria, hypertension, male sex, African descent/APOL1, and failure to achieve early complete remission.
- ▶ **Pregnancy:** plan for ≥6 months remission; AZA, tacrolimus and HCQ are compatible; anti-Ro antibodies risk **neonatal lupus** and congenital heart block.
- ▶ **Drug-induced lupus** (procainamide, hydralazine, minocycline, anti-TNF) rarely causes nephritis; **anti-histone** antibodies positive, renal involvement uncommon.

High-yield exam pointers

- ▶ ISN/RPS classes I–VI; class III <50% vs class IV ≥50% glomeruli; class VI ≥90% sclerosed.
- ▶ “Full-house” IF = IgG + IgA + IgM + C1q + C3 — pathognomonic clue to LN.
- ▶ Wire-loop = subendothelial; spikes/subepithelial = membranous (class V); hyaline thrombi, hematoxylin bodies, tubuloreticular inclusions (“IFN footprints”).
- ▶ Anti-dsDNA + low C3/C4 correlate with renal activity; **hypocomplementaemia in 70–90% of acute LN**.
- ▶ **Activity index 0–24** (crescents + fibrinoid necrosis double-weighted); **chronicity index 0–12** (irreversible).
- ▶ **Euro-Lupus CYC = 500 mg IV q2wk ×6**; MMF 2–3 g/day first-line, preferred in Black/Hispanic patients.
- ▶ **Triple therapy** = standard + **belimumab** (2020) or **voclosporin** (2021); **rituximab** for refractory disease.
- ▶ **All patients: hydroxychloroquine + ACEi/ARB**; **AZA preferred in pregnancy**; screen TPMT before azathioprine.
- ▶ **Targets:** UPCR ↓25% at 3 mo, ↓50% (<3 g/d) at 6 mo, <0.5–0.7 g/d at 12–24 mo.

SOURCE & COVERAGE

- ▶ **Brenner & Rector's The Kidney** — “Secondary Glomerular Disease” (ISN/RPS 2003 classification with 2018 revision, full-house IF, NIH activity 0–24 / chronicity 0–12 indices, induction/maintenance trial evidence — NIH, Euro-Lupus, ALMS, MAINTAIN).
- ▶ **CMDT 2026** — “Kidney Disease” (lupus nephritis; KDIGO 2024 induction/maintenance regimens, obinutuzumab + MMF).

Medullary sponge kidney

Asked in: Paper IV Nov 2019 — RGUHS MD General Medicine

Definition / Introduction — Medullary sponge kidney (MSK), also called *precalyceal canalicular ectasia* or *renal tubular ectasia* and eponymously *Lenarduzzi–Cacchi–Ricci disease*, is a developmental malformation characterised by ectasia (dilatation) and cystic transformation of the **terminal (papillary) collecting ducts**, strictly confined to the **medullary pyramids**. It is usually a sporadic, benign, often incidentally-discovered condition, but is clinically important because it predisposes to **recurrent calcium nephrolithiasis, nephrocalcinosis, haematuria and urinary tract infection**. It affects roughly <1% of the general population yet is found in ~13% of patients with calcium urolithiasis, and is typically diagnosed in the **third to fourth decade**.

Etiology, genetics and pathogenesis

- ▶ **Developmental basis** — thought to arise from disruption of the **ureteric bud–metanephric mesenchyme interface** during nephrogenesis, producing malformation and cystic dilatation of the collecting ducts. Although the lesion is present from birth, its rarity in children suggests an **acquired/progressive** component, with documented progression of tubular ectasia and cyst development in some patients.
- ▶ **Inheritance** — classically regarded as **non-hereditary and sporadic**, but **autosomal dominant** inheritance has been demonstrated in several families. Variants of the **GDNF (glial cell–derived neurotrophic factor)** gene cosegregated with disease in five MSK families. A study of family members of 50 MSK patients identified 59 affected first- and second-degree relatives, supporting **familial clustering with autosomal dominant inheritance, reduced penetrance and variable expressivity**.

- ▶ **Tubular/metabolic consequences** — dilated, stagnant precalyceal ducts cause urinary stasis, which together with frequent tubular dysfunction promotes crystal nidus formation and infection.

Pathology and disease associations

- ▶ Despite the name the kidney does **not** truly resemble a sponge; it is usually **normal-sized or slightly enlarged**. On sectioning the medulla shows dilated ducts containing small calculi — gross specimens give a “*Swiss-cheese*” appearance.
- ▶ Ectasia may involve **one or more papillae in one or both kidneys**; lesions are **bilateral in ~70%** of cases (may be asymmetric, occasionally only a single calyx).
- ▶ Dilated ducts communicate proximally with normal-calibre collecting tubules and show a **relative constriction at the calyceal junction**; duct diameter is typically **1–3 mm, occasionally 5 mm, rarely up to 7.5 mm**.

Associated condition	Note
Calcium nephrolithiasis	Strongest association; ~13% of calcium-stone formers have MSK
Primary hyperparathyroidism	“Puzzling association”; possibly via calcium leak / hypercalciuria
Hemihypertrophy	Reported developmental association
Ehlers–Danlos syndrome	Several reported cases
ADPKD	Precalyceal canalicular ectasia frequently seen
Congenital hepatic fibrosis / Caroli (ARPKD)	Medullary ductal ectasia of ARPKD may mimic MSK (different prognosis)

Clinical features

- ▶ **Often asymptomatic** and may remain undetected for life; frequently an **incidental** radiological finding.
- ▶ **Nephrolithiasis** is the commonest presentation — up to **60–70% lifetime stone risk**; stones are **calcium oxalate and calcium phosphate**, forming in the ectatic ducts.
- ▶ **Gross or microscopic haematuria** — may be recurrent.
- ▶ **Recurrent urinary tract infections** — often the first manifestation; patients (especially women) are more susceptible, and infected stones may need long-term antimicrobial suppression.
- ▶ **Tubular dysfunction:**
 - **Mild renal concentrating defect** (impaired urine concentrating ability).
 - **Incomplete distal (type 1) renal tubular acidosis** in **30–40%** — reduced capacity to lower urine pH after an ammonium-chloride load.

- Occasionally a low maximal potassium-excretory capacity.
- ▶ **Metabolic stone risk factors** — chiefly **hypercalciuria** and **hypocitraturia**. Among MSK stone-formers, hypercalciuria is **absorptive** in ~59% and due to a **renal calcium leak** in ~18%.
- ▶ **Prognosis is benign** — MSK **seldom progresses to ESKD**; morbidity stems from recurrent stones, infection, nephrocalcinosis and acidosis. A minority have a poorer course from relapsing urolithiasis and pyelonephritis.

Investigations and diagnosis

- ▶ **Excretory urography (IVU/IVP)** is the historical **gold standard** — early and delayed films (without ureteric compression and without obstruction) show contrast pooling in the dilated terminal collecting ducts:
 - **Parallel brush-like striations** / “**paintbrush**” appearance radiating from the calyceal border.
 - With more severe disease, **grape-like or bead-like** (“**bouquet of flowers**”) clusters.
- ▶ **Plain film / non-contrast CT** — characteristic **medullary nephrocalcinosis** with calculi **clustered fanning away from the calyx**; CT best demonstrates the calculi.
- ▶ **CT urography** (which has largely replaced IVU) is **less sensitive** for the ectasia itself, but shows cystic dilatation of distal collecting tubules with a **striated “papillary brush” pattern** and collecting-system calcification.
- ▶ **Ultrasonography** — **medullary hyperechogenicity** / **nephrocalcinosis**: suggestive but **not diagnostic**.
- ▶ **Metabolic stone work-up** — 24-h urine for calcium, citrate, oxalate, uric acid, volume and pH; serum calcium/PTH to exclude hyperparathyroidism; urinary acidification testing for incomplete dRTA.

Modality	MSK finding
IVU/excretory urography	“Paintbrush” striations / “bouquet of flowers” calyceal blush — most specific
Non-contrast CT	Medullary nephrocalcinosis; stones clustered around papillae
CT urography	Striated papillary brush pattern; less sensitive than IVU
Ultrasound	Medullary hyperechogenicity (non-specific)

Differential diagnosis

Entity	Distinguishing feature
Medullary nephrocalcinosis (1° hyperparathyroidism, dRTA, sarcoid, vit-D excess)	Diffuse calcification without ductal ectasia / brush pattern

Entity	Distinguishing feature
Renal papillary necrosis	Sloughed papillae, ring/club calyx; analgesics, diabetes, sickle cell
Calyceal diverticulum	Single, communicates with calyx; not diffuse papillary ectasia
ARPKD with medullary ductal ectasia	Childhood, congenital hepatic fibrosis, far worse prognosis
Autosomal dominant tubulointerstitial / medullary cystic kidney disease	Progressive CKD, corticomedullary cysts, no stone-clustering

Management

- ▶ **No specific cure** — management is **supportive**, directed at stone prevention and treating complications; incidental asymptomatic MSK warrants **reassurance** (benign, not life-threatening).
- ▶ **High fluid intake** — aim for urine output $\geq 2.5\text{--}3\text{ L/day}$.
- ▶ **Dietary** — low-salt, low-animal-protein diet to reduce calcium excretion and stone risk.
- ▶ **Potassium citrate (oral alkali)** — **first-line** for any metabolic risk factor (hypercalciuria, hypocitraturia, hyperuricosuria, hyperoxaluria): start **~20 mEq citrate/day in two divided doses**, titrate up by **10 mEq** to achieve citraturia **>450 mg/24 h**, while keeping **24-h urine pH <7.5** (to avoid promoting calcium-phosphate stones). This regimen reduced the stone event rate from **0.58 to 0.10 stones/patient/year** and improved bone density (vertebral T-score $-2.82 \rightarrow -1.98$).
- ▶ **Thiazide diuretics** — added/reserved for persistent stone-formation or hypercalciuria despite optimal citrate.
- ▶ **Infection** — prompt treatment of UTIs; preventive measures (especially in women); long-term suppressive antibiotics if infected stones cannot be cleared. Avoid repeated unnecessary investigation of benign recurrent haematuria.
- ▶ **Urological intervention** (ESWL / ureteroscopy) for obstructing or symptomatic stones, as for any stone-former.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Labelled coronal section of the kidney in MSK** — label: *cortex, medullary pyramid, papilla, dilated/ectatic terminal (precalyceal) collecting ducts, small calculi within ducts, minor calyx, normal-calibre proximal collecting tubule with constriction at calyceal junction, renal pelvis*.
- ▶ **IVU schematic of a single calyx** — label: *“paintbrush” parallel striations radiating from the calyx, “bouquet of flowers”/grape-like contrast clusters in ectatic ducts, medullary nephrocalcinosis (clustered stones fanning from calyx)*.

Clinical / Diagnostic significance

- ▶ Consider MSK in any young/middle-aged recurrent calcium-stone former with bilateral medullary nephrocalcinosis and haematuria/recurrent UTI.
- ▶ Always screen for the treatable/contributory associations — **incomplete distal RTA, hypocitraturia, hypercalciuria and primary hyperparathyroidism** — as these guide therapy.
- ▶ IVU's "paintbrush"/"bouquet-of-flowers" sign remains the single most diagnostic feature; CT urography may miss the ectasia, so a high index of suspicion is needed in the post-IVU era.
- ▶ Distinguishing MSK (benign, normal renal function) from **ARPKD-related medullary ductal ectasia** (progressive, hepatic involvement) is prognostically critical.

High-yield exam pointers

- ▶ MSK = ectasia + cystic dilatation of papillary collecting ducts confined to medullary pyramids; eponym *Cacchi-Ricci (Lenarduzzi-Cacchi-Ricci) disease*.
- ▶ **Bilateral in ~70%**; kidneys **normal-sized**; "Swiss-cheese" cut surface.
- ▶ **~60–70% lifetime risk of stones** (calcium oxalate/phosphate); F > M among calcium-stone formers.
- ▶ **Incomplete distal RTA in 30–40%**; with **hypocitraturia + hypercalciuria** (mostly absorptive) and a **urinary concentrating defect**.
- ▶ Diagnostic imaging — "paintbrush" striations and "bouquet of flowers" on IVU; **medullary nephrocalcinosis** on CT.
- ▶ GDNF gene variants; **autosomal dominant, reduced penetrance, variable expressivity** in familial cases; classically sporadic.
- ▶ Associations: **primary hyperparathyroidism, hemihypertrophy, Ehlers–Danlos syndrome, ADPKD**.
- ▶ Treatment — **fluids ≥ 2.5 –3 L/day + potassium citrate (keep urine pH <7.5) $\pm$ thiazide**; rarely progresses to ESKD.

SOURCE & COVERAGE

- ▶ **Brenner & Rector's The Kidney** — "Cystic Diseases of the Kidney" (Medullary Sponge Kidney section: epidemiology, GDNF/autosomal-dominant genetics, pathology, diagnosis, metabolic abnormalities, potassium-citrate regimen) and "Diagnostic Kidney Imaging" (paintbrush/bouquet IVU signs, medullary nephrocalcinosis); "Urolithiasis" (potassium-citrate stone data).
- ▶ **Harrison's Principles of Internal Medicine, 22e** — "Polycystic Kidney Disease and Other Inherited Disorders of Tubule Growth and Development" (MSK as developmental collecting-duct dilatation; stones, concentrating defect, UTI; CT urography less sensitive

than IVP) and “Approach to the Patient with Renal Disease” (MSK among congenital anomalies/nephrocalcinosis).

- **CMDT 2026** — “Kidney Disease” (MSK: <1% prevalence, ureteric-bud–metanephric mesenchyme aetiology, “Swiss-cheese” appearance, up to 70% nephrolithiasis, type 1 dRTA, supportive treatment with alkali/citrate, thiazide, fluids; benign prognosis).

Coverage note: The corpus covers MSK well (Brenner provides full subspecialty depth). Harrison’s dedicated coverage is brief (as flagged in the spec); the depth, genetics (GDNF), imaging eponyms and citrate-regimen detail are drawn from Brenner & Rector and CMDT. The *Lenarduzzi–Cacchi–Ricci* / *Cacchi–Ricci* eponym is documented in the Brenner reference list (Padua Medical School, 1930s).

Nephrotic syndrome

Asked in: Paper IV Nov 2022 — RGUHS MD General Medicine

Definition / Introduction — Nephrotic syndrome is a glomerular disorder defined by **heavy proteinuria** (>3.0 g/24 h) together with **hypoalbuminaemia**, **oedema/anasarca**, **hypercholesterolaemia** and **hypertension**, classically accompanied by *minimal (microscopic) haematuria* and an acellular urinary sediment. When large amounts of protein are excreted without the full clinical picture, the term **nephrotic-range proteinuria** is used. It arises from injury to the glomerular filtration barrier (predominantly the **podocyte and its slit-diaphragm**), and may be a *primary* (idiopathic) glomerulopathy or *secondary* to systemic disease. Untreated, persistent heavy proteinuria progressively damages nephrons and lowers GFR — the higher the 24-h protein excretion, the more rapid the decline.

Diagnostic criteria & pathophysiology

- **Nephrotic “pentad”**: heavy proteinuria + hypoalbuminaemia + oedema + hyperlipidaemia (hypercholesterolaemia) + hypertension; haematuria, when present, is minimal/microscopic.
- **Filtration-barrier injury** — loss of the size- and charge-selective barrier (effacement of podocyte foot processes, weakening of slit-pore membranes) allows albumin and larger proteins to escape. In children the loss is predominantly albumin (*selective proteinuria*); in adults it is typically *non-selective*.
- **Oedema** — due to renal **salt and water retention**; intravascular hypoalbuminaemia (low oncotic pressure) contributes. Severe hypoalbuminaemia with intrarenal oedema (*nephrosarca*) can cause a diuretic-responsive fall in GFR that must be distinguished from acute kidney failure due to **hypovolaemia**.
- **Hyperlipidaemia** — hypoalbuminaemia drives hepatic lipoprotein overproduction with reduced catabolism; patients are at increased **cardiovascular risk**.

- ▶ **Hypercoagulable state** — urinary loss of anticoagulant proteins produces a thrombotic tendency; renal vein thrombosis, pulmonary embolism and deep-vein thrombosis are the major venous complications (highest with membranous nephropathy).
- ▶ **Loss of other binding/transport proteins** — e.g. thyroid-binding globulin loss alters thyroid function tests; loss of immunoglobulins predisposes to infection [standard medicine].

Classification — causes by histology

Category	Lesion / disease	Key features (Harrison 22e)
Primary glomerular	Minimal change disease (MCD)	70–90% of childhood, 10–15% of adult nephrotic syndrome; normal light microscopy, IgM ± in mesangium, foot-process effacement on EM; steroid-responsive
	Focal segmental glomerulosclerosis (FSGS)	Most common cause of <i>primary</i> glomerular disease in ESKD (US); segmental scars at the corticomedullary junction ; <i>APOL1</i> risk variants; collapsing variant with HIV (HIVAN)
	Membranous glomerulonephritis (MGN)	~25% of adult nephrotic syndrome; peak 30–50 y, M:F 2:1; subepithelial deposits , silver-stain “spikes” ; anti-PLA2R IgG4 in 70–80% of primary cases
	Membranoproliferative GN / C3 glomerulopathy	May present nephrotic with low complement
Secondary / systemic	Diabetic nephropathy	Single most common cause of CKD worldwide; Kimmelstiel-Wilson nodules , GBM thickening, mesangial expansion
	Amyloidosis (AL primary, AA secondary)	Congo-red positive fibrils; nephrotic syndrome common; AL → ~20% dialysis, AA → ~40–60% dialysis
	Light-chain deposition disease / MGRS	Plasma-cell dyscrasia; non-fibrillar, Congo-red negative light-chain deposits
	Fibrillary-immunotactoid disease; Fabry’s disease	Fabry: α-Gal A deficiency, <i>Maltese-cross</i> lipid bodies, FSGS pattern

Category	Lesion / disease	Key features (Harrison 22e)
	Infection / drug / malignancy / autoimmune (secondary MGN)	HBV, HCV, syphilis, malaria; gold, penicillamine, NSAIDs; solid tumours (breast, lung, colon); SLE (membranous lupus, ISN/RPS class V)

Clinical features & complications

- ▶ **Presentation** — peri-orbital and dependent **oedema**, weight gain, frothy urine, ascites, anasarca; often abrupt in MCD.
- ▶ **Infections** — increased susceptibility (urinary immunoglobulin loss); spontaneous bacterial peritonitis and pneumococcal sepsis are classic in nephrotic children [standard medicine].
- ▶ **Thromboembolism** — renal vein thrombosis (esp. MGN), PE, DVT from the hypercoagulable state.
- ▶ **Acute kidney injury** — from hypovolaemia/over-diuresis, *nephrosarca*, acute tubular necrosis or interstitial inflammation.
- ▶ **Metabolic** — accelerated **atherosclerosis** (dyslipidaemia), protein malnutrition, and altered drug/hormone protein binding.

Investigations / approach

- ▶ **Urinalysis** — heavy proteinuria; *bland/acellular* sediment; **oval fat bodies** and “**Maltese-cross**” lipid-laden casts under polarised light; *selective* (children) vs *non-selective* (adults) proteinuria.
- ▶ **Quantify proteinuria** — 24-h urine protein (nephrotic = >3.0 g/24 h; MCD averages ~10 g) or spot **albumin/protein-to-creatinine ratio** (Table 326-1: albuminuria >300 mg/g).
- ▶ **Blood** — serum albumin, lipid profile, creatinine/eGFR, fasting glucose/HbA1c, complement (C3/C4), serology (ANA, anti-dsDNA, ANCA, hepatitis B/C, HIV, syphilis), and serum/urine **electrophoresis with free light chains** when paraproteinaemia suspected.
- ▶ **Serology that may obviate biopsy** — **anti-PLA2R antibody** positive with normal creatinine and no other cause supports primary MGN.
- ▶ **Kidney biopsy** — the diagnostic cornerstone in adults (light + immunofluorescence + electron microscopy). In children, MCD is assumed and **only steroid non-responders are biopsied**. Diabetic nephropathy with typical features and retinopathy usually needs **no biopsy**.

Principles of management

- ▶ **General / supportive (all causes):**
 - **Reduce proteinuria & preserve GFR** — inhibitors of the **renin–angiotensin system** (ACEi/ARB) plus **SGLT2 inhibitors**.
 - **Oedema** — dietary salt restriction and **diuretics**, avoiding intravascular volume depletion.

- **Dyslipidaemia** — **lipid-lowering (statin)** therapy, given the raised cardiovascular risk.
- **Thromboprophylaxis/anticoagulation** for venous thrombotic complications; prophylaxis considered in select patients with severe hypoalbuminaemia (esp. MGN).
- ▶ **Disease-specific immunosuppression:**
 - **MCD** — **prednisone** first-line; 90–95% of children and 80–90% of adults achieve complete remission (adults respond more slowly; not called steroid-resistant until 4 months). Cyclophosphamide, MMF, **calcineurin inhibitors (CNIs)** or **rituximab** for frequent relapsers/steroid-dependent/steroid-resistant disease.
 - **Primary FSGS** — steroids (remission in only 20–45% over 6–12 months), CNIs as steroid-sparing; *secondary/genetic FSGS* — treat the cause, **no role for immunosuppression**; recurs in ~30% of transplants (plasmapheresis for presumed circulating factor).
 - **Primary MGN** — immunosuppression for persistent proteinuria, risk-stratified by proteinuria/GFR/albumin: **steroids + cyclophosphamide, CNIs, or rituximab**.
 - **Diabetic nephropathy** — glycaemic and BP control, ACEi/ARB, SGLT2i, and the non-steroidal MRA **finerenone**.
 - **Amyloid/paraprotein** — treat the underlying plasma-cell dyscrasia/inflammatory disease.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Glomerular filtration barrier (normal vs MCD)** — label: *capillary lumen, fenestrated endothelium, glomerular basement membrane (GBM), podocyte with foot processes, slit diaphragm/slit-pore membrane*; show **foot-process effacement (fusion)** in MCD and **subepithelial deposits with “spikes”** in MGN (“Foot process fusion”, “Subepithelial deposits”, “MEMBRANOUS GLOMERULONEPHRITIS”).
- ▶ **FSGS schematic (Glomerular Schematic 5)** — label: *Detachment of cell from GBM, Collapsed capillary and scar, Proliferation of subepithelial cells, Afferent arteriole, Efferent arteriole, FOCAL SCLEROSING GLOMERULONEPHRITIS*.

Clinical / Diagnostic significance

- ▶ Distinguishing **nephrotic** (bland sediment, heavy proteinuria) from **nephritic** (haematuria, RBC casts, hypertension, azotaemia) syndrome directs the whole work-up.
- ▶ **Age stratifies the differential:** child → MCD; adult → MGN/FSGS/diabetes; older adult with paraproteinaemia → amyloid/LCDD/MGRS.
- ▶ **Secondary screen is mandatory** — diabetes, SLE, hepatitis B/C, HIV, malignancy and drugs are reversible/treatable causes.
- ▶ **Anti-PLA2R** has transformed MGN into a partly serology-based, biopsy-sparing diagnosis and a **biomarker of disease activity/response**.

- ▶ Remission of proteinuria is the key prognostic goal: it markedly improves outcome across MCD, FSGS and MGN.

High-yield exam pointers

- ▶ Nephrotic syndrome = proteinuria >3.0 g/24 h + hypoalbuminaemia + oedema + hyperlipidaemia + hypertension; sediment is **bland**.
- ▶ MCD = commonest cause in children (70–90%); EM shows **foot-process effacement**; exquisitely **steroid-responsive**.
- ▶ MGN = commonest *primary* cause in adults (~25%); **anti-PLA2R IgG4**; **subepithelial deposits** + silver “**spikes**”; highest risk of **renal vein thrombosis**.
- ▶ FSGS = leading cause of primary glomerular ESKD (US); **APOL1**; collapsing variant in HIVAN; biopsy from corticomedullary junction (else misdiagnosed as MCD).
- ▶ **Diabetic nephropathy** = most common cause of CKD overall; **Kimmelstiel-Wilson nodules**; usually no biopsy if retinopathy present.
- ▶ **Amyloid** = **Congo-red positive**, apple-green birefringence; LCDD is **Congo-red negative**.
- ▶ Universal therapy = **RAAS blockade** + **SGLT2i** + **statin** + **diuretic** ± **anticoagulation**; add disease-specific immunosuppression.
- ▶ Complications to write: **infection**, **thromboembolism** (renal vein thrombosis), **AKI**, **dyslipidaemia/CVD**, **protein malnutrition**.
- ▶ Urine clue: **oval fat bodies** / **Maltese-cross** lipiduria.

SOURCE & COVERAGE

Harrison 22e — Ch 326 “Glomerular Diseases” (Tables 326-1, 326-2, 326-4, 326-5; Glomerular Schematics 5 & 6). **Coverage note:** the chapter is organised by individual glomerulopathy rather than as a single “nephrotic syndrome” review — the unified definition, oedema/hyperlipidaemia mechanisms and the infection/thrombosis complication list above are assembled from scattered passages plus universally accepted standard internal medicine; points marked [*standard medicine*] (immunoglobulin-loss infection susceptibility, detailed lipid mechanism) are not given verbatim in this chapter but are standard and accurate.

Renal manifestations in Systemic Lupus Erythematosus (SLE)

Asked in: Paper I Dec 2023 — RGUHS MD General Medicine

Definition / Introduction — **Lupus nephritis (LN)** is the immune-complex-mediated glomerular injury of SLE and is one of its most common and serious organ complications. Nephritis occurs in ~35% of patients with SLE; clinical kidney involvement is present in about 30% at diagnosis, and the majority

develop renal abnormalities during the disease course. It is more severe in non-White patients, who more often progress to **end-stage renal disease (ESRD)** despite therapy. Renal involvement carries major weight in classification (a biopsy showing class III/IV LN alone meets diagnostic criteria) and is the dominant driver of morbidity, mortality and treatment intensity in SLE.

Pathogenesis

- ▶ LN results from deposition of **circulating immune complexes** composed primarily of **DNA and anti-DNA**, which activate the **complement cascade** → complement-mediated damage, leukocyte infiltration, activation of procoagulant factors and cytokine release.
- ▶ **In-situ immune-complex formation** in the glomerulus also contributes to injury.
- ▶ The anatomical site of deposits determines the histological class and clinical picture — deposits may be **mesangial, subendothelial and/or subepithelial**.
 - *Subendothelial/mesangial deposits* (accessible to inflammatory cells) → proliferative, **nephritic** lesions (class III/IV).
 - *Subepithelial deposits* (separated from the circulation by the GBM) → **membranous**, largely non-inflammatory, **nephrotic** lesion (class V).
- ▶ **Anti-dsDNA antibodies that fix complement** correlate best with the presence of kidney disease; **hypocomplementemia** (low C3/C4) is present in **70–90%** of acute LN.
- ▶ **Antiphospholipid antibodies** can produce **glomerular microthrombi and thrombotic microangiopathy (antiphospholipid nephropathy)**, worsening renal prognosis despite anticoagulation.

Clinical spectrum of renal involvement

- ▶ Manifestations parallel the underlying pathology and range from clinically silent to rapidly progressive renal failure.
- ▶ **Proteinuria** is the most common sign — sub-nephrotic to **nephrotic-range**.
- ▶ **Glomerular (active) urinary sediment** — microscopic **haematuria**, dysmorphic red cells and **red-blood-cell casts**.
- ▶ **Hypertension** and varying degrees of reduced GFR / acute kidney injury.
- ▶ **Nephrotic syndrome** — characteristic of class V and severe class IV; class V predisposes to **renal vein thrombosis** and other thrombotic complications.
- ▶ **Rapidly progressive glomerulonephritis (RPGN)** — when crescents complicate class III/IV.
- ▶ Nephritis may occur **with or without extrarenal SLE activity** and is frequently **asymptomatic**, mandating active surveillance.

Histological classification (ISN/RPS, revised 2003–04)

First outlined by the WHO (1974) and revised by the International Society of Nephrology / Renal Pathology Society (ISN/RPS) Study Group in 2003–04 (with a 2018 revision recommendation). It guides therapy and prognosis.

Class	Designation	Key histology	Clinical correlate
I	Minimal mesangial	Normal light microscopy; mesangial deposits on IF/EM	Minimal manifestations; excellent prognosis
II	Mesangial proliferative	Mesangial hypercellularity + matrix expansion	Mild haematuria/proteinuria; nephrotic syndrome rare
III	Focal nephritis (<50% glomeruli)	Focal endocapillary ± extracapillary hypercellularity, focal subendothelial deposits ± fibrinoid necrosis	Haematuria, proteinuria, ± active sediment/nephrotic; variable course
IV	Diffuse nephritis (>50% glomeruli)	Diffuse endocapillary ± extracapillary hypercellularity, diffuse subendothelial deposits; segmental (IV-S) or global (IV-G); ± crescents ± fibrinoid necrosis	Most severe — high anti-dsDNA, low complement, RBC casts, ~50% nephrotic; worst untreated prognosis (IV-S worse than IV-G)
V	Membranous	Thickened GBM with diffuse subepithelial deposits; may coexist with III/IV (mixed membranous + proliferative)	Nephrotic syndrome (~60%); thrombotic risk; ~20% of LN with significant proteinuria
VI	Advanced sclerosing	Global sclerosis of >90% of glomeruli, interstitial fibrosis	ESKD; immunosuppression not useful

- ▶ Lesions are **dynamic** — patients can **transform** between classes, so **repeat biopsy** is often required (e.g., non-response or change in trajectory).
- ▶ Class III/IV are presented under **acute nephritic syndromes** because of their aggressive proliferative behaviour; class V behaves like a nephrotic/membranous lesion.

Investigations, serology and monitoring

- ▶ **Urinalysis** — proteinuria, haematuria, RBC/cellular casts (active sediment).
- ▶ **Quantitation** — random urine **protein-to-creatinine ratio (UPCr)** or 24-h urine protein; screen every 3 months.

- ▶ **Renal function** — serum creatinine, eGFR.
- ▶ **Serology** — **anti-dsDNA titre** (rising titre + falling C3/C4 herald a flare and impending active nephritis).
- ▶ **Renal biopsy** — the key investigation; generally prompted by **UPCr >0.5 and/or declining kidney function**. It establishes the **ISN/RPS class**, distinguishes active (treatable) from chronic (sclerotic) lesions, and guides therapy. Note: a biopsy showing class III/IV LN independently satisfies SLE classification criteria.

Management by class

- ▶ **General/adjunctive measures (all classes):** **hydroxychloroquine** (renoprotective, reduces flares); **ACE inhibitor or ARB** for class III/IV/V to reduce proteinuria and glomerular hypertension; an **SGLT2 inhibitor** if eGFR is reduced; blood-pressure, lipid and cardiovascular-risk control; **anticoagulation (vitamin K antagonist/heparin)** if antiphospholipid nephropathy is present on biopsy.
- ▶ **Class I / II:** little or no specific immunosuppression; excellent prognosis.
- ▶ **Class III / IV (± V) — proliferative LN (aggressive therapy):**
 - **Induction (2–6 months):** high-dose glucocorticoids — including **IV methylprednisolone 125–1000 mg/day for 1–3 days** for severe/crescentic disease — **plus either IV cyclophosphamide or mycophenolate mofetil (MMF)**.
 - **Cyclophosphamide regimens:** **low-dose 500 mg IV every 2 weeks for six doses** (the *Euro-Lupus* regimen — as effective as high dose with better tolerability) or **high-dose monthly pulses for 6 months**; a **GnRH agonist** can be given before each dose to protect against ovarian failure.
 - **MMF 2–3 g/day** is particularly favoured for induction in **Black/Hispanic** patients.
 - **Newer triple therapies (FDA-approved, steroid-sparing):** **belimumab** (anti-BAFF, 2020) added to MMF or low-dose cyclophosphamide; **voclosporin** (a calcineurin-inhibitor/cyclosporine analogue, 2021) added to MMF + glucocorticoids.
 - **Maintenance:** lower-dose glucocorticoids (taper prednisone to **≤5 mg/day**) plus **MMF or azathioprine**; total immunosuppression (induction + maintenance) generally **≥36 months** (KDIGO).
 - **Refractory disease:** **rituximab** (anti-CD20) may be considered.
- ▶ **Class V — membranous LN:** treat nephrotic syndrome; severe nephrosis, rising creatinine or progressive course warrant steroids + an additional immunosuppressant; RAS blockade reduces proteinuria.
- ▶ **Class VI:** advanced sclerosis — manage as CKD/ESKD with **dialysis or transplantation**; kidney transplant after **~6 months of inactive disease** gives allograft survival comparable to other indications.

- ▶ **Treatment targets:** $\geq 25\%$ reduction in UPCr by **3 months**, $\geq 50\%$ reduction to **< 3 g/day** by **6 months**, and **< 0.5 – 0.7 g/day** by **12–24 months**, each with eGFR within 10% of baseline.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Glomerular capillary loop — sites of immune deposits.** Labels: *Capillary lumen, Endothelial cell, Glomerular basement membrane (GBM), Visceral epithelial cell (podocyte), Mesangium, Mesangial deposits (Class I/II), Subendothelial deposits (Class III/IV), Subepithelial deposits (Class V), Crescent in Bowman's space (extracapillary proliferation), Fibrinoid necrosis, Bowman's capsule.*
- ▶ **LN management algorithm.** Labels: *Renal biopsy $\rightarrow$ ISN/RPS class $\rightarrow$ Class I/II (HCQ + RAS blockade, no specific immunosuppression); Class III/IV $\pm$ V (Induction: glucocorticoid + MMF or low-dose IV cyclophosphamide $\pm$ belimumab/voclosporin $\rightarrow$ Maintenance: low-dose steroid + MMF or azathioprine); Pure Class V (nephrotic management); Class VI (dialysis/transplant) — with the adjunct box HCQ, ACEi/ARB, SGLT2i, anticoagulation if APS nephropathy.*

Clinical / Diagnostic significance

- ▶ LN is a leading determinant of prognosis: **up to 20% reach ESKD** requiring dialysis/transplant, and in the USA **$\sim 20\%$ of class IV patients die or develop ESRD within 10 years**; LN markedly raises mortality versus the general population.
- ▶ Achieving **remission** (near-normal kidney function with proteinuria reduced to near-normal) dramatically improves renal outcome.
- ▶ A **renal biopsy showing class III or IV LN** is the only single item that, by itself, satisfies the SLE classification criteria — underscoring renal disease as a defining feature.
- ▶ Both LN and its corticosteroid treatment accelerate **atherosclerosis, hypertension, hyperglycaemia and hyperlipidaemia**, so cardiovascular risk reduction is integral to care.

High-yield exam pointers

- ▶ Nephritis in $\sim 35\%$ of SLE; $\sim 30\%$ have renal disease at diagnosis.
- ▶ ISN/RPS classes I–VI — *III = focal ($< 50\%$), IV = diffuse ($> 50\%$), V = membranous, VI = sclerotic; IV-S worse than IV-G.*
- ▶ Subendothelial/mesangial deposits $\rightarrow$ **proliferative/nephritic**; subepithelial $\rightarrow$ **membranous/nephrotic**.
- ▶ **Anti-dsDNA high + C3/C4 low** = best correlate of active LN; hypocomplementemia in **70–90%**.
- ▶ **Renal biopsy** is essential to assign class and guide therapy (prompted by UPCr > 0.5 / falling GFR); screen UPCr **every 3 months**.

- ▶ Proliferative LN (III/IV): induction = steroids + MMF or cyclophosphamide; maintenance = MMF or azathioprine.
- ▶ Newer agents: belimumab (2020) and voclosporin (2021) for steroid-sparing triple therapy.
- ▶ Class V → nephrotic syndrome + renal vein thrombosis risk; antiphospholipid antibodies → thrombotic microangiopathy with worse prognosis.
- ▶ HCQ, ACEi/ARB and (if low eGFR) SGLT2 inhibitor in all proliferative/membranous LN.

SOURCE & COVERAGE

Harrison's Principles of Internal Medicine, 22e — Ch 326 "Glomerular Diseases" (lupus nephritis section, Table 326-3 ISN/RPS classification) and Ch 368 "Systemic Lupus Erythematosus" (Renal Manifestations; Fig. 368-5 treatment of lupus nephritis). *Coverage note:* the "Euro-Lupus" eponym for the low-dose cyclophosphamide regimen (500 mg q2-weekly × 6) is standard, universally accepted internal medicine added for completeness; Harrison describes the regimen and dose but does not use the eponym.

Renal Osteodystrophy

Asked in: Paper IV May 2022 — RGUHS MD General Medicine

Definition / Introduction — *Renal osteodystrophy* is the spectrum of bone histological abnormalities that complicates chronic kidney disease (CKD), arising from disordered calcium, phosphate, parathyroid hormone (PTH), fibroblast growth factor-23 (FGF-23) and vitamin D metabolism. It is the skeletal component of the wider systemic disorder of mineral metabolism in CKD (which also encompasses biochemical derangements and extraskeletal/vascular calcification). The principal complications of abnormal mineral metabolism in CKD occur in the **skeleton** and the **vascular bed**, with occasional soft-tissue involvement, and disorders of bone turnover and of vascular calcification are pathophysiologically linked.

Pathophysiology — the engine of secondary hyperparathyroidism

The high-turnover lesion is driven by a self-amplifying cascade that begins early (changes start as GFR falls below 60 mL/min, with phosphate retention and FGF-23 rise possibly antedating measurable GFR decline):

- ▶ Declining GFR → phosphate retention. Reduced excretion of phosphate is the initiating event.
- ▶ Retained phosphate stimulates increased synthesis of FGF-23 by osteocytes, increased PTH synthesis, and growth of parathyroid gland mass.

- ▶ **Decreased ionized calcium** results from reduced renal calcitriol [$1,25(\text{OH})_2\text{D}_3$] production — itself a consequence of phosphate retention and of elevated FGF-23, which both suppresses 1α -hydroxylation and *increases calcitriol degradation*.
- ▶ **Low calcitriol** drives hyperparathyroidism in two ways: by causing hypocalcaemia, and by a *direct effect on PTH gene transcription*.
- ▶ The normal inhibitory effect of FGF-23 on PTH secretion is **Klotho-dependent** and is *attenuated* in CKD, removing a brake on PTH.
- ▶ Net result: **secondary hyperparathyroidism**, sustained high bone turnover, and progressive parathyroid hyperplasia. PTH itself acts as a **uremic toxin** (muscle weakness, cardiac muscle fibrosis, constitutional symptoms, and ESA-resistant anaemia from marrow fibrosis).

Classification — histological types of renal bone disease

The major bone disorders are classified by **bone turnover** and **PTH level** (with mineralisation as a third axis); most patients show a *combination*.

Type	Bone turnover / PTH	Underlying mechanism	Hallmark
Osteitis fibrosa cystica	High turnover, high PTH	Secondary hyperparathyroidism	Abnormal osteoid, peritrabecular & marrow fibrosis; bone cysts with haemorrhage = *brown tumours*
Osteomalacia	Low/defective mineralisation	Reduced production & action of $1,25(\text{OH})_2\text{D}_3$	Accumulation of non-mineralised osteoid; fractures, bowing
Adynamic bone disease	Low turnover, low/normal PTH	Over-suppression of PTH (vitamin D, high-Ca binders/dialysate), chronic inflammation	Reduced bone volume & mineralisation; microfractures unrepaired
Mixed uremic osteodystrophy	Combined	Osteitis fibrosa + osteomalacia coexisting	Features of both

- ▶ **Osteitis fibrosa cystica** is the *classic lesion of secondary hyperparathyroidism*: bone pain, fragility, *brown tumours* with compression syndromes, and erythropoiesis-stimulating-agent (ESA) resistance from marrow fibrosis.
- ▶ **Adynamic bone disease** is *increasing in prevalence*, especially among **diabetics and older patients**. Complications include increased **fracture**, bone pain, and an association with **vascular and cardiac calcification**; calcium that cannot enter low-turnover bone may deposit in soft tissue as ***tumoral calcinosis**. *These patients often have the most severe musculoskeletal pain** owing to inability to repair normal microfractures.

Extraskkeletal manifestations

- ▶ **Vascular / valvular calcification:** strong association between **hyperphosphataemia** and cardiovascular mortality. CKD patients show calcification of the **media of coronary arteries** and **heart valves** far exceeding non-CKD patients; magnitude is proportional to age, hyperphosphataemia, and (paradoxically) **low PTH/low turnover**. Hyperphosphataemia induces an **osteoblast-like gene-expression** switch in vascular cells → calcification/ossification; low **fetuin** permits more rapid calcification.
- ▶ **Calciophylaxis** (calcific uraemic arteriolopathy): a devastating disorder almost exclusive to advanced CKD. Heralded by painful **livedo reticularis** and subcutaneous nodules that progress to **ischaemic necrosis/ulceration** (legs, thighs, abdomen, breasts), with vascular occlusion plus extensive vascular & soft-tissue calcification. **Warfarin** is a recognised risk factor (it decreases vitamin-K-dependent activation of **matrix GLA protein**, which normally inhibits vascular calcification).
- ▶ **Tumoral calcinosis:** large periarticular calcified concretions in severely, chronically hyperphosphataemic, non-adherent dialysis patients.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Vicious-cycle flow diagram of CKD secondary hyperparathyroidism.** Labels: ↓GFR → *Phosphate retention* → ↑FGF-23 (osteocytes) and ↑PTH / *parathyroid hyperplasia*; ↓Renal 1 α -hydroxylase → ↓Calcitriol; ↓Ionised calcium; *Klotho-dependent FGF-23 brake on PTH attenuated*; outputs → *High-turnover bone (osteitis fibrosa cystica)* and *Vascular calcification*.
- ▶ **Spectrum bar of renal bone disease.** Single horizontal axis labelled *Bone turnover / PTH*: left end *Low (Adynamic bone disease)* → middle *Normal* → right end *High (Osteitis fibrosa cystica)*; place *Osteomalacia* (mineralisation defect) and *Mixed uremic osteodystrophy* annotated on the bar.

Clinical / Diagnostic significance

- ▶ **Biochemistry (serial trends):** serum **phosphate** (hyperphosphataemia, defined in adults as >1.8 mmol/L [5.5 mg/dL]), **calcium**, **intact PTH**, **alkaline phosphatase** (turnover marker), **25-OH vitamin D**; FGF-23 is elevated early. High FGF-23 is an *independent risk factor for left ventricular hypertrophy* and increased mortality in CKD, dialysis and transplant patients.
- ▶ **Bone biopsy with double tetracycline labelling** (TMV system — turnover, mineralisation, volume) is the definitive method to distinguish high- from low-turnover disease and to confirm adynamic bone or osteomalacia (*standard nephrology practice; see Coverage note*).
- ▶ **Imaging:** radiographs may show subperiosteal resorption, brown tumours, vascular calcification; CT/electron-beam CT quantifies coronary and valvular calcification.

- **Management pearls:** prevention is paramount — *once parathyroid mass is very large the disease is hard to control*. KDOQI guidance targets **intact PTH 2–9 × the upper limit of normal**, because *very low PTH predisposes to adynamic bone disease, fracture and ectopic calcification*. Avoid over-suppression of PTH (excess vitamin D analogue, calcium-based binders, high-calcium dialysate). For anticoagulation in CKD, **avoid warfarin** where feasible to reduce calciphylaxis risk.

Management / Treatment

Strategy	Agents (per Harrison)	Rationale / caution
Lower serum phosphate	Low-phosphate diet; phosphate binders with meals — Ca acetate, Ca carbonate (Ca-based); sevelamer , lanthanum (non-Ca polymers); tenapanor (Na ⁺ /H ⁺ inhibitor reducing GI phosphate absorption)	Ca-based binders risk hypercalcaemia & worsen low-turnover/adynamic bone; non-Ca binders avoid this and may attenuate vascular calcification
Suppress PTH (vitamin D)	Calcitriol ; analogue paricalcitol	Direct PTH suppression + raises ionised Ca; calcitriol can cause hyperCa/hyperphosphataemia → paricalcitol suppresses PTH with less hypercalcaemia
Calcimimetics	Cinacalcet , etelcalcetide	Increase parathyroid sensitivity to extracellular calcium → dose-dependent fall in PTH and plasma calcium; help lower calciphylaxis risk
Refractory disease	Parathyroidectomy	For severe, autonomous (tertiary) hyperparathyroidism unresponsive to medical therapy (<i>standard; see Coverage note</i>)
Calciphylaxis	Sodium thiosulfate (IV) , hyperbaric oxygen , discontinue warfarin	Multimodal; correct mineral derangements; wound care

High-yield exam pointers

- Renal osteodystrophy = **bone-histology arm** of CKD mineral-bone disorder; turnover + PTH axis classifies it.
- **Phosphate retention** is the prime mover → ↑FGF-23 + ↑PTH + ↓calcitriol → **secondary hyperparathyroidism**; begins at GFR <60 mL/min.
- **Osteitis fibrosa cystica** (high PTH) ↔ ***brown tumours**; *adynamic bone disease** (low PTH) — rising in diabetics/elderly, over-suppression risk, fracture + calcification.
- **Osteomalacia** = defective mineralisation from low 1,25(OH)₂D₃ → excess **osteoid**.

- ▶ **FGF-23** is Klotho-dependent, raised early, an independent predictor of LVH and mortality.
- ▶ **Calciphylaxis**: painful livedo reticularis → ischaemic skin necrosis; **warfarin** (anti-matrix-GLA-protein) is a risk factor; treat with **IV sodium thiosulfate**.
- ▶ Drugs to recall: binders (Ca acetate/carbonate, **sevelamer**, **lanthanum**, **tenapanor**); vitamin D (**calcitriol**, **paricalcitol**); calcimimetics (**cinacalcet**, **etelcalcetide**).
- ▶ Target **intact PTH 2–9× ULN**; avoid both extremes — high PTH → osteitis fibrosa, over-suppressed PTH → adynamic bone.

SOURCE & COVERAGE

Harrison's Principles of Internal Medicine, 22e — Ch 322 "Chronic Kidney Disease" (Disorders of Calcium and Phosphate Metabolism; bone manifestations, calciphylaxis, treatment) and Ch 421 "Bone and Mineral Metabolism in Health and Disease" (FGF-23, hyperphosphataemia, osteomalacia, secondary hyperparathyroidism of renal failure). *Coverage note*: The eponymous term "*renal osteodystrophy*" and the KDIGO "CKD-MBD" label are not used verbatim in Harrison 22e Ch 322 (which titles the section "Disorders of Calcium and Phosphate Metabolism"); the histological entities, mechanisms, drugs and doses above are all faithful to the provided text. The **TMV bone-biopsy/double-tetracycline-labelling** classification and **parathyroidectomy** for refractory disease are universally accepted standard nephrology not detailed in these two chapters, and are flagged accordingly.

Renal replacement therapy

Asked in: Paper IV 17 Apr 2026 · Paper IV Nov 2022 (2×) — RGUHS MD General Medicine

Definition / Introduction — **Renal replacement therapy (RRT)** denotes the techniques that substitute for the excretory (and partly the endocrine/metabolic) functions of the kidney when native function is inadequate, whether transiently in acute kidney injury (AKI) or permanently in end-stage kidney disease (ESKD). The three pillars are **haemodialysis (HD)**, **peritoneal dialysis (PD)** and **kidney transplantation**, supplemented in the critically ill by **continuous renal replacement therapy (CRRT)**. Dialysis exploits two physical principles — **diffusion** of solute down a concentration gradient across a semipermeable membrane, and **convection** (solvent drag with ultrafiltrated plasma water) — while transplantation alone restores all renal functions and is the treatment of choice for ESKD.

Indications for RRT

- ▶ **Chronic / ESKD (maintenance dialysis)**: uraemic symptoms; **hyperkalaemia** unresponsive to conservative measures; persistent **extracellular volume expansion** despite diuretics; **acidosis** refractory to medical therapy; uraemic **bleeding diathesis**; and an eGFR/creatinine clearance **<10 mL/min/1.73 m²**. There is *no absolute* level of creatinine, BUN, cystatin C or eGFR that

mandates dialysis, and no benefit to preemptive initiation at GFR 10–14 over symptom-guided start (IDEAL trial). CMDT: consider initiation as GFR nears 5–10 mL/min/1.73 m² with uraemic symptoms.

- ▶ **Acute (AKI) — mnemonic “AEIOU”:** Acid–base (refractory metabolic acidosis); Electrolyte (hyperkalaemia unresponsive to medical therapy); Intoxications (dialysable poisons); volume Overload unresponsive to diuretics; Uraemic complications — encephalopathy, asterixis, pericarditis/rub, seizures, uraemic bleeding. Randomised trials (STARRT-AKI) show **no survival benefit from earlier vs later** initiation; dialysis should not, however, await a life-threatening complication.
- ▶ **Nephrology referral** is advised when GFR <30 mL/min/1.73 m², rapid decline (>5 mL/min/1.73 m²/yr) or albuminuria >300 mg/day — to plan access and modality.

Modalities at a glance

Feature	Haemodialysis	Peritoneal dialysis	CRRT (AKI)	Transplantation
Membrane	Synthetic hollow-fibre dialyzer	Patient's own peritoneum	Extracorporeal haemofilter	— (whole organ)
Clearance	Diffusion + convection	Diffusion + osmotic UF	Convective ± diffusive	Physiological
Setting	In-centre (>80% US) or home	Home, self-care	ICU, haemodynamically unstable	Definitive
Tempo	3–4 h × 3/week	Continuous, daily	Continuous (24 h)	Permanent
Key limit	Intradialytic hypotension	Peritonitis	Needs ICU/anticoagulation	Donor shortage, immunosuppression

Haemodialysis

- ▶ **Three components:** the dialyzer (hollow-fibre, **biocompatible synthetic polysulfone** membrane — replaced older “bioincompatible” cellulose membranes that activated complement); the dialysate; and the **blood-delivery system**.
- ▶ **Dialysate composition:** potassium 0–4 mmol/L (very low-K baths increase sudden-death risk), calcium usually 1.25 mmol/L (2.5 mEq/L), sodium 135–140 mmol/L (*sodium modelling* may reduce intradialytic hypotension). Water is purified by softening, deionisation and **reverse osmosis** (~120 L exposure per session).
- ▶ **Prescription:** heparinised blood pumped at 250–450 mL/min with dialysate running **counter-current** at 500–800 mL/min; small molecules (urea, 60 Da) cleared far better than larger ones (creatinine, 113 Da).

- ▶ **Vascular access (in order of preference — “Fistula First”):** native arteriovenous fistula (*Brescia–Cimino*: cephalic vein at wrist anastomosed end-to-side to radial artery) — highest patency, lowest infection, matures in 6–8 weeks; **AV graft** (interposed PTFE, usable ~2 weeks, fails by intimal hyperplasia/thrombosis); **tunnelled cuffed catheter** (internal jugular preferred; highest infection/thrombosis — a “lifeline” only). Subclavian access is avoided (stenosis risk).
- ▶ **Adequacy: urea reduction ratio (URR) >65–70 %** and **Kt/V >1.2** (single-pool) or 1.05 (equilibrated); standard schedule 9–12 h/week in 3 sessions.
- ▶ **Acute complications: hypotension** (commonest — excess/rapid ultrafiltration; avoid removal >13 mL/kg/h), muscle cramps, and **dialyzer reactions** — *type A* (IgE-mediated anaphylaxis to ethylene-oxide, within minutes) and *type B* (complement/cytokine-mediated chest & back pain). **Dialysis disequilibrium syndrome** (cerebral oedema from rapid urea/osmolar shifts) may occur with aggressive early sessions — mitigated by short, low-efficiency initial runs.

Peritoneal dialysis

- ▶ **Principle:** 1.5–3 L of hypertonic **dextrose** solution dwells in the peritoneal cavity (2–4 h); solute is removed by diffusion and water by **osmotic ultrafiltration**. **Icodextrin**, a non-absorbable glucose polymer, gives sustained ultrafiltration in the long dwell of high transporters.
- ▶ **Forms:** CAPD (manual exchanges, 3–5/day with an overnight dwell) and CCPD/APD (automated cycler performs exchanges overnight). The **peritoneal equilibration test (PET)** classifies membranes as **low, low-average, high-average, high transporters** — high transporters need short, frequent (cycler) dwells.
- ▶ **Access:** soft silicone catheter with **two Dacron cuffs** that scar to anchor and seal against bacterial tracking.
- ▶ **Complications: peritonitis** (commonest serious complication) — cloudy effluent + abdominal pain, **dialysate leukocytes >100/mm³ with >50% neutrophils**; usually **gram-positive cocci** (*Staphylococcus*, skin origin), treated with intraperitoneal/oral antibiotics; *Pseudomonas* or fungal peritonitis mandates **catheter removal**. Also tunnel-exit infections, **protein loss/hypoalbuminaemia**, hyperglycaemia, weight gain, hypertriglyceridaemia and late **encapsulating peritoneal sclerosis**. Advantage: continuous potassium/phosphate removal allows a more liberal diet and suits haemodynamically labile patients.

Continuous & hybrid therapies (AKI)

- ▶ **CVVH** (purely convective — plasma water forced across the membrane, replaced by crystalloid), **CVVHD** (diffusive, low blood/dialysate flows), **CVVHDF** (combined). **SLED/EDD** (“hybrid”, ≤12 h) capture CRRT’s gentleness without 24-h staffing.
- ▶ Preferred for **haemodynamic instability, cerebral oedema or severe volume overload**; trials show no survival/recovery superiority over intermittent HD, and no benefit of higher dialysis dose.

Kidney transplantation — the definitive RRT

- ▶ **Treatment of choice for ESKD**, conferring longer survival and better quality of life than dialysis; first successful transplant Boston 1954 (identical twins). One-year graft survival ~98% (**living**) and 93% (**deceased**); mean graft survival ~19 vs 12 years. The graft is placed **extraperitoneally in the iliac fossa** — donor renal artery→external iliac artery, renal vein→external iliac vein, ureter→bladder.
- ▶ **Matching**: ABO compatibility plus **HLA** (chromosome 6; class I = A, B, C; class II = DR, DQ, DP) — more A/B/DR mismatches predict poorer survival. A **positive cytotoxic T-cell crossmatch** (preformed donor-specific anti-HLA class I antibody) predicts **hyperacute rejection** and is the *only absolute immunologic contraindication*.
- ▶ **Absolute contraindications**: predicted survival <2 years, active malignancy, active infection, non-adherence/psychosocial barriers, active substance abuse.
- ▶ **Rejection**: *hyperacute* (preformed antibody, minutes); *acute T-cell-mediated* (Banff-graded interstitial/tubular/vascular infiltrate → IV **methylprednisolone 500–1000 mg/day × 3**, then ATG); *antibody-mediated* (C4d in peritubular capillaries + circulating DSA → plasmapheresis, IVIG, rituximab, bortezomib); and chronic (fibrosis/vasculopathy).
- ▶ **Immunosuppression**: *Induction* — depleting **antithymocyte globulin (ATG)** or **alemtuzumab** (anti-CD52); non-depleting **basiliximab** (anti-IL-2Rα/CD25). *Maintenance* — a **calcineurin inhibitor** (tacrolimus [binds FKBP-12] or cyclosporine [binds cyclophilin] → blocks IL-2 transcription) + an **antimetabolite** (mycophenolate, or azathioprine — check TPMT) + **steroids**; alternatives **mTOR inhibitors** (sirolimus/everolimus) and **belatacept** (CTLA-4-Ig, blocks CD80/86–CD28 costimulation). CNI toxicity: nephrotoxicity, hypertension; cyclosporine causes hirsutism & gingival hyperplasia, tacrolimus causes post-transplant diabetes.
- ▶ **Post-transplant infection timeline**: <1 month — bacterial wound/UTI, HSV, candidiasis; 1–6 months — opportunistic CMV (D+/R– highest risk; valganciclovir), **Pneumocystis** (TMP-SMX prophylaxis 6 months), **BK polyomavirus nephropathy** (manage by reducing immunosuppression), Listeria, Nocardia; >6 months — Aspergillus, zoster, community pathogens. **Malignancy** (~100× general population): **skin/lip cancers** commonest; **EBV-driven PTLD**. Leading causes of recipient death: cardiovascular (~29%), infection (~18%), malignancy (~17%).

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Haemodialysis circuit**: label *arterial line from AV fistula → blood pump → heparin infusion → hollow-fibre dialyzer (blood vs counter-current dialysate compartments) → air/leak detector → venous line back to patient*; on the dialysate side label *purified water (reverse osmosis) + acid/bicarbonate concentrate → dialysate inflow → drain*. Mark **diffusion** and **ultrafiltration/convection** across the membrane.

- ▶ **Transplant anatomy:** label *graft kidney in right iliac fossa, donor renal artery → external iliac artery, donor renal vein → external iliac vein, donor ureter → recipient bladder*, native kidneys left in situ.

Clinical / Diagnostic significance

- ▶ **Modality choice** balances comorbidity, vascular/peritoneal access, lifestyle and resources; outcomes of HD vs PD are broadly similar, so quality-of-life often decides. PD predominates in resource-limited settings (lower cost).
- ▶ **Pre-emptive transplantation** (before dialysis) gives the best outcomes; living-donor grafts outperform deceased-donor.
- ▶ **Cardiovascular disease** is the leading cause of death in both dialysis and transplant populations; aggressive BP, lipid and volume control are essential.
- ▶ Monitoring tools: **URR/Kt/V** for HD adequacy, **PET** for PD membrane typing, **donor-specific antibody + allograft biopsy (Banff)** for rejection.

High-yield exam pointers

- ▶ RRT = HD + PD + CRRT + **transplantation**; dialysis works by **diffusion + convection**.
- ▶ AEIOU = AKI dialysis indications; ESKD dialysis when GFR ~5–10 with uraemia.
- ▶ **Brescia–Cimino radiocephalic fistula** = preferred access (“Fistula First”); matures 6–8 weeks; highest patency, lowest infection.
- ▶ **HD adequacy:** URR >65–70 %, Kt/V >1.2; commonest acute complication = **hypotension**.
- ▶ **PD peritonitis:** cloudy effluent, >100 WBC/mm³ (>50% **neutrophils**), usually **gram-positive cocci**; *Pseudomonas*/fungal → remove catheter.
- ▶ **CRRT** preferred in haemodynamic instability/cerebral oedema; no survival edge over intermittent HD.
- ▶ **Positive cytotoxic crossmatch** = only absolute immunologic contraindication (hyperacute rejection).
- ▶ Transplant maintenance = **CNI + antimetabolite + steroid**; **C4d** in peritubular capillaries = antibody-mediated rejection.
- ▶ Commonest post-transplant malignancy = **skin cancer**; **CMV** and **BK virus** are key opportunists.

SOURCE & COVERAGE

- ▶ **Harrison’s Principles of Internal Medicine, 22e** — “Dialysis in the Treatment of Kidney Failure”; “Kidney Transplantation”; “Acute Kidney Injury” (CRRT/SLED modalities); “Interventional Nephrology” (access).

- **Brenner & Rector's The Kidney** — “Hemodialysis” (Kt/V, adequacy, urea kinetics) and “Peritoneal Dialysis” (icodextrin, transporter status, automated PD).
- **CMDT 2026** — “Kidney Disease” (AEIOU indications, ESKD treatment thresholds, access maturation times, prognosis).

Coverage note: “Dialysis disequilibrium syndrome” and the AEIOU framing are universally accepted standard internal medicine, included for completeness; the Harrison/Brenner dialysis chapters describe the underlying osmolar-shift and indication concepts but do not use these exact labels.

Renal tubular Acidosis

Asked in: Paper IV May 2022 · Paper IV Nov 2021 (2×) — RGUHS MD General Medicine

Definition / Introduction — Renal tubular acidosis (RTA) is a group of disorders characterised by a **normal anion-gap (hyperchloraemic) metabolic acidosis** caused by impaired renal tubular acidification—either failure of the proximal tubule to reabsorb filtered bicarbonate or failure of the distal nephron to secrete H^+ / generate ammonium—**despite a relatively preserved glomerular filtration rate**. It is recognised biochemically by a hyperchloraemic acidosis with reciprocal fall in $[\text{HCO}_3^-]$ and a **positive urine anion gap** (signifying low urinary NH_4^+ of renal origin). The clinically important forms are **proximal (type 2)**, **classic distal (type 1)**, and **hyperkalaemic / generalised distal nephron dysfunction (type 4) RTA**.

Classification (Harrison Table 58-5)

Type	Defect	Serum K^+	Representative causes
Proximal (type 2)	Reduced proximal HCO_3^- reabsorptive threshold (T_m) → bicarbonaturia	Low	Acetazolamide, topiramate, ifosfamide; Fanconi syndrome; light-chain (myeloma) injury; inherited <i>SLC4A4</i> (basolateral NBCe1, with ocular abnormalities), <i>NHE3</i> (AD, short stature)
Distal / classic (type 1)	Impaired distal H^+ secretion / acidification	Low	Amphotericin B, ifosfamide; Sjögren's syndrome; SLE; inherited <i>ATP6V1B1</i> defect (distal tubule/collecting duct)

Type	Defect	Serum K ⁺	Representative causes
Generalised distal nephron dysfunction (type 4)	Aldosterone deficiency or resistance → impaired NH ₄ ⁺ generation + impaired K ⁺ /H ⁺ secretion	High	Hyporeninaemic hypoaldosteronism (diabetes, tubulointerstitial disease); mineralocorticoid resistance (PHA I); voltage defect (PHA I recessive, PHA II); drugs

- ▶ Within type 4, Harrison subdivides causes into (a) **selective aldosterone deficiency**, (b) **mineralocorticoid resistance** — pseudohypoaldosteronism (PHA) I, autosomal dominant, (c) **voltage defect** — PHA I autosomal recessive and PHA II, (d) **hyporeninaemic hypoaldosteronism**, and (e) **tubulointerstitial disease**.
- ▶ **Normokalaemic renal acidosis** of chronic progressive kidney disease (the “uraemic” non-AG acidosis of CKD stages 3–4) is a separate category requiring oral alkali.

Pathophysiology by type

- ▶ **Proximal RTA (type 2)**: generalised proximal tubular dysfunction reduces the bicarbonate reabsorptive threshold. At normal plasma [HCO₃⁻] there is **bicarbonaturia** with an inappropriately alkaline urine; once plasma [HCO₃⁻] falls **below the reduced threshold**, the distal nephron is intact, so the urine can be acidified to **pH <5.5**. It is frequently part of **Fanconi syndrome** — glycosuria, generalised aminoaciduria and phosphaturia. Alkali therapy enhances distal Na⁺/HCO₃⁻ delivery and **renal K⁺ secretion**, aggravating hypokalaemia.
- ▶ **Distal RTA (type 1)**: failure of distal H⁺ secretion produces an inability to lower urine pH appropriately. Classic features are **hypokalaemia**, **non-AG metabolic acidosis**, **low urinary NH₄⁺ excretion (positive urine anion gap)**, and an **inappropriately high urine pH (>5.5)** for the degree of systemic acidosis. **Hypocitraturia** and **hypercalciuria** are usual, so **nephrolithiasis**, **nephrocalcinosis** and **metabolic bone disease** are common.
- ▶ **Type 4 (hyperkalaemic) RTA**: aldosterone deficiency or tubular resistance impairs both potassium and acid secretion. **Hyperkalaemia** is **disproportionate to the reduction in GFR**, and hyperkalaemia itself **suppresses renal ammoniogenesis**, depressing urinary NH₄⁺ and net acid excretion. **Hyporeninaemic hypoaldosteronism** typically presents in **older adults with diabetes mellitus or tubulointerstitial disease and stage 3–4 CKD**, with K⁺ 5.2–6.0 mmol/L, **hypertension and congestive heart failure**, both acidosis and hyperkalaemia being out of proportion to the GFR. NSAIDs, trimethoprim, pentamidine, ACE inhibitors and ARBs increase the risk, especially in diabetic nephropathy.

Diagnostic approach

- ▶ **Confirm a normal anion-gap (hyperchloraemic) acidosis** — reciprocal rise in $[\text{Cl}^-]$ with the fall in $[\text{HCO}_3^-]$; calculate AG (correct for albumin) to exclude a high-AG process.
- ▶ **Urine anion gap (UAG)** = $([\text{Na}^+] + [\text{K}^+])_{\text{u}} - [\text{Cl}^-]_{\text{u}}$ to estimate urinary NH_4^+ :
 - **Negative UAG** → urinary NH_4^+ appropriately high → **extrarenal / gastrointestinal (diarrhoea)** cause.
 - **Positive UAG** → urinary NH_4^+ inappropriately low → **renal (RTA)** origin.
- ▶ **Urine pH**: inappropriately >5.5 in classic distal RTA and during the bicarbonaturic phase of proximal RTA; in proximal RTA the urine acidifies to <5.5 once plasma $[\text{HCO}_3^-]$ falls below threshold; in type 4 the dominant abnormality is **depressed urinary NH_4^+** .
- ▶ **Caveat (Harrison)**: the UAG correlates poorly with directly measured urine ammonium, so laboratories are encouraged to **measure urine NH_4^+ directly** (enzymatic assay on a 1:200 saline-diluted sample) rather than rely on the UAG.
- ▶ **Supportive findings**: proximal — glycosuria, aminoaciduria, phosphaturia (Fanconi); distal — hypokalaemia, hypercalciuria, hypocitraturia, nephrocalcinosis; type 4 — hyperkalaemia disproportionate to GFR, often diabetic/obstructive/tubulointerstitial kidney disease.

Treatment

- ▶ **Proximal RTA (type 2)**: the **most difficult RTA to fully correct**, because alkali increases urinary bicarbonate and potassium loss; **potassium supplementation is usually required**. An oral **sodium + potassium citrate** solution (citric acid 334 mg, sodium citrate 500 mg, potassium citrate 550 mg per 5 mL) is used; large alkali doses are often needed to restore serum $[\text{HCO}_3^-]$ (important for normal growth in children).
- ▶ **Distal RTA (type 1)**: **correct hypokalaemia first**, then give alkali — **sodium citrate (Shohl's solution)** or NaHCO_3 tablets (650-mg tablet = 7.8 meq) — to maintain serum $[\text{HCO}_3^-]$ at 24–26 meq/L. Patients respond readily; benefits include **fewer kidney stones, improved bone density, resumption of normal growth, and preservation of kidney function**.
- ▶ **Type 4 RTA**: **correct the metabolic acidosis** (alkali, as for type 1) and **correct the plasma $[\text{K}^+]$** ; restoring normokalaemia restores ammoniagenesis and net acid excretion. Hyperkalaemia is managed with the **calcium–potassium cation-exchange polymer patiromer** (8.4-g packets PO twice daily, titrated weekly to plasma K^+ , **max 25.2 g/day**) plus a **low-potassium diet** and withdrawal of potassium-retaining drugs; **documented isolated hypoaldosteronism is treated with fludrocortisone** (cautiously, with furosemide if there is oedema/hypertension).
- ▶ **CKD acidosis**: oral alkali to keep $[\text{HCO}_3^-] >22\text{--}24\text{ mmol/L}$ ($\approx 1.0\text{--}1.5\text{ mmol/kg/day}$ as NaHCO_3 or Shohl's solution); a diet rich in fruit and vegetables also raises plasma $[\text{HCO}_3^-]$ and slows CKD progression.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Nephron schematic of acidification** — label: *proximal tubule* (Na^+/H^+ exchanger NHE3, basolateral NBCe1, HCO_3^- reabsorption — site of **type 2**); *distal tubule / α -intercalated cell of collecting duct* (apical H^+ -ATPase, basolateral $\text{Cl}^-/\text{HCO}_3^-$ exchanger AE1 — site of **type 1**); *principal cell / aldosterone action* (ENaC, $\text{Na}^+/\text{K}^+/\text{H}^+$ secretion — site of **type 4**); annotate **urine pH** and **serum K^+** for each.
- ▶ **Diagnostic flow box** — label: *Hyperchloraemic non-AG acidosis* → *Urine anion gap*; *Negative UAG = GI/diarrhoea*; *Positive UAG = RTA* → *check serum K^+ (low = type 1/2; high = type 4) and urine pH (>5.5 distal)*.

Clinical / Diagnostic significance

- ▶ **Tubulointerstitial disease** is a major secondary cause: chronic TIN produces **type II RTA** from bicarbonaturia (Fanconi) or **type IV RTA** from impaired ammoniogenesis; Sjögren's syndrome classically causes **distal RTA** and **nephrogenic diabetes insipidus** (anti-Ro/SS-A, anti-La/SS-B positive); **lupus nephritis** may present with **type IV RTA**; **calcineurin inhibitors** cause hyperkalaemia via **tubular resistance to aldosterone**.
- ▶ **Proximal RTA** points to Fanconi syndrome — screen for **multiple myeloma / light-chain cast nephropathy**, drugs (ifosfamide, acetazolamide, topiramate) and heavy-metal (lead) tubulopathy.
- ▶ **Distal RTA** must be considered in any patient with **recurrent calcium nephrolithiasis**, **nephrocalcinosis**, **hypokalaemic paralysis**, or **unexplained osteomalacia/rickets**.
- ▶ **Type 4 RTA** is the commonest RTA in adult practice — suspect it in a **diabetic with mild CKD** and **hyperkalaemia disproportionate to GFR**, particularly on ACE inhibitors/ARBs, NSAIDs, trimethoprim, pentamidine or heparin.

High-yield exam pointers

- ▶ RTA = normal anion-gap (hyperchloraemic) metabolic acidosis with positive urine anion gap.
- ▶ Type 1 & 2 → hypokalaemia; Type 4 → hyperkalaemia.
- ▶ **Distal (type 1)**: urine pH >5.5, stones/nephrocalcinosis, hypercalciuria + hypocitraturia; causes — amphotericin B, Sjögren's, SLE, ATP6V1B1.
- ▶ **Proximal (type 2)**: Fanconi syndrome (glycosuria, aminoaciduria, phosphaturia); urine can still acidify <5.5 when plasma HCO_3^- is low; causes — acetazolamide, topiramate, ifosfamide, myeloma.
- ▶ **Type 4**: hyporeninaemic hypoaldosteronism in elderly diabetics; hyperkalaemia suppresses ammoniogenesis.
- ▶ **Positive UAG = renal cause**; **negative UAG = diarrhoea/GI** (but Harrison: measure urine NH_4^+ directly as UAG is unreliable).

- ▶ Treatment anchors: **Shohl's solution** / NaHCO_3 (650 mg = 7.8 meq); K^+ + alkali (citrate) for type 2; **patiomer + fludrocortisone** for type 4.

SOURCE & COVERAGE

Harrison's Principles of Internal Medicine, 22e — Ch 58 "Acidosis and Alkalosis" (non-AG acidoses, Table 58-5 classification, UAG, treatment of types 1/2/4) and Ch 328 "Tubulointerstitial Diseases of the Kidney" (Fanconi/type II and type IV RTA in TIN, Sjögren's, SLE, CNI hyperkalaemia). **Coverage note:** the *SLC4A1* (*AE1/band-3*) gene for autosomal-dominant distal RTA, the formal "type 3 (mixed)" designation, and the ammonium chloride / bicarbonate-infusion (fractional excretion of HCO_3^- >10–15% in type 2) provocative tests are standard textbook additions used here for completeness but are not detailed in the two provided chapters; Harrison lists *ATP6V1B1* as the inherited distal-RTA gene.

Renovascular Hypertension

Asked in: Paper IV Jun 2024 — RGUHS MD General Medicine

Definition / Introduction — **Renovascular hypertension (RVH)** is a rise in systemic arterial pressure *definitely induced by reduced renal perfusion*, most often from occlusive disease of a main or branch renal artery. It is the prototypical **potentially curable** ("secondary") **cause of hypertension**, because restoration of renal perfusion can reverse the pressor pathways. *Renal artery stenosis (RAS)* denotes the anatomical lesion; RVH is the *functional* consequence — the two are not synonymous, since many incidentally found stenoses are haemodynamically trivial. Renovascular disease is found in up to 25% of autopsies, yet RVH accounts for only ~1–2% of all hypertension.

Aetiology & Classification

- ▶ **Two dominant causes** account for the vast majority:
 - **Atherosclerotic RAS (ARAS)** — ~90%; older patients with diffuse atherosclerotic risk factors.
 - **Fibromuscular dysplasia (FMD)** — ~10%; younger women (age 15–50).
- ▶ ARAS is *common*: ~6.8% of a community sample over age 65, rising to 18–23% with coronary artery disease and >30% with peripheral/aortic disease. Untreated, ARAS **progresses in ~50% over 5 years**, sometimes to total occlusion.
- ▶ Other causes (Brenner Box 47.1): renal artery aneurysm, arterial embolus/thrombosis, dissection, arteriovenous fistula, extrinsic compression (e.g. pheochromocytoma, tumour), aortic coarctation, systemic vasculitis (**Takayasu arteritis**, polyarteritis), atheroembolic disease, and iatrogenic occlusion by an **endovascular aortic stent-graft**.

Feature	Atherosclerotic RAS (ARAS)	Fibromuscular dysplasia (FMD)
Proportion	~90%	~10%
Typical patient	Older, M≈F, ASCVD risk factors, smoker, diabetic	Young/middle-aged women (15–50 y)
Lesion site	Ostial / proximal third of renal artery	Mid–distal artery, branches; often bilateral
Angiographic look	Discrete proximal stenosis, often aortic plaque extension	“String of beads” / sawtooth (medial fibroplasia) ± aneurysm
Natural history	Progressive; causes ischaemic nephropathy	Rarely threatens GFR; may occlude / form aneurysm
Response to angioplasty	Poor — medical therapy preferred	Often curative (PTR)

- **FMD subtypes** (Brenner Box 47.1): *medial fibroplasia* (commonest, classic string-of-beads), *perimedial fibroplasia*, *intimal fibroplasia*, and *medial hyperplasia*.

Pathophysiology — the Goldblatt paradigm

- **Goldblatt (1932–34)** showed that clipping a renal artery reliably produces hypertension — the foundation of RAAS discovery.
- A lesion becomes **haemodynamically “critical”** only when **luminal obstruction reaches ~70–80%**; a translesional aorto-renal pressure gradient of **10–20 mmHg** is needed before measurable renin release occurs.
- Two physiologically distinct models explain the syndrome:

	Two-kidney, one-clip (2K1C) — unilateral RAS, normal contralateral kidney	One-kidney, one-clip (1K1C) — bilateral RAS or stenosis to a solitary kidney
Driving mechanism	Renin → Angiotensin II–dependent	Volume-dependent (impaired Na ⁺ /water excretion)
Contralateral kidney	Intact → pressure natriuresis keeps it volume-deplete → <i>sustained</i> renin release from stenotic side	Absent escape → Na ⁺ /water retention, volume expansion
Plasma renin activity	Elevated	Normal or low
Lateralisation of tests	Present (renal-vein renin, captopril renography)	None

	Two-kidney, one-clip (2K1C) — unilateral RAS, normal contralateral kidney	One-kidney, one-clip (1K1C) — bilateral RAS or stenosis to a solitary kidney
Effect of RAAS blockade	Lowers BP; may drop GFR in stenotic kidney; sharpens test lateralisation	Lowers BP only after volume depletion; may sharply lower GFR

- ▶ **Downstream Angiotensin II effects:** efferent arteriolar vasoconstriction, aldosterone secretion ($\rightarrow$ Na^+ retention, hypokalaemia), sympathetic activation, plus chronic **vascular remodelling**, LV hypertrophy, endothelin release, oxidative stress and fibrosis.
- ▶ **Three temporal phases (experimental):** **Phase I** — high circulating renin, BP fully reversible by clip removal; **Phase II** — renin returns to normal, BP persists but still clip-reversible; **Phase III** — BP becomes *clip-independent* (structural remodelling, oxidative injury, contralateral microvascular damage) and is no longer cured by revascularisation. This explains why **late revascularisation often fails to normalise BP**.
- ▶ **Ischaemic nephropathy:** with advanced ARAS, falling cortical perfusion and tissue hypoxia $\rightarrow$ tubulointerstitial fibrosis and loss of GFR. ~85% of revascularisation candidates already have stage 3–5 CKD (eGFR <60).

Clinical features — when to suspect RVH

- ▶ **Demographic/temporal clues:** onset of hypertension **before age 20–30 or after 50–55 years**; abrupt-onset or rapidly worsening previously controlled hypertension.
- ▶ **Resistant hypertension** — uncontrolled despite ≥ 3 drugs (one a diuretic).
- ▶ **Abdominal / flank (epigastric) bruit**; evidence of atherosclerosis elsewhere (claudication, CAD) — 15–25% of symptomatic lower-limb PAD have RAS.
- ▶ **Abrupt rise in serum creatinine** (>25–30%) after starting an ACE inhibitor / ARB — a *functional, reversible* loss of GFR from removing efferent vasoconstriction; strongly suggests **bilateral RAS or stenosis to a solitary kidney**.
- ▶ **Recurrent “flash” pulmonary oedema** with surges of BP and preserved LV systolic function (*Pickering syndrome*).
- ▶ **Unprovoked hypokalaemia** (secondary hyperaldosteronism), proteinuria, and **asymmetric kidney size** (>1.5 cm difference) on ultrasound.
- ▶ *Note:* the Cooperative Study (Simon 1972) confirmed that although early age of onset, abdominal bruit, hypokalaemia and grade 3–4 fundi are commoner in RVH, **no single clinical feature reliably discriminates it from essential hypertension**.

Diagnostic evaluation

- **Principle:** screen non-invasively, confirm by angiography — and *only investigate aggressively if a corrective procedure would be undertaken on a positive result.*

Modality	Role / strength	Caveat
Duplex Doppler ultrasonography	Peak systolic velocity >200 cm/s predicts >60% stenosis; renal resistive index predicts viability; cheap, repeatable	Highly operator- and habitus-dependent
CT angiography (CTA)	Excellent vascular images; best for accessory vessels & distal disease; no stent artefact	Iodinated contrast toxicity
MR angiography (MRA)	Good images of artery + perirenal aorta	Gadolinium / nephrogenic systemic fibrosis risk — avoid if eGFR <30; cannot image stents
Captopril renography (^{99m}Tc -MAG3)	Strong negative predictive value — a normal study excludes RVH	Affected by drugs, Na^+ , bilateral disease
Intra-arterial (digital subtraction) angiography	Gold standard; usually combined with intended intervention	Invasive; atheroembolism, contrast, dissection

- **Plasma renin activity / renal-vein renin sampling** is transient and drug/sodium-sensitive — it does **not** reliably predict response and is now **rarely performed** (high false-positive and false-negative rates).

Management

- **Optimal medical therapy is the cornerstone** for most patients (especially ARAS):
 - **RAAS blockade (ACE inhibitor or ARB)** — most effective antihypertensives in RVH; **monitor creatinine and potassium** after initiation; not absolutely contraindicated in unilateral disease.
 - **Statin, antiplatelet (aspirin), smoking cessation, attainment of goal BP, glycaemic control.**
- **Revascularisation** — endovascular stenting (ARAS) or **percutaneous transluminal renal angioplasty (PTRA)**:
 - **FMD** → PTRA is **often curative** — the single most important reason to *identify* FMD.
 - **ARAS** → the randomised trials **ASTRAL (2009), STAR (2009) and CORAL (2014)** showed **no added benefit of stenting over optimal medical therapy** for BP or renal preservation in moderate stenosis.
 - **Reserve intervention** (Harrison Table 289-2; AHA 2022) for: refractory hypertension / medical failure; **rapidly declining or recurrent fall in GFR**, including a fall precipitated by ACEi/ARB; **flash pulmonary oedema** or recurrent unexplained heart failure; high-grade (>70%) stenosis to the whole functioning renal mass; transplant renal-artery stenosis.

- **Procedural risk** <5% with experienced operators: renal artery dissection, capsular perforation, haemorrhage, and **atheroembolic disease** (which can paradoxically accelerate hypertension and renal failure). Renal flow is usually restored, but function recovers in only ~25% of cases.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Goldblatt 2K1C vs 1K1C schematic** — Draw two kidneys. *Left (2K1C)*: stenosed renal artery → “↓perfusion → ↑Renin → Angiotensin II → Aldosterone → Angiotensin-II-dependent HTN; PRA HIGH; lateralises”; contralateral kidney labelled “pressure natriuresis (volume-deplete)”. *Right (1K1C)*: bilateral stenoses / solitary kidney → “↓perfusion → Na⁺ + water retention → Volume expansion → volume-dependent HTN; PRA normal/low; NO lateralisation”.
- ▶ **RAAS cascade box** — Labels: *Angiotensinogen* → (*Renin*) → *Angiotensin I* → (*ACE*) → *Angiotensin II* → branches to **Vasoconstriction**, **Aldosterone** → Na⁺ retention, **Sympathetic activation**, LV hypertrophy / vascular remodelling.

Clinical / Diagnostic significance

- ▶ RVH is a **treatable secondary hypertension** — but in the modern era the chief goal has shifted from *curing BP* to **preserving renal function and preventing cardiovascular events**.
- ▶ A >25–30% **creatinine rise after ACEi/ARB** is a clinical “stress test” that unmasks bilateral RAS/solitary-kidney stenosis — recognise it early, as it is reversible.
- ▶ ARAS is an independent marker of **cardiovascular morbidity and mortality** regardless of whether revascularisation is done.
- ▶ **Atheroembolic (cholesterol-crystal) renal disease** is a key differential/complication after angiography or vascular surgery: **livedo reticularis**, **blue toes**, **eosinophilia** (60–80%), **hypocomplementaemia** (15%), stuttering renal failure, biopsy showing biconvex cholesterol “clefts”; 1-year mortality >38%. Withdraw anticoagulation; no specific therapy.

High-yield exam pointers

- ▶ RVH = **functional consequence**; RAS = **anatomical lesion** — not interchangeable.
- ▶ ~90% ARAS (ostial, older men) vs ~10% FMD (string-of-beads, young women); FMD responds to PTCA, ARAS usually does not.
- ▶ **Critical stenosis** = 70–80% lumen loss; **gradient 10–20 mmHg** triggers renin release.
- ▶ 2K1C = **renin/angiotensin-dependent**, PRA high, lateralises; 1K1C = **volume-dependent**, PRA normal/low, no lateralisation.
- ▶ **Captopril renography**: a *normal* scan excludes RVH (high NPV); DSA = **gold standard**.
- ▶ **Suspect RVH**: age <30 or >50, resistant HTN, abdominal bruit, flash pulmonary oedema, **creatinine** ↑ >25% on ACEi/ARB, hypokalaemia, asymmetric kidneys.

- ▶ **ASTRAL / CORAL / STAR:** stenting **no better than medical therapy** in ARAS — reserve intervention for refractory HTN, flash pulmonary oedema, or rapidly falling GFR.
- ▶ Medical bundle = RAAS blockade + statin + antiplatelet + smoking cessation + BP control.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Renovascular Disease” (Textor) and “Hypertension” (secondary hypertension / renovascular section).
- ▶ **Brenner & Rector's The Kidney** — “Renovascular Hypertension and Ischemic Nephropathy” (Goldblatt 2K1C/1K1C models, phases of RVH, critical-stenosis thresholds, lesion classification Box 47.1, Cooperative Study clinical clues).
- ▶ **CMDT 2026** — “Systemic Hypertension” (renal vascular hypertension) and “Kidney Disease — Renal Artery Stenosis” (diagnostic criteria, ASTRAL/CORAL evidence, revascularisation indications, AHA 2022 statement).

Coverage note: The eponym “Pickering syndrome” for recurrent flash pulmonary oedema with bilateral RAS is universally accepted standard medicine but is not named in the cited corpus (which uses “flash pulmonary edema”); trial acronyms ASTRAL/CORAL/STAR appear in the corpus on the RVD historical timeline and CMDT's “two large randomized trials” statement.

Tubulointerstitial Diseases of the Kidney

Asked in: Paper IV Jun 2024 — RGUHS MD General Medicine

Definition / Introduction — Tubulointerstitial diseases are a group of disorders that **primarily** target the renal tubules and the interstitium, with relative sparing of the glomeruli and renal vessels (distinguishing them from the *secondary* interstitial fibrosis that complicates almost every chronic glomerular or vascular disease). They are conveniently divided into **acute** (acute tubulointerstitial/interstitial nephritis, AIN/ATIN) and **chronic** (CIN/CTIN) forms. They account for roughly **10–20% of acute kidney injury (AKI)** and are an important, frequently unrecognised, cause of chronic kidney disease (CKD), with **interstitial fibrosis and tubular atrophy** as the final common pathway.

Classification (Causes)

Acute tubulointerstitial disorders	Chronic tubulointerstitial disorders
Drug-induced AIN — antibiotics (β -lactams, sulfonamides, quinolones, vancomycin, rifampin, ethambutol, acyclovir), NSAIDs/COX-2 inhibitors, PPIs/H ₂ -blockers, diuretics (thiazide, loop, triamterene), anticonvulsants (phenytoin, valproate,	Toxins/drugs — analgesics (phenacetin), lithium, heavy metals (lead, cadmium), aristolochic acid , calcineurin inhibitors (cyclosporine, tacrolimus)

Acute tubulointerstitial disorders	Chronic tubulointerstitial disorders
carbamazepine), allopurinol, mesalazine, immune checkpoint inhibitors , lenalidomide	
Infection-associated — <i>Streptococcus</i> , <i>Staphylococcus</i> , <i>Legionella</i> , <i>Leptospira</i> ; EBV, CMV, hantavirus, polyomavirus (BK), HIV	Reflux nephropathy (vesicoureteral reflux); sickle cell nephropathy
Autoimmune — TINU, Sjögren's, SLE, sarcoidosis (granulomatous), IgG4-related disease , anti-brush-border (anti-LRP2) disease	Metabolic — hypercalcaemia/nephrocalcinosis, hyperuricaemia (gouty), chronic hypokalaemia, hyperoxaluria
Acute obstructive (crystal) — light-chain cast nephropathy, acute urate nephropathy, acute phosphate nephropathy	Cystic/hereditary — ADPKD, nephronophthisis, ADTKD (medullary cystic kidney disease), medullary sponge kidney
	Other — chronic GN, obstruction, ischaemia, radiation; CINAC/CKDu (agricultural communities)

Pathogenesis / Mechanisms of injury

- ▶ **Acute** disease results from aggressive inflammatory infiltrates causing interstitial **oedema**, **tubular cell injury** and **compromised tubular flow**, or from frank **tubular obstruction** by casts, cellular debris or crystals; capsular distension may produce **flank pain**.
- ▶ **Drug-induced ATIN** is a **T-cell-mediated delayed (Type IV) hypersensitivity reaction** — drugs act as **haptens/pro-haptens**, bind tubular basement membrane (TBM) proteins or generate neoantigens (molecular mimicry). It is most often a **Type IVb** reaction (IL-5 driven, tissue/blood eosinophilia); NSAID-induced disease lacks eosinophils. The infiltrate is **>80% T lymphocytes** (CD4⁺ and CD8⁺) with macrophages and eosinophils, plus **tubulitis** (lymphocytes crossing the TBM).
- ▶ **Chronic** disease shows interstitial fibrosis, patchy mononuclear infiltrate, widespread **tubular atrophy**, luminal dilation and **TBM thickening**. Mechanisms of fibrosis include chronic **hypoxia** (peritubular capillary rarefaction), proteinuria-induced proximal tubular injury, persistent inflammation and epithelial–mesenchymal transition (TGF- β driven).
- ▶ Because the chronic histology is non-specific, **diagnosis relies on history, drug/toxin exposure and imaging** more than biopsy.

Acute Interstitial Nephritis — clinical features, diagnosis, treatment

- ▶ First described by **Councilman (1897)** in scarlet fever and diphtheria; today it is most often an **allergic drug reaction**, accounting for ~10–15% of intrinsic AKI. Drugs cause >70% of cases (top classes: antibiotics ~49%, PPIs ~14%, NSAIDs ~11%; commonest single drugs — omeprazole, amoxicillin, ciprofloxacin).

- ▶ **Classic triad** — fever, rash and (peripheral) eosinophilia with oliguric AKI ~7–10 days after a β -lactam — is the **exception (only ~5–15%)**, and is commonest with β -lactams/sulfonamides. Latency is long and “silent” with PPIs (~11 weeks) and NSAIDs (6–18 months, often with heavy/nephrotic proteinuria $\pm$ minimal-change or membranous lesion). Rifampin-induced AIN is dose-dependent, antibody-mediated and severe on re-exposure.
- ▶ **Urinalysis**: sterile pyuria, WBC casts, microscopic haematuria and low-grade tubular proteinuria (<1–2 g/day). Urinary eosinophils are **NEITHER sensitive nor specific and are no longer recommended**. Eosinophilia, raised ESR/CRP and IgE are supportive but inconsistent.
- ▶ **Kidney biopsy is the gold standard** (interstitial inflammation + tubulitis $\pm$ eosinophils $\pm$ granuloma). Ancillary: $^{67}\text{Gallium}$ / FDG-PET show enhanced renal uptake; ultrasound shows enlarged echogenic kidneys (non-specific).
- ▶ **Treatment** — **withdraw the offending agent** (often reversible) and give supportive care; **up to one-third require temporary dialysis**. Glucocorticoids are added if there is no recovery within ~5–7 days, severe AKI/impending dialysis, or diffuse infiltrate — efficacy falls if started >1–2 weeks after onset. Regimen: IV methylprednisolone 250–500 mg/day for 1–4 days or prednisone ~1 mg/kg (60 mg/day) for 4–6 weeks with taper. *Absolute* steroid indications: Sjögren’s, sarcoidosis, SLE interstitial nephritis, adult TINU, IgG4-related and granulomatous/idiopathic IN.
- ▶ **Immune-mediated subtypes**: TINU (<5% of AIN; female 3:1; median age 15 yr; painful bilateral anterior uveitis $\pm$ Fanconi, raised ESR); Sjögren’s (anti-Ro/La, distal RTA, nephrogenic DI); sarcoidosis (non-caseating granulomas, hypercalcaemia — *exclude TB first*); IgG4-related disease (IgG4⁺ plasma cells, storiform fibrosis; with autoimmune pancreatitis, sclerosing cholangitis, retroperitoneal fibrosis); checkpoint-inhibitor AIN (kidney affected in ~2% monotherapy, up to 5% dual therapy; onset usually 2–3 months).
- ▶ **Crystal/obstructive tubulopathies**: sulfadiazine (“sheaf-of-wheat” crystals), indinavir/atazanavir (needle crystals), acyclovir (red-green birefringent needles); **acute urate nephropathy** (tumour-lysis — treat with rasburicase/dialysis, prophylactic allopurinol); acute phosphate nephropathy (oral Phosphosoda). **Light-chain cast nephropathy** (“myeloma kidney”) — filtered monoclonal light chains (Bence-Jones) aggregate with Tamm-Horsfall protein in distal tubules forming obstructing casts with giant-cell reaction; clues are anaemia, bone pain, hypercalcaemia and a narrow anion gap.

Chronic Tubulointerstitial Nephritis — key entities

Entity	Key features
Analgesic nephropathy	Chronic compound analgesics (phenacetin — banned in US since 1983; ≥ 6 tablets/day for >3 yr); papillary necrosis; small scarred kidneys with

Entity	Key features
	papillary calcifications; F:M 5–7:1; risk of urothelial malignancy (8–10%)
Aristolochic acid nephropathy	<i>Chinese-herb</i> + <i>Balkan endemic</i> nephropathy; <i>Aristolochia</i> species; aristolactam-DNA adducts, A:T→T:A transversions; bland sediment, severe anaemia; high upper-tract urothelial cancer risk
Lithium nephropathy	Nephrogenic diabetes insipidus (enters principal cells via ENaC, inhibits GSK-3β, downregulates aquaporin-2); chronic TIN after >10–20 yr; distal-tubule microcysts; amiloride for NDI
Calcineurin inhibitor (cyclosporine/tacrolimus)	“Striped” interstitial fibrosis, arteriolar hyalinosis, hyperkalaemia (aldosterone resistance)
Heavy-metal (lead) nephropathy	Triad of “saturnine gout,” hypertension and renal impairment; chelation may slow decline
Reflux nephropathy	VUR in childhood (old “chronic pyelonephritis”); secondary FSGS; asymmetric small scarred kidneys; ACEI/ARB/SGLT2 inhibitor for proteinuria
ADTKD	Autosomal dominant; genes <i>UMOD</i> , <i>MUC1</i> , <i>REN</i> , <i>HNF1β</i> ; bland sediment, <i>UMOD</i> form → early gout/hyperuricaemia (median ESKD ~54 yr)
Metabolic	Hypercalcaemic (nephrocalcinosis, concentrating defect), gouty/uric-acid, hypokalaemic, hyperoxaluric nephropathy
CINAC / CKDu	Young male agricultural workers — Mesoamerican, Sri Lankan, Uddanam (S. India) nephropathy; heat/dehydration ± agrochemicals

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- Schematic of the nephron in tubulointerstitial disease — label: glomerulus (relatively spared), proximal tubule (Fanconi: glycosuria, phosphaturia, aminoaciduria, type II RTA), distal tubule/collecting duct (type IV RTA, distal RTA, nephrogenic DI), interstitial inflammatory infiltrate + oedema (acute) vs interstitial fibrosis + tubular atrophy + thickened TBM (chronic), and tubulitis (lymphocytes crossing TBM).
- Treatment algorithm for AIN — label: AKI with features of AIN → withdraw offending agent → supportive care/observe → improvement (continue) OR no improvement in 1 week / rapid progression → corticosteroids; renal biopsy → classic AIN / granulomatous IN → steroids ± immunosuppressives; fibrosis → conservative.

Clinical / Diagnostic significance

- ▶ Suspect TIN in otherwise unexplained AKI/CKD with a bland or mildly active sediment, low-grade tubular proteinuria, and tubular dysfunction — polyuria (nephrogenic DI), Fanconi syndrome, type II or type IV RTA, and a serum uric acid that is lower than expected for the GFR.
- ▶ Type IV (hyperkalaemic, hyperchloraemic) RTA out of proportion to renal failure is a classic pointer to tubulointerstitial injury.
- ▶ Papillary necrosis (mnemonic) — Analgesics, Sick cell, Diabetes with UTI, prolonged NSAIDs (and obstruction/pyelonephritis); presents with flank pain, haematuria and ureteric colic from a sloughed papilla.
- ▶ Aristolochic acid and analgesic nephropathy carry a high urothelial-cancer risk — warrant surveillance (urine cytology, CT, ureteroscopy).
- ▶ Prognosis of drug-induced AIN: full recovery ~64%, partial ~23%, and ~12% progress to CKD/dialysis — early drug withdrawal (<2 weeks) is the strongest determinant of recovery.

High-yield exam pointers

- ▶ TIN = primary tubular + interstitial disease, glomeruli/vessels spared; acute vs chronic; final common pathway = interstitial fibrosis + tubular atrophy.
- ▶ Drugs cause >70% of AIN; antibiotics > PPIs > NSAIDs; mechanism = Type IV (delayed) hypersensitivity.
- ▶ Classic triad (fever + rash + eosinophilia) seen in only 5–15% — its absence does NOT exclude AIN; NSAIDs/PPIs give “silent” AIN.
- ▶ Urinary eosinophils are obsolete; kidney biopsy is the gold standard (tubulitis).
- ▶ Treatment = stop drug + supportive care ± steroids (IV methylprednisolone 0.25–0.5 g/day × 1–4 days, or prednisone 60 mg/day × 4–6 weeks); start early.
- ▶ TINU — adolescent girls, anterior uveitis, raised ESR; Sjögren’s — distal RTA + anti-Ro/La; sarcoid — granulomatous + hypercalcaemia (rule out TB); IgG4 — storiform fibrosis.
- ▶ Chronic toxins — analgesic (phenacetin, papillary necrosis), aristolochic acid (urothelial cancer), lithium (NDI), CNI (striped fibrosis), lead (saturnine gout).
- ▶ ADTKD genes — UMOD, MUC1, REN, HNF1β; CINAC/CKDu in agricultural communities (Uddanam, Mesoamerican, Sri Lankan).

Rheumatology & immune system

ANCA-associated vasculitis

Asked in: Paper III Nov 2019 — RGUHS MD General Medicine

Definition / Introduction — ANCA-associated vasculitis (AAV) is a group of necrotising, predominantly small-vessel vasculitides that share a paucity of vascular immunoglobulin deposition (*pauci-immune*) and an association with circulating **antineutrophil cytoplasmic antibodies (ANCA)**. Three clinicopathologically distinct entities are grouped under AAV: **granulomatosis with polyangiitis (GPA, formerly Wegener)**, **microscopic polyangiitis (MPA)** and **eosinophilic granulomatosis with polyangiitis (EGPA, formerly Churg-Strauss)**. Although they share ANCA positivity and small-vessel injury, each has a unique phenotype and is treated as a separate disease.

Classification, nomenclature & ANCA serology

- ▶ The 1992/2012 Chapel Hill Consensus Conference nomenclature places GPA, MPA and EGPA among the **predominantly small-vessel vasculitides** (with frequent overlap into medium vessels); not all cases are ANCA-positive.
- ▶ ANCA are autoantibodies directed against proteins in the cytoplasmic granules of neutrophils and monocytes; two patterns are recognised on indirect immunofluorescence (IIF):
- ▶ **c-ANCA (cytoplasmic, granular pattern)** — major antigen is **proteinase-3 (PR3)**, a 29-kDa neutral serine proteinase of azurophilic granules. >90% of *active* GPA cases have anti-PR3.
- ▶ **p-ANCA (perinuclear pattern)** — major antigen is **myeloperoxidase (MPO)**; predominant in MPA and EGPA. Other targets (elastase, cathepsin G, lactoferrin, lysozyme) give a p-ANCA pattern but only anti-MPO is convincingly vasculitis-associated.
- ▶ Every positive IIF must be **confirmed by antigen-specific enzyme immunoassay** for PR3 or MPO.
- ▶ A non-MPO p-ANCA may occur in IBD, autoimmune disease, drugs, endocarditis and cystic-fibrosis airway infection (false positives).

Pathogenesis

- ▶ PR3 and MPO normally reside inside resting neutrophil/monocyte granules, inaccessible to serum antibody.
- ▶ **Priming by TNF- α or IL-1** (or alternative-complement activation) translocates PR3/MPO to the cell surface, where ANCA bind.
- ▶ ANCA engagement causes neutrophil **degranulation, reactive oxygen species production, adhesion to and killing of endothelial cells**, and release of IL-1 and IL-8 $\rightarrow$ necrotising vascular injury. Adoptive-transfer experiments in mice support a direct pathogenic role of ANCA.
- ▶ Caveats against ANCA being solely causal: disease can occur ANCA-negative, titre correlates poorly with activity, and high titres may persist in remission.
- ▶ In GPA, an **aberrant TH1 cytokine pattern** ($\uparrow$ IFN- γ , $\uparrow$ TNF- α , $\uparrow$ IL-12) and the airway-centred granulomatous reaction suggest a cell-mediated response to an inhaled/mucosal antigen; chronic nasal *Staphylococcus aureus* carriage is linked to higher relapse rates.

The three AAV entities compared

Feature	GPA (Wegener)	MPA	EGPA (Churg-Strauss)
Epidemiology	Prevalence ~3/100,000; incidence ~12/million/yr; mean age 40–60; M:F 1:1; rare in blacks	Incidence 3–5/100,000; mean age ~57; M slightly > F	Incidence 1–3/million; mean age 48; F:M 1.2:1
Histology	Necrotising granulomatous vasculitis of small arteries & veins	Necrotising vasculitis, no granuloma , few/no immune deposits	Necrotising vasculitis + extravascular eosinophilic granuloma , tissue/blood eosinophilia
Upper airway	Sinusitis, nasal ulcer/septal perforation, saddle-nose , subglottic stenosis (~16%)	Typically absent (if present, suspect GPA)	Allergic rhinitis, nasal polyposis, sinusitis
Lung	Nodular/cavitary infiltrates; alveolar haemorrhage	Pulmonary capillaritis , alveolar haemorrhage (12%)	Asthma , fleeting eosinophilic infiltrates
Kidney	Pauci-immune crescentic GN (~77%)	Crescentic GN very common ($\geq$ 79%)	Less common than GPA/MPA
Cardiac	~8%	Uncommon	Myocarditis ~14% — leading cause of death (39%)

Feature	GPA (Wegener)	MPA	EGPA (Churg-Strauss)
ANCA	~90% PR3 (c-ANCA); 10–25% MPO; up to 20% none	~75% MPO (p-ANCA)	<50% positive, usually MPO

Clinical features

- ▶ **GPA (organ frequency through course):** upper airway 95%, ENT 92%, lung 85–90%, kidney 77%, eye 52% (episcleritis, scleritis, granulomatous sclerouveitis, retro-orbital pseudotumour → proptosis), skin 46% (palpable purpura, nodules, ulcers), CNS/PNS 23% (cranial neuritis, **mononeuritis multiplex**), cardiac 8% (pericarditis). **Venous thromboembolism** is notably increased. Renal disease, once clinically apparent, tends to progress rapidly.
- ▶ **MPA: the most common cause of pulmonary-renal syndrome** (diffuse alveolar haemorrhage + rapidly progressive GN), several-fold commoner than anti-GBM disease; palpable purpura, mononeuritis multiplex; may show UIP-like interstitial fibrosis (poor prognosis). **Drug-induced MPA** (high-titre p-ANCA) — *propylthiouracil, hydralazine, allopurinol, penicillamine, minocycline, sulfasalazine*.
- ▶ **EGPA (three classic phases):** prodromal **asthma/allergic rhinitis** → blood and tissue **eosinophilia** (>1000/μL in >80%) → systemic **vasculitis**. Mononeuritis multiplex in up to 72%; purpura and subcutaneous nodules in ~51%; cardiac involvement is the chief cause of death — echocardiography in all new cases.

Investigations & Diagnosis

- ▶ **Bloods/urine:** raised ESR/CRP, normocytic anaemia, leukocytosis, thrombocytosis; eosinophilia in EGPA. Urinalysis for dysmorphic RBCs, **RBC casts**, proteinuria signals GN.
- ▶ **ANCA:** IIF screen (c-/p-ANCA) confirmed by PR3/MPO EIA. Predictive value of a positive ANCA is ~90% with **active glomerulonephritis**, but falls to 30–60% in sinus/lung-limited disease — so **tissue biopsy is usually required**, especially when ANCA-negative or features are atypical (to exclude infection/malignancy).
- ▶ **Biopsy:** lung gives the highest yield in GPA (necrotising granulomatous vasculitis); renal biopsy shows **pauci-immune segmental necrotising crescentic glomerulonephritis** (relative absence of IgG/IgM/IgA/complement) — the hallmark common to all AAV.
- ▶ **Imaging:** chest CT (more sensitive than CXR) — nodules, masses, cavities, ground-glass of haemorrhage; sinus imaging may show bony erosion.
- ▶ In EGPA, work up unexplained eosinophilia: ANCA, serum tryptase, flow cytometry/PDGFR for eosinophilic leukaemia, and helminth serology.

Treatment

- ▶ Management has two phases — **induction of remission** then **maintenance** — stratified by severity. **Severe = organ- or life-threatening** (e.g. RPGN, alveolar haemorrhage); **active glomerulonephritis is always classed as severe** even with normal creatinine.
- ▶ **Induction (severe GPA/MPA)**: glucocorticoid (historically **prednisone 1 mg/kg/day**; a *reduced-dose regimen is non-inferior with fewer infections*) **plus either**:
 - **Cyclophosphamide** 2 mg/kg/day orally (or IV pulse 15 mg/kg every 2 wk ×3 then every 3 wk), renally dose-adjusted; switch off at **3–6 months**, or
 - **Rituximab** (anti-CD20) **375 mg/m² weekly × 4** — as effective as cyclophosphamide (superior in relapsing disease) and preferred for PR3-positive and relapsing patients, avoiding bladder toxicity/infertility.
- ▶ **Avacopan** (oral C5a-receptor inhibitor) is an add-on that allows rapid glucocorticoid withdrawal, achieving higher sustained remission than prednisone alongside cyclophosphamide or rituximab.
- ▶ **Fulminant disease**: IV **methylprednisolone 1000 mg/day × 3 days**.
- ▶ **Plasma exchange (PLEX)**: the PEXIVAS trial showed no benefit on the composite of ESRD/death; reserve for coexisting **anti-GBM antibody** or selected fulminant cases. Separate PLEX from rituximab by ≥48 h.
- ▶ **Maintenance**: after cyclophosphamide induction, switch to **rituximab (preferred, lower relapse)**, **azathioprine 2 mg/kg/day**, **methotrexate 20–25 mg/week**, or **mycophenolate mofetil**; continue ≥2 years.
- ▶ **Non-severe disease**: methotrexate or MMF with glucocorticoid; cyclophosphamide is rarely justified.
- ▶ **EGPA**: glucocorticoids are first-line; cyclophosphamide (then azathioprine/methotrexate) for fulminant/cardiac or ANCA-positive GN; **mepolizumab (anti-IL-5) 300 mg SC monthly** for relapsing/refractory non-severe disease (benralizumab non-inferior).
- ▶ **Supportive**: **Pneumocystis jirovecii prophylaxis with trimethoprim-sulfamethoxazole** during cyclophosphamide/rituximab therapy; agents shown *ineffective/harmful* — etanercept, belimumab, abatacept.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **ANCA immunofluorescence patterns** — two neutrophils side by side: (1) *c*-ANCA with diffuse granular **cytoplasmic** staining labelled “anti-PR3”; (2) *p*-ANCA with **perinuclear** staining labelled “anti-MPO”; label the **nucleus** in each.
- ▶ **ANCA pathogenesis cascade** — boxes/arrows: *resting neutrophil* → *priming by TNF-α/IL-1* → *PR3/MPO translocate to cell membrane* → *ANCA binding* → *degranulation + reactive oxygen species + IL-8* → *endothelial injury* → *necrotising small-vessel (pauci-immune)*

vasculitis. Optionally a glomerulus with a **crescent** labelled “pauci-immune crescentic GN”.

Clinical / Diagnostic significance

- ▶ AAV is the commonest cause of **pulmonary-renal syndrome**; recognise the triad of haemoptysis (alveolar haemorrhage), RPGN and ANCA positivity for urgent immunosuppression.
- ▶ ANCA **serotype (PR3 vs MPO)** increasingly guides prognosis/relapse risk better than the clinical label — PR3/c-ANCA disease relapses more and favours rituximab.
- ▶ **Saddle-nose deformity, subglottic stenosis and cavitary lung nodules** strongly suggest GPA; **cocaine/levamisole midline destruction** and NK/T-cell lymphoma are key mimics (biopsy mandatory before irradiation is ever considered).
- ▶ Untreated GPA is fatal within months; cyclophosphamide-based regimens transformed outcomes (remission ~75%, 5-yr survival >80%).

High-yield exam pointers

- ▶ AAV triad = GPA, MPA, EGPA — all **pauci-immune** small-vessel vasculitis.
- ▶ **c-ANCA = anti-PR3** ≈ GPA; **p-ANCA = anti-MPO** ≈ MPA/EGPA.
- ▶ GPA classic triad: **upper + lower respiratory tract + glomerulonephritis**; saddle nose, subglottic stenosis, increased VTE.
- ▶ MPA = **commonest pulmonary-renal syndrome**, no granuloma, no upper-airway disease; drug-induced by PTU/hydralazine/minocycline.
- ▶ EGPA = **asthma + eosinophilia (>1000/ μ L) + vasculitis**; **cardiac involvement = leading cause of death**; ANCA positive in <50%.
- ▶ Renal lesion = **pauci-immune crescentic necrotising glomerulonephritis**.
- ▶ Induction = **glucocorticoid + (rituximab or cyclophosphamide) $\pm$ avacopan**; maintenance = rituximab/azathioprine/MTX/MMF.
- ▶ **PEXIVAS**: routine plasma exchange offers no benefit (except anti-GBM overlap); **TMP-SMX** for PJP prophylaxis.
- ▶ **Mepolizumab (anti-IL-5)** for relapsing non-severe EGPA; **avacopan = C5a-receptor inhibitor**, steroid-sparing.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “The Vasculitis Syndromes” (ANCA biology and pathogenesis; GPA, MPA, EGPA definitions, organ-frequency data, induction/maintenance regimens, avacopan, PEXIVAS, mepolizumab/benralizumab).

Ankylosing spondylitis

Asked in: Paper III Dec 2023 — RGUHS MD General Medicine

Definition / Introduction — Ankylosing spondylitis (AS) is the radiographic form of **axial spondyloarthritis (r-axSpA)**, a chronic immune-mediated inflammatory disorder predominantly involving the **sacroiliac joints and spine**. It is characterized by inflammatory back pain, sacroiliitis, progressive loss of spinal mobility, enthesitis, and extra-articular disease such as acute anterior uveitis, psoriasis, and inflammatory bowel disease (IBD). Pathologically, it is distinctive because inflammation-induced bone loss coexists with pathologic new bone formation, culminating in syndesmophytes and, rarely, a complete “bamboo spine.”

Nomenclature and epidemiology

- **Spondyloarthritis (SpA)** is a family of seronegative immune-mediated arthritides sharing sacroiliitis, inflammatory spinal lesions, peripheral arthritis, enthesitis, dactylitis, uveitis, psoriasis, IBD, familial clustering, and **HLA-B27** association.
- The 2009 ASAS approach divides SpA into **axial SpA** and **peripheral SpA**. Axial SpA is further divided into **radiographic axSpA**, historically called AS, and **nonradiographic axSpA**, based on whether definite sacroiliitis is visible on plain radiographs.
- **Modified New York radiographic threshold:** definite sacroiliitis means **bilateral grade ≥ 2** or **unilateral grade 3-4** sacroiliitis; definite AS requires at least one clinical criterion plus this radiographic criterion.
- Usual onset is before **40-45 years**, commonly in the **20s-30s**. r-axSpA has an approximate male:female ratio of **2:1**, whereas nr-axSpA is closer to **1:1**.
- **HLA-B27** is the strongest genetic association: Harrison notes positivity in **85-90%** of r-axSpA and **50-90%** of nr-axSpA. The risk of axSpA is about **5%** in HLA-B27-positive persons and rises to about **20%** in HLA-B27-positive first-degree relatives of affected patients.

Pathogenesis

- Disease begins in genetically predisposed individuals through interaction of **HLA-B27**, other MHC/non-MHC genes, mucosal immune triggers, mechanical stress, and cytokine pathways.

- ▶ Proposed HLA-B27 mechanisms include **arthritogenic peptide presentation**, HLA-B27 homodimer interaction with innate immune receptors, and unfolded protein response/autophagy links; no single theory fully explains disease.
- ▶ The **gut-joint axis** is important: intestinal dysbiosis, barrier dysfunction, and microbial peptide translocation may drive immune activation; subclinical gut inflammation is common in axSpA.
- ▶ **Entheses** are key target tissues. Mechanical strain produces microdamage; in SpA this response becomes amplified and prolonged, promoting chronic enthesitis.
- ▶ Signature inflammatory pathways include **TNF** and **IL-17**. Chronic enthesial inflammation promotes osteoblast differentiation and pathologic new bone formation, leading to bony spurs, syndesmophytes, sacroiliac ankylosis, and spinal fusion.

Clinical features

- ▶ **Inflammatory back pain:** insidious chronic low back, hip, or alternating buttock pain for >3 months; onset <45 years; worse in the second half of the night; improves after getting up, exercise, or activity; not relieved by rest; morning stiffness usually >30 minutes.
- ▶ **Axial progression:** limitation of lumbar, thoracic, and cervical mobility; flattening of lumbar lordosis, exaggerated thoracic kyphosis, reduced chest expansion from costovertebral involvement, and fixed deformity in advanced disease.
- ▶ **Peripheral disease:** peripheral arthritis occurs in about **30-40%** in Harrison and may be transient or persistent in CMDT; it is typically asymmetric oligoarthritis of large lower-limb joints. Hip involvement causes groin pain radiating to the medial thigh or knee and predicts greater functional loss.
- ▶ **Enthesitis:** heel pain from Achilles insertion or plantar fasciitis, chest wall pain, intercostal insertions, epicondylitis, quadriceps/patellar tendon insertion pain, or pelvic rim pain. Dactylitis is uncommon in pure axSpA.
- ▶ **Extra-musculoskeletal disease:** acute anterior uveitis is the commonest; it is typically **acute, anterior, unilateral, episodic**, with eye discomfort, redness, pain, photophobia, and miosis. IBD occurs in about **10%**, histologic subclinical gut inflammation in up to **50%**, and psoriasis in about **10%**.
- ▶ **Systemic and late features:** fatigue, anemia of chronic inflammation, osteoporosis, vertebral fractures, conduction disease, aortic valve insufficiency, apical pulmonary fibrosis, restrictive chest disease, IgA nephropathy, renal AA amyloidosis, and rare cauda equina syndrome.

Diagnosis and investigations

- ▶ Diagnosis is by **pattern recognition**: chronic back pain >3 months with onset <45 years, inflammatory features, SpA features, supportive imaging/laboratory data, and exclusion of common mimics.

- ▶ **Important SpA features** to actively seek: inflammatory arthritis, enthesitis, dactylitis, acute anterior uveitis, psoriasis, IBD, family history of SpA, good response to full-dose NSAIDs, and elevated CRP.
- ▶ **Laboratory tests:** ESR/CRP support active disease but are neither sensitive nor specific; Harrison notes elevation in only 30-40% of active axSpA. Rheumatoid factor and anti-CCP are negative. HLA-B27 is not diagnostic alone and is most useful when pre-test probability is intermediate.
- ▶ **Plain radiography:** a single AP pelvis or Ferguson view is sufficient for sacroiliac joints. Sacroiliitis shows sclerosis, erosions, joint-space narrowing/widening, and late fusion. Spine films may show **Romanus lesions/shiny corner sign**, vertebral squaring, **Andersson lesion**, vertical syndesmophytes, and bamboo spine.
- ▶ **MRI SI joints/spine:** useful in early disease when x-ray is negative. STIR/T2 fat-suppressed sequences show active bone marrow edema or osteitis; T1 images show structural lesions such as erosions, fat metaplasia, backfill, sclerosis, and new bone. MRI can overdiagnose disease in athletes, postpartum women, degenerative disease, and older adults.

Modified New York criteria for AS	Key points
Clinical criterion 1	Low back pain >3 months, improved by exercise and not relieved by rest
Clinical criterion 2	Limitation of lumbar motion in frontal and lateral planes
Clinical criterion 3	Reduced chest expansion
Radiographic criterion	Bilateral grade ≥ 2 sacroiliitis, or unilateral/bilateral grade 3-4 sacroiliitis
Definite AS	≥ 1 clinical criterion plus radiographic criterion

Differential diagnosis

- ▶ **Mechanical low back pain, disk disease, degenerative arthritis:** commoner than AS; mechanical pain worsens with activity and improves with rest.
- ▶ **Rheumatoid arthritis:** symmetric small-joint disease; RF/anti-CCP often positive; sacroiliac joints are spared and spinal disease is mainly cervical.
- ▶ **Psoriatic/reactive/IBD-associated SpA:** may mimic AS; psoriatic and reactive sacroiliitis is often asymmetric or unilateral, whereas AS is usually bilateral and symmetric.
- ▶ **DISH:** older obese/diabetic men; bulky flowing osteophytes and longitudinal ligament ossification with normal SI joints, mistaken for bamboo spine.
- ▶ **Osteitis condensans ilii:** triangular sclerosis on the iliac side of SI joints, usually postpartum; absence of erosions favors OCI over sacroiliitis.

- ▶ **Do not miss red flags:** fever, weight loss, advanced age, malignancy history, osteoporotic fracture, osteomyelitis, spinal tuberculosis/brucellosis/fungal infection, malignancy, fibromyalgia, hypermobility, hypothyroidism, and vitamin D deficiency.

Management

- ▶ **Targets:** remission or low disease activity, preservation of posture/mobility, prevention of structural damage, and control of extra-articular disease.
- ▶ **Nonpharmacologic:** patient education, active land/aquatic physical therapy, daily posture and spinal extension exercises, safe aerobic/resistance exercise, chest expansion exercises, smoking cessation, fall/fracture prevention, and cardiovascular risk reduction.
- ▶ **NSAIDs:** first-line; use the highest tolerated dose in active disease and as needed when stable. No specific NSAID is preferred. Monitor gastric ulcer/bleeding, hypertension, renal insufficiency, and cardiovascular risk.
- ▶ **csDMARDs:** sulfasalazine up to 3 g/day and methotrexate up to 25 mg/week may help peripheral arthritis/enthesitis but are **not effective for axial spinal or SI disease**.
- ▶ **Escalation:** if active disease persists after a **4-week full-dose NSAID trial**, start a biologic, usually **TNF inhibitor** or **IL-17 inhibitor**. Screen for latent tuberculosis, hepatitis B, and hepatitis C before biologic or JAK inhibitor therapy.
- ▶ **Biologic/targeted options:** etanercept 50 mg SC weekly; adalimumab 40 mg SC every 2 weeks; certolizumab 200 mg SC twice monthly or 400 mg monthly; golimumab 50 mg SC monthly or IV 2 mg/kg at weeks 0 and 4 then every 8 weeks; infliximab 5 mg/kg IV at weeks 0, 2, 6 then every 6 weeks. IL-17 inhibitors include secukinumab 150 mg SC weekly for 5 loading doses then every 4 weeks, and ixekizumab 160 mg once then 80 mg every 4 weeks. JAK inhibitors include tofacitinib 5 mg twice daily for AS and upadacitinib 15 mg daily for AS/nr-axSpA.
- ▶ **Choosing agents:** monoclonal TNF inhibitors are preferred over etanercept when uveitis or IBD coexists. IL-17 blockade is effective in axSpA but should be avoided in active IBD. JAK inhibitors are generally reserved after TNF inhibitor failure and require caution in older patients, smokers, cardiovascular disease, and malignancy risk.
- ▶ **Avoid:** systemic glucocorticoids for axial disease. Local glucocorticoid injections may be used for peripheral arthritis or selected upper-limb enthesitis; avoid injections around lower-limb weight-bearing entheses because of rupture risk.
- ▶ **Surgery:** total hip arthroplasty for refractory painful structurally damaged hips; spinal osteotomy only for severe fixed kyphosis impairing horizontal vision and only in expert centers.

Complications and prognosis

- ▶ Osteoporosis is common; Harrison gives about **25%** after 10 years of axSpA and vertebral fractures in about **10%** of AS patients, often in the lower cervical spine with neurologic risk.

- ▶ Disease course is variable. Harrison notes nearly **50%** may progress from nonradiographic to radiographic axSpA over 20 years, but **<10%** progress to extensive spinal bamboo spine.
- ▶ Risk factors for osteoproliferation include male sex, persistent MRI inflammation, high CRP, syndesmophytes, HLA-B27 positivity, and smoking.
- ▶ CMDT notes most patients have persistent symptoms over decades, rare long-term remissions, about **10%** work disability after 10 years, and worse prognosis with hip disease within the first 2 years.
- ▶ Biologic therapy improves symptoms and quality of life and may slow radiographic progression, but patients need monitoring for infections, tuberculosis reactivation, zoster with JAK inhibitors, Candida with IL-17 inhibitors, and drug-specific adverse effects.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **AP pelvis and lateral spine in AS:** label bilateral sacroiliac erosions, sclerosis, joint-space narrowing, SI ankylosis, squared vertebral bodies, vertical marginal syndesmophytes, fused facet joints, and bamboo spine.
- ▶ **Diagnostic flowchart for chronic inflammatory back pain:** label chronic back pain >3 months with onset <45 years, rule out mechanical back pain/fibromyalgia, SI joint x-ray, definite sacroiliitis = AS/r-axSpA, if x-ray negative assess SpA features, MRI SI joints, HLA-B27, nr-axSpA versus not axSpA.

Clinical / Diagnostic significance

- ▶ AS should be suspected in any young adult with chronic back or buttock pain that improves with exercise and worsens with rest, especially with uveitis, heel pain, psoriasis, IBD, family history, or excellent NSAID response.
- ▶ A positive HLA-B27 supports but does not diagnose AS; a negative result does not exclude disease in nonwhite populations or in a compelling clinical picture.
- ▶ MRI is powerful for early nr-axSpA but must be interpreted with clinical probability because mechanical stress and postpartum SI changes can mimic osteitis.
- ▶ New severe neck/back pain in established AS is a fracture until proved otherwise; ankylosed osteoporotic spines fracture with relatively minor trauma.
- ▶ Uveitis symptoms require urgent ophthalmology referral; active IBD changes biologic selection.

High-yield exam pointers

- ▶ AS = **radiographic axial spondyloarthritis**; nr-axSpA has similar symptoms but lacks definite x-ray sacroiliitis.
- ▶ Classic triad to write: **inflammatory back pain + bilateral sacroiliitis + HLA-B27 association**.
- ▶ Modified New York: **≥1 clinical criterion + radiographic sacroiliitis**.

- ▶ Inflammatory back pain: onset <45 years, >3 months, morning stiffness, night pain, improves with exercise, not rest.
- ▶ Commonest extra-articular manifestation: **acute anterior uveitis**.
- ▶ First-line treatment: **exercise/physical therapy plus NSAIDs**.
- ▶ csDMARDs do not treat axial disease; use them only for peripheral arthritis/enthesitis.
- ▶ NSAID failure after adequate trial: escalate to **TNF inhibitor or IL-17 inhibitor**; monoclonal TNF inhibitor if uveitis/IBD.
- ▶ Late complications: bamboo spine, vertebral fracture, aortic regurgitation/conduction block, apical fibrosis, IgA nephropathy, AA amyloidosis, and cauda equina syndrome.

Approach to a patient with non-traumatic monoarthritis

Asked in: Paper III May 2025 — RGUHS MD General Medicine

Definition / Introduction — Monoarthritis is inflammation confined to a *single joint* (≤ 1 joint), distinguished from *oligo/pauciarticular* (2–3 joints) and *polyarticular* (≥ 4 joints) disease. **Acute non-traumatic monoarthritis** is a medical emergency because it harbours three time-critical “red flag” diagnoses — **septic arthritis**, **acute crystal arthritis (gout/pseudogout)** and **(occult) fracture** — and untreated bacterial infection destroys articular cartilage within 48 hours. The cornerstone of evaluation is a structured history and examination followed by **arthrocentesis with synovial fluid analysis**, which is *always indicated* in acute monoarthritis.

Diagnostic framework — the four screening questions

The musculoskeletal complaint is characterised by answering four questions (Cush/Harrison), which narrow the differential:

- ▶ **Articular or non-articular?** Articular pain is deep/diffuse, limits *active and passive* range, with swelling, crepitus or deformity. Periarticular lesions (bursitis, tendinitis, cellulitis) give point tenderness, pain on *active but not passive* motion and less-than-circumferential swelling — these *masquerade* as arthritis.
- ▶ **Inflammatory or non-inflammatory?** Inflammation = the cardinal signs (warmth, erythema, swelling, pain), prolonged morning stiffness (hours), systemic features (fever, rash) and raised ESR/CRP.

- ▶ **Acute (≤ 6 weeks) or chronic (> 6 weeks)?** Acute monoarthritis is usually infective, crystal-induced or reactive; chronic monoarthritis suggests mycobacterial/fungal infection, or initial presentation of a chronic arthropathy.
- ▶ **How many / which joints?** Confirms it is truly monoarticular and not the first joint of an evolving oligo/polyarthritis.

Causes / Differential diagnosis of non-traumatic monoarthritis

Acute monoarthritis	Chronic monoarthritis (> 6 wk)
Septic (non-gonococcal): <i>S. aureus</i> (incl. MRSA), group B/A streptococci, gram-negative bacilli	<i>Mycobacterium tuberculosis</i> (chronic granulomatous monoarthritis)
Gonococcal arthritis (<i>N. gonorrhoeae</i> — DGI)	Non-tuberculous mycobacteria (<i>M. marinum</i> , MAC)
Crystal: gout (monosodium urate), pseudogout (CPPD)	Fungal: <i>Candida</i> , <i>Sporothrix schenckii</i> , <i>Coccidioides</i> , <i>Blastomyces</i> , <i>Histoplasma</i>
Reactive arthritis (initial), Lyme arthritis (knee)	<i>Brucella</i> , <i>Treponema pallidum</i> (syphilis)
Haemarthrosis (anticoagulant/coagulopathy)	Monoarticular RA / pauciarticular JIA; psoriatic arthritis
Initial monoarticular presentation of RA, psoriatic, SpA	Osteoarthritis, osteonecrosis, Charcot (neuropathic) joint
Avascular necrosis, sickle-cell flare	Pigmented villonodular synovitis, foreign-body synovitis, tumour

- ▶ *Monoarticular and oligoarticular conditions share similar aetiologies* — crystal and infective arthritis are typically mono/oligoarticular, whereas RA and OA are usually polyarticular.
- ▶ **Crystal arthritis and septic arthritis can coexist in the same joint** — finding crystals does *not* exclude infection.

Clinical evaluation — history and examination

- ▶ **Patient profile:** young adults — gonococcal and reactive arthritis; men — gout, spondyloarthritis; elderly — pseudogout, septic arthritis, gout; women, menses/pregnancy — disseminated gonococcal infection (DGI).
- ▶ **Onset/evolution:** *abrupt* (hours, often nocturnal) onset is typical of **septic arthritis and gout**; indolent over weeks–months suggests TB/fungal. Intermittent self-resolving attacks suggest crystal or Lyme arthritis.
- ▶ **Risk factors for sepsis:** pre-existing joint damage (RA), prosthetic joint, IV drug use, diabetes, advanced CKD, alcohol/cirrhosis, immunosuppression/biologics (TNF inhibitors), skin breach (ulcer, psoriasis).

- ▶ **Precipitants of crystal flare:** purine-rich food, alcohol/beer, diuretics, starting urate-lowering therapy, surgery (esp. parathyroidectomy → pseudogout), acute illness.
- ▶ **Examination:** confirm true articular swelling vs periarticular; distinguish effusion (fluctuant, *bulge/patellar tap*) from synovial hypertrophy (“boggy”) and bony enlargement. Document erythema, warmth, range of motion, and seek an **extra-articular focus** — tophi (pinna, olecranon), podagra, skin pustules on palms/soles + **tenosynovitis** (DGI), tick-bite/erythema migrans (Lyme), psoriatic plaques/nail pitting, fever and a portal of infection (boil, pneumonia, endocarditis).

Arthrocentesis and synovial fluid analysis — the pivotal test

Aspiration and analysis of synovial fluid are always indicated in acute monoarthritis or when infection/crystal arthropathy is suspected. Never pass the needle through overlying cellulitis or a psoriatic plaque. Analyse immediately for **appearance, viscosity, cell count + differential, Gram stain & culture, and crystals under compensated polarised light.**

Parameter	Normal	Group I Non-inflammatory	Group II Inflammatory	Group III Septic/Purulent
Clarity / colour	Transparent, clear	Transparent, yellow	Translucent–opaque, yellow	Opaque, yellow-green
Viscosity (“string sign”)	High	High	Low	Low
WBC/ μ L	<200	<2000	2000–75,000 (PMN $\geq$ 50%)	>50,000 (often >100,000), PMN $\geq$ 75–90%
Typical causes	—	OA, osteonecrosis	Gout, pseudogout, RA, reactive	Bacterial septic arthritis

- ▶ **Crystals:** **Monosodium urate (gout)** — *needle-shaped, strongly negatively birefringent* (yellow when parallel to compensator), usually intracellular. **Calcium pyrophosphate (pseudogout)** — *rhomboid/rod-shaped, weakly positively birefringent*.
- ▶ **Microbiology:** Gram stain positive in ~75% of staphylococcal, ~50% of gram-negative septic arthritis; synovial culture positive in 70–90% of non-gonococcal cases (blood cultures ~50%). Send NAAT if gonococcal/chlamydial suspected; culture synovial fluid for **TB and fungi** in chronic monoarthritis. MALDI-TOF/metagenomics aid culture-negative cases.
- ▶ **Caveat:** septic arthritis can present with Group II fluid (<50,000) with low-virulence organisms (gonococcus) or after antibiotics — a “non-septic” count never fully excludes infection.

Investigations beyond joint fluid

- ▶ **Bloods:** CBC with differential, ESR/CRP (discriminate inflammatory vs not; elevated but non-specific in sepsis), serum **urate** (may be normal in up to 50% during an acute gout flare — IL-6 is uricosuric; seek historical/post-flare values), creatinine, LFTs, blood cultures.
- ▶ **Targeted serology** only when pretest probability is adequate: RF, anti-CCP, ANA, Lyme, ASO, procalcitonin (~50% sensitive — does *not* rule out sepsis).
- ▶ **Imaging:** plain radiograph (baseline; early shows only soft-tissue swelling/effusion; chondrocalcinosis suggests CPPD; erosions with overhanging edges suggest tophaceous gout). **Ultrasound** detects effusion and the *double-contour sign* of urate deposition and guides aspiration of hip/shoulder; **MRI/CT** for deep joints (hip, sacroiliac, sternoclavicular), early osteomyelitis and to demonstrate effusion not clinically apparent. **Dual-energy CT** characterises urate deposits.

Specific entities and management pearls

- ▶ **Non-gonococcal septic arthritis** — *S. aureus* causes ~50%; the **knee** is most often involved (~90% single joint). It is a *medical/surgical emergency*. After cultures, give empirical IV bactericidal antibiotics: gram-positive cocci → **vancomycin 15–20 mg/kg q8–12h**; gram-negative bacilli → third-generation cephalosporin (**ceftriaxone 2 g q24h / cefotaxime 2 g q8h**), with anti-pseudomonal cover (cefepime/ceftazidime) in IVDU/immunocompromised. Add **joint drainage** (repeated needle aspiration, arthroscopic lavage, or arthrotomy — hip needs arthrotomy). Typical course ~4 weeks (staphylococci). CMDT empirical regimen: vancomycin + third-generation cephalosporin, 4–6 weeks.
- ▶ **Gonococcal arthritis (DGI)** — young, healthy, often women (menses/pregnancy); *triad* of **migratory polyarthralgia** → **tenosynovitis (60%)** → **purulent monoarthritis (40%)** with necrotic pustules on palms/soles. Synovial cultures often negative; diagnosis via mucosal NAAT/culture. Treat with **ceftriaxone 1 g IV/IM daily**, switch to oral after 24–48 h improvement to complete 7 days; dramatic response is characteristic. Test CH50 for terminal complement deficiency if recurrent.
- ▶ **Acute gout** — **podagra** (first MTP) in 70–90%; nocturnal, exquisitely painful, mimics cellulitis. Confirm with MSU crystals. Treat the flare early with **colchicine (1.2 mg at onset, 0.6 mg 1 h later)**, an NSAID (indomethacin 25–50 mg tid, naproxen 500 mg bid), or **glucocorticoid** (prednisone 30–50 mg/d tapered, or intra-articular). Start **urate-lowering therapy** later (allopurinol — screen *HLA-B*5801 in at-risk groups; febuxostat; probenecid*) targeting urate <6 mg/dL (<5 if tophi)* under anti-inflammatory prophylaxis.
- ▶ **Pseudogout (CPPD)** — elderly; **knee** > wrist; weakly positively birefringent rhomboid crystals + **chondrocalcinosis** on radiograph. In patients <50 yr, screen for haemochromatosis, hyperparathyroidism, hypophosphatasia, hypomagnesaemia. Treat as for acute gout (NSAID/colchicine/steroid).

- ▶ **Tuberculous arthritis** — chronic granulomatous monoarthritis of large weight-bearing joints (hip, knee, ankle); synovial fluid ~20,000 cells/ μ L (~50% PMN), AFB smear positive $<1/3$, culture ~80%, **synovial biopsy culture ~90%**; treat with standard multidrug ATT for 6–9 months.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Algorithm for acute non-traumatic monoarthritis (flow chart):** *Acute monoarthritis* → assess for **red flags** → **Arthrocentesis** → branch on synovial WBC: <2000 (*non-inflammatory* → OA, osteonecrosis) | $2000-50,000$ (*inflammatory* → check crystals: MSU → gout, CPP → pseudogout; if none → reactive/early inflammatory) | $>50,000$, PMN $>75\%$, +Gram stain/culture → **septic arthritis** → IV antibiotics + drainage. Label boxes: History/exam, WBC count, % PMN, Crystals, Gram stain, Culture.
- ▶ **Polarised-light crystal comparison:** two crystals with compensator axis — label MSU: needle-shaped, **NEGATIVELY** birefringent, intracellular (gout) and CPP: rhomboid, weakly **POSITIVELY** birefringent (pseudogout).

Clinical / Diagnostic significance

- ▶ **Septic arthritis is the diagnosis to exclude first** in every acute hot joint — delayed therapy causes irreversible cartilage destruction, ankylosis and a 30% mortality in polyarticular sepsis. Arthrocentesis precedes antibiotics.
- ▶ A single joint “*out of proportion*” to the rest in established RA must be aspirated to exclude superimposed sepsis, especially on biologic DMARDs.
- ▶ Crystals and infection coexist — always Gram stain/culture even when crystals are seen.
- ▶ Serum urate is unreliable during an acute flare; definitive gout diagnosis rests on crystal identification, not urate level.

High-yield exam pointers

- ▶ Three **red-flag** causes of acute monoarthritis: **septic arthritis, crystal arthritis, fracture**.
- ▶ **Arthrocentesis is mandatory** in acute monoarthritis; synovial WBC $>50,000/\mu$ L with $>75\%$ PMN = presume septic until proven otherwise.
- ▶ **MSU = needle-shaped, negatively birefringent (gout); CPP = rhomboid, positively birefringent (pseudogout).**
- ▶ *S. aureus* is the commonest cause of non-gonococcal septic arthritis; **knee** is the commonest joint; ~90% are monoarticular.
- ▶ **DGI** = arthritis–dermatitis–tenosynovitis triad in a young adult; treat with ceftriaxone.
- ▶ **Podagra** (first MTP gout) in 70–90%; acute gout treated with colchicine/NSAID/steroid, not urate-lowering during the flare.
- ▶ **Chronic monoarthritis** → think **TB and fungi**; culture/biopsy synovium.

- ▶ Empirical septic-arthritis therapy: **vancomycin + third-generation cephalosporin** plus joint drainage.

SOURCE & COVERAGE

- ▶ Harrison's Principles of Internal Medicine, 22e — "*Approach to Articular and Musculoskeletal Disorders*" (four screening questions, synovial fluid algorithm, laboratory evaluation); "*Infectious Arthritis*" (differential of arthritis syndromes, septic/gonococcal/tuberculous/fungal arthritis, antibiotic regimens); "*Gout and Other Crystal-Associated Arthropathies*" (acute gout, MSU/CPP crystals, colchicine/NSAID/steroid and urate-lowering therapy).
- ▶ CMDT 2026 — "*Rheumatologic, Immunologic, & Allergic Disorders*" (joint-pattern table, examination of joint fluid Groups I–III, nongonococcal & gonococcal septic arthritis, osteoarthritis, gout/pseudogout management).

Coverage note: The corpus has no dedicated rheumatology subspecialty textbook for this topic (spec.specialty_books empty); depth is drawn from Harrison 22e and CMDT 2026, which fully cover the approach, synovial fluid classification, crystal identification and management regimens.

Behçet's Syndrome

Asked in: Paper III Jul 2020 — RGUHS MD General Medicine

Definition / Introduction — Behçet's syndrome is a chronic, relapsing **systemic vasculitis** of unknown cause, first described by the Turkish dermatologist *Hulusi Behçet*. It is characterised by recurrent **oral and genital aphthous ulcers**, skin lesions, **uveitis**, arthritis, and variable involvement of major arteries and veins, the gastrointestinal tract and the central nervous system, occurring in differing combinations and sequences over time. Uniquely among the vasculitides it can involve vessels of **any size, on both the arterial and venous side** of the circulation, and is diagnosed clinically as there is no confirmatory laboratory test.

Epidemiology

- ▶ Strongly clustered along the ancient "*Silk Road*" — the **Middle East, Mediterranean, and the Far East**. Most prevalent in **Turkey** (≈ 1 in 250 adults).
- ▶ Onset typically in the **20s–30s**; relatively rare before the late teens and after age 50.
- ▶ **Males and females are affected equally**, but **males tend to have more severe disease and a poorer prognosis** (worse ocular, vascular and neurologic outcomes); young age and male sex are adverse prognostic markers.
- ▶ **HLA-B*51** is positive in **50–60%** of patients (regional variation) but is found in $\sim 20\%$ of the normal population, so it is *not* a diagnostic test.

Pathogenesis

- ▶ Aetiology unknown; a **genetic predisposition** (family clustering; HLA-B*51 association) interacts with dysregulated **innate and adaptive immunity** and increased inflammation.
- ▶ Underlying pathology is a **leukocytoclastic vasculitis**, though vessels of any calibre and any organ may be affected.
- ▶ Marked **neutrophil hyperreactivity** is characteristic (primary vs cytokine-driven is unsettled).
- ▶ Behçet's occupies a **niche between classic autoimmune and autoinflammatory disease**:
 - *Unlike autoimmune disease* — no autoantibodies, and no association with Raynaud's, Sjögren's, thrombocytopenia, haemolytic anaemia, photosensitivity or serositis.
 - *Unlike autoinflammatory disease* — it tends to **abate with time**, lacks the defining gene mutations (e.g. of familial Mediterranean fever), and is far more prevalent than typical periodic-fever syndromes.

Clinical features

- ▶ **Mucocutaneous (the hallmark)**:
 - **Oral ulcers** — in virtually all patients (~98%) and usually the **first manifestation**; multiple, painful, canker-sore-like, last ~10 days, recur; only uncommon “major” ulcers scar.
 - **Genital ulcers** — the **most specific** lesion; on scrotum/labia; larger, deeper, slower to heal, and characteristically scar.
 - **Skin lesions** — *acne-like / papulopustular* lesions (including atypical sites such as the legs); **erythema nodosum**-like nodules (panniculitis); and **superficial thrombophlebitis** (common in men; flags risk of deep-vein thrombosis and pulmonary artery aneurysm).
- ▶ **Ocular** — in ~50% overall and up to ~70% of males; typically a **bilateral panuveitis**. *Hypopyon* (sterile pus layering in the anterior chamber) occurs in ~10% of those with eye disease and is highly suggestive. Posterior uveitis (retinal vasculitis/venulitis) can silently destroy the retina. Poor ocular prognostic factors: **male sex, posterior involvement, >3 attacks/year, dense vitreous opacity, macular oedema**.
- ▶ **Musculoskeletal** — a **non-erosive, non-deforming mono- or oligoarthritis** of the lower limbs (knees, ankles) in about half of patients.
- ▶ **Vascular** — in up to 40%; an intense, relapsing **thrombotic** tendency. Venous: superficial and deep-vein thrombosis, *Budd-Chiari syndrome*, inferior vena cava syndrome, intracardiac thrombosis, and **cerebral venous sinus thrombosis**. Arterial: **pulmonary artery aneurysms** (5-year mortality 20–25%, may cause fatal haemoptysis).
- ▶ **Neurologic (neuro-Behçet)** — in ~5%; two largely non-overlapping forms:
 - **Parenchymal (~75%)** — affects the **telencephalic-diencephalic junction, brainstem and spinal cord**; subacute headache, cranial-nerve palsy, dysarthria, ataxia, hemiparesis. Can radiologically mimic *multiple sclerosis*.

- **Cerebral venous sinus thrombosis** (~25%) — headache, raised intracranial pressure.
- ▶ **Gastrointestinal** — frequency is markedly regional (up to ~50% in the Far East, ~30% in the US, rare in Turkey/Middle East). Few (usually <5), **deep, round ulcers confined to the ileocaecal area**, prone to **perforation**; perianal/rectal disease rare. Clinically and endoscopically **difficult to distinguish from Crohn's disease** without extra-intestinal clues.

Diagnostic criteria

Behçet's is a **clinical diagnosis of exclusion**. The most validated tool is the **International Study Group (ISG) criteria** (sensitivity ~95%, specificity ~96%):

Criterion	Frequency	Comment
Recurrent oral ulceration (mandatory)	~98%	At least 3 times in a 12-month period
PLUS any 2 of the following 4:		
Recurrent genital ulceration	~80%	Usually scarring
Skin lesions	~80%	Erythema nodosum, pseudofolliculitis, papulopustular/acneiform nodules (post-adolescent, not on corticosteroids)
Eye lesions	~50%	Anterior/posterior uveitis, vitreous cells, or retinal vasculitis
Positive pathergy test	~50%	Read at 24–48 h after pricking the skin with a 20–21-gauge needle

- ▶ **Pathergy** = non-specific cutaneous hyperreactivity to trauma; a sterile papule/pustule forms within 24–48 h. Rather unique to Behçet's; more often positive in patients from the Middle/Far East.
- ▶ No pathognomonic laboratory finding — **acute-phase reactants** (ESR/CRP) are often raised; **no specific autoantibody**. HLA-B*51 supports but does not establish the diagnosis.

Differential diagnosis

- ▶ **Oral/genital ulcers:** complex aphthosis, inflammatory bowel disease, coeliac disease, IgA deficiency, infections (HIV, herpes, histoplasmosis), and mucosal conditions (pemphigus vulgaris, lichen planus, mucous membrane pemphigoid).
- ▶ **GI disease:** *Crohn's disease* (key mimic).
- ▶ **Neuro-Behçet:** multiple sclerosis, CNS infection/vasculitis.
- ▶ **Uveitis:** sarcoidosis, HLA-B27 spondyloarthropathy, infective uveitis.

Treatment

Treatment is **organ- and severity-directed**, aiming to prevent irreversible damage; young males warrant more aggressive therapy. Most new manifestations appear within the **first 5 years**, after which disease tends to wane — **tapering/stopping drugs may be attempted 2–3 years** after remission, with immunosuppressants usually continued ≥ 2 years.

Manifestation	Preferred / first-line	Add-on / severe disease
Oral & genital ulcers, mucocutaneous	Topical glucocorticoids; colchicine ; apremilast (PDE-4 inhibitor; FDA-approved for oral ulcers)	Azathioprine; TNF-α inhibitor (infliximab) for resistant disease
Ocular (uveitis)	Brief glucocorticoid courses + azathioprine (preferred long-term agent)	TNF inhibitors (infliximab/adalimumab) ; cyclosporine; interferon- α
Gastrointestinal	Glucocorticoids + azathioprine	$\pm$ infliximab
Venous thrombosis	Immunosuppression (azathioprine; cyclophosphamide if severe) to control inflammation — <i>not primarily anticoagulation</i>	Anticoagulate only if low bleeding risk and no pulmonary artery aneurysm
CNS (parenchymal neuro-Behçet)	Azathioprine + a TNF inhibitor	Glucocorticoids; cyclophosphamide

- ▶ Management follows the **2018 EULAR recommendations** (Hatemi et al). Key principle for vascular disease: thrombosis is **inflammatory**, so suppress inflammation rather than relying on anticoagulants, and **always exclude a pulmonary artery aneurysm before anticoagulating** (risk of catastrophic haemorrhage).
- ▶ Recent evidence (Saadoun et al, 2024) compared **infliximab vs cyclophosphamide** for severe Behçet's, reflecting the growing role of biologics in major-organ disease.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Figure 1 — “Clinical map of Behçet's syndrome”**: a central figure with labelled arrows to: Oral aphthous ulcer (tongue/buccal mucosa); Genital (scrotal/labial) ulcer — scarring; Eye — hypopyon / panuveitis; Skin — erythema nodosum, papulopustular lesions, superficial thrombophlebitis; Pathergy site (forearm); Vascular — DVT, pulmonary artery aneurysm, Budd-Chiari, cerebral venous sinus thrombosis; CNS — brainstem lesion; GI — ileocaecal ulcer.
- ▶ **Figure 2 — Pathergy test**: label 20–21-gauge needle prick $\rightarrow$ sterile papule/pustule at 24–48 h.

Clinical / Diagnostic significance

- ▶ A young patient with recurrent oral + genital ulceration and uveitis from a Silk-Road region should prompt consideration of Behçet's.
- ▶ Hypopyon uveitis and a positive pathergy test are the most disease-specific bedside clues.
- ▶ Superficial thrombophlebitis must trigger a search for occult vascular disease, especially pulmonary artery aneurysm, the most lethal complication.
- ▶ Distinguishing GI Behçet's from Crohn's and neuro-Behçet's from MS is a recurring clinical challenge — extra-intestinal/systemic features and lesion distribution guide diagnosis.
- ▶ HLA-B*51 positivity supports the diagnosis and correlates with disease but is **neither necessary nor sufficient**.

High-yield exam pointers

- ▶ First described by Hulusi Behçet (Turkish dermatologist); classic triad = oral ulcers + genital ulcers + uveitis.
- ▶ Silk Road distribution; highest prevalence in Turkey (1 in 250); HLA-B*51 associated.
- ▶ ISG criteria: recurrent oral ulcers ($\geq 3 \times / \text{yr}$) plus 2 of 4 (genital ulcers, skin lesions, eye lesions, positive pathergy); sensitivity ~95%, specificity ~96%.
- ▶ Pathergy = sterile pustule 24–48 h after a 20–21-G needle prick — read at 24–48 h.
- ▶ Hypopyon + bilateral panuveitis; eye disease commoner/severer in males.
- ▶ Pulmonary artery aneurysm = most feared lesion (5-yr mortality 20–25%); **do not anticoagulate** without excluding it.
- ▶ Venous thrombosis is **inflammatory** → treat with **immunosuppression**, not anticoagulation alone.
- ▶ Apremilast (PDE-4 inhibitor) is FDA-approved for oral ulcers; azathioprine is the workhorse steroid-sparing agent; TNF inhibitors for severe ocular/CNS/GI disease.
- ▶ Behçet's **abates with time**, unlike most chronic rheumatic diseases — many patients can taper therapy at 2–3 years.

SOURCE & COVERAGE

- ▶ Harrison's Principles of Internal Medicine, 22e — "Behçet Syndrome" (ISG criteria, clinical features, organ-directed treatment) and "The Vasculitis Syndromes" (classification; leukocytoclastic vasculitis).
- ▶ CMDT 2026 — "Behçet Disease" (Rheumatologic, Immunologic & Allergic Disorders; clinical findings, differential diagnosis, current drug regimens and recent trial data).
- ▶ Management framework consistent with the 2018 EULAR recommendations for the management of Behçet's syndrome (cited in Harrison).

Biologicals in Rheumatoid Arthritis

Asked in: Paper III May 2022 — RGUHS MD General Medicine

Definition / Introduction — **Biologic DMARDs (bDMARDs)** are protein therapeutics, predominantly monoclonal antibodies and soluble receptor-fusion constructs, engineered to neutralise specific cytokines (TNF- α , IL-6, IL-1) or block cell-surface molecules (CD20, CD80/86) central to the pathobiology of rheumatoid arthritis (RA). Introduced from 1999, they have **revolutionised RA therapy**, reducing signs and symptoms, slowing radiographic joint damage, and improving physical function and quality of life. They are used after an inadequate response to methotrexate (MTX), usually in combination with it, within a **treat-to-target** strategy aiming at remission or low disease activity.

Rationale — Cytokine targets in RA pathobiology

- ▶ **TNF- α** is a pivotal upstream cytokine secreted by synovial macrophages and fibroblasts. It upregulates **endothelial adhesion molecules** (promoting leukocyte influx), drives production of **IL-1, IL-6 and GM-CSF**, stimulates **osteoclastogenesis**, and suppresses bone formation via **DKK-1**–mediated inhibition of the Wnt pathway.
- ▶ **IL-6** activates intracellular signalling that drives the acute-phase response, cytokine production and osteoclast activation.
- ▶ **IL-1** is antagonised physiologically by the IL-1 receptor antagonist (the basis of anakinra).
- ▶ **B cells (CD20+)** and **T-cell co-stimulation (CD28–CD80/86)** are additional non-cytokine targets exploited by rituximab and abatacept respectively.
- ▶ **Biosimilars** — agents with the same active properties as a licensed reference biological — are now available for several products with similar efficacy and side-effect profiles.

Classification of biologic DMARDs with doses

Class / Target	Agent & molecular design	Representative dose (Harrison Table 370-2)
TNF- α inhibitors	<i>Infliximab</i> — chimeric (mouse–human) mAb	3 mg/kg IV at weeks 0, 2, 6, then every 8 weeks (up to 10 mg/kg q4w)
	<i>Adalimumab</i> — humanised mAb	40 mg SC every other week
	<i>Golimumab</i> — humanised mAb	50 mg SC monthly
	<i>Certolizumab pegol</i> — pegylated Fab' fragment of humanised mAb	400 mg SC at weeks 0, 2, 4, then 200 mg every other week
	<i>Etanercept</i> — soluble TNF receptor-2–Fc(IgG1) fusion protein	50 mg SC weekly (or 25 mg SC twice weekly)
Anti-IL-6 receptor	<i>Tocilizumab, Sarilumab</i> — anti-IL-6R mAbs	Tocilizumab 4–8 mg/kg IV monthly or 162 mg SC

Class / Target	Agent & molecular design	Representative dose (Harrison Table 370-2)
		q2w/weekly; Sarilumab 200 mg SC every other week
IL-1 receptor antagonist	<i>Anakinra</i> — recombinant IL-1Ra	100 mg SC daily
T-cell co-stimulation blocker	<i>Abatacept</i> — CTLA-4-IgG fusion protein	Weight-based IV (500/750/1000 mg) at weeks 0, 2, 4, then q4w; or 125 mg SC weekly
Anti-CD20 (B-cell depletion)	<i>Rituximab</i> — chimeric anti-CD20 mAb	1000 mg IV ×2 (days 0 and 14); may repeat every ≥24 weeks; premedicate with methylprednisolone 100 mg

Note: JAK inhibitors (tofacitinib, baricitinib, upadacitinib) are oral **targeted synthetic DMARDs**, not biologicals, but are discussed below as the closely allied “non-biologic targeted” class.

Individual agents — mechanism and clinical use

- ▶ **Anti-TNF agents** — *Five original “innovator” TNF inhibitors* are approved. Three are anti-TNF monoclonal antibodies (infliximab chimeric; adalimumab and golimumab humanised); certolizumab is a pegylated Fab’ fragment; etanercept is a soluble TNF receptor-2–Fc fusion protein. All reduce symptoms and slow radiographic progression and may be used alone or, more effectively, with background MTX. They are the first-line biologic added when MTX response is inadequate.
- ▶ **Anti-IL-6 receptor agents (tocilizumab, sarilumab)** — mAbs against membrane and soluble IL-6R; effective as monotherapy or with conventional DMARDs. They **raise LDL cholesterol** and carry a risk of **GI perforation** (avoid with diverticulitis or recent peptic ulcer).
- ▶ **Anakinra** — recombinant IL-1 receptor antagonist; *limited use* in RA because other biologics show greater efficacy.
- ▶ **Abatacept** — soluble CTLA-4–IgG fusion protein that blocks CD28–CD80/86 co-stimulation of T cells; reduces disease activity and slows radiographic damage; usually combined with a conventional DMARD. Some studies suggest switching to abatacept is more effective than switching to a second anti-TNF.
- ▶ **Rituximab** — chimeric anti-CD20 mAb that **depletes B cells**; approved for **refractory RA (failure of a TNF inhibitor) in combination with MTX**; more effective in **seropositive** than seronegative disease. Associated with rare **progressive multifocal leukoencephalopathy (PML)** (~1:25,000) and blunting of vaccine responses (e.g. SARS-CoV-2).

Targeted synthetic DMARDs — JAK inhibitors (allied oral agents)

- ▶ Inhibit the Janus kinase (JAK1, JAK2, JAK3, Tyk2) family that links extracellular cytokine receptors to intracellular signalling; oral route is their key advantage over biologics.

- ▶ *Tofacitinib* — JAK1/JAK3 inhibitor, 5 mg BD or 11 mg OD; *Baricitinib* — JAK1/JAK2, 2 mg OD; *Upadacitinib* — selective JAK1, 15 mg OD. Used as monotherapy or with MTX.
- ▶ Risks: infections including **herpes zoster**, raised transaminases, neutropenia, dyslipidaemia, hypertension; tofacitinib carries increased **thrombosis, MACE and malignancy** versus TNF inhibitors, highest in the **elderly**.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Cytokine-network/target schematic of the RA synovium:** label *Macrophage* and *Synovial fibroblast* secreting *TNF- α* , *IL-1*, *IL-6*, *GM-CSF*; *T cell* with *CD28-CD80/86* co-stimulation; *B cell* (*CD20*); *Osteoclast precursor* → *RANKL/RANK* → *activated osteoclast* → *bone erosion*; *DKK-1* → *Wnt inhibition* → *reduced osteoblast bone formation*. Superimpose drug blocks: *Anti-TNF*, *Anti-IL-6R* (*tocilizumab/sarilumab*), *Anakinra* (*IL-1Ra*), *Abatacept* (*CTLA-4-Ig*), *Rituximab* (*anti-CD20*).
- ▶ **Treat-to-target ladder:** *MTX (anchor)* → *inadequate response at 3–6 months* → *add anti-TNF or non-TNF biologic $\pm$ MTX* → *switch within class or to alternative mechanism* (*abatacept/anti-IL-6R/rituximab*) or *JAK inhibitor* → *goal: DAS-28 low disease activity / remission*.

Clinical / Diagnostic significance

- ▶ **Pre-treatment screening (initial evaluation):** CBC with differential, viral hepatitis panel (HBsAg, anti-HCV), and **latent TB screening** (Mantoux/PPD or IFN- γ release assay). If LTBI positive, give anti-TB therapy for **at least 1 month before** starting an anti-TNF agent.
- ▶ **Contraindications to anti-TNF:** active infection, hypersensitivity, **chronic hepatitis B**, and **class III/IV congestive heart failure**.
- ▶ **Key class adverse effects:** increased serious bacterial and opportunistic fungal infection, **reactivation of latent TB**; anti-TNF also linked to infusion/injection-site reactions, drug-induced lupus, demyelination, and (controversially) lymphoma.
- ▶ **Positioning:** begin with MTX; if inadequate after 3–6 months, step up to combination conventional DMARDs or add an anti-TNF/non-TNF biologic. Initial anti-TNF responders who later worsen may switch to another anti-TNF or to a biologic with a different mechanism (often more effective).
- ▶ **Pregnancy:** anti-TNF agents are generally accepted as safe but **guidelines advise stopping them in the third trimester**; data are insufficient for abatacept, anti-IL-6R, rituximab and JAK inhibitors (discontinue at conception). Hydroxychloroquine and sulfasalazine are the safest DMARDs in pregnancy; MTX and leflunomide are contraindicated (teratogenic).

- ▶ **Combination superiority:** randomised trials show **MTX plus an anti-TNF agent is superior to MTX alone**, and an early intensive combination approach yields better long-term outcomes than starting MTX monotherapy.
- ▶ **Monitoring on therapy:** periodic CBC, LFTs and (for IL-6 inhibitors and JAK inhibitors) lipids; vigilance for infection.

High-yield exam pointers

- ▶ **TNF inhibitors were the first biologicals** approved for RA (1999); MTX remains the **anchor drug** and is usually co-prescribed.
- ▶ Know the **molecular designs**: infliximab = chimeric mAb; adalimumab/golimumab = humanised mAb; certolizumab = pegylated Fab'; **etanercept** = **TNF receptor-2-Fc fusion protein** (the odd one out).
- ▶ **Screen for latent TB and hepatitis B** before any anti-TNF; treat LTBI ≥ 1 month first.
- ▶ Anti-TNF **contraindicated in NYHA class III/IV heart failure** and chronic hepatitis B.
- ▶ **Rituximab** = anti-CD20, for **TNF-failure refractory RA + MTX**, better in **seropositive** disease; rare PML.
- ▶ **Abatacept** = CTLA-4-Ig blocking CD28-CD80/86 co-stimulation; **anakinra** = IL-1Ra (limited efficacy).
- ▶ **Tocilizumab/sarilumab (anti-IL-6R)** raise **LDL cholesterol** and risk **GI perforation**.
- ▶ **JAK inhibitors are oral targeted synthetic DMARDs (not biologics); watch for herpes zoster, thrombosis, MACE and malignancy* (tofacitinib, elderly).*
- ▶ **Biosimilars** offer comparable efficacy/safety to reference biologicals.

SOURCE & COVERAGE

Harrison 22e — Ch 370 “Rheumatoid Arthritis” (Treatment: Biologicals & Targeted Synthetic DMARDs section and Table 370-2 “DMARDs Used for the Treatment of Rheumatoid Arthritis”). All agents, molecular designs, doses, mechanisms, screening and contraindications are grounded in this chapter. Coverage note: JAK inhibitors are included as the allied oral targeted-synthetic class (Harrison classifies them separately from biologicals); ACR/EULAR treat-to-target step-up framing and DAS-28 are from the same chapter’s “Approach to the Patient.”

Biologics in Autoimmune Disease

Asked in: Paper III Jun 2024 — RGUHS MD General Medicine

Definition / Introduction — **Biologic agents (biologic DMARDs)** are large, protein-based therapeutics — chiefly **monoclonal antibodies, soluble receptor-Fc fusion proteins and recombinant receptor**

antagonists — engineered to neutralise specific cytokines, deplete or modulate immune cells, or block co-stimulatory and trafficking pathways central to autoimmune inflammation. By targeting a single defined node rather than broadly suppressing the immune system (as glucocorticoids or cyclophosphamide do), they have **revolutionised the treatment of rheumatoid arthritis (RA), spondyloarthritis, SLE, ANCA-associated vasculitis (AAV), inflammatory bowel disease (IBD) and psoriasis** over the past two decades. The first class approved (TNF inhibitors, from 1999) was followed by B-cell-, IL-6-, IL-1-, IL-17-, IL-23- and IFN-targeted agents; **biosimilars** (highly similar copies of an off-patent reference biologic with comparable efficacy and safety) have since broadened access.

Classification of biologics by structure and target

Class / structure	Molecular target	Representative agents (autoimmune use)
Anti-TNF- α monoclonal antibodies	Soluble + membrane TNF- α	Infliximab (chimeric), Adalimumab, Golimumab (human/humanised), Certolizumab pegol (PEGylated Fab')
Anti-TNF fusion protein	TNF- α	Etanercept (TNF-R2-IgG1 Fc fusion protein)
B-cell depleting (anti-CD20)	CD20 on mature B cells	Rituximab (chimeric), Obinutuzumab (type II, investigational in SLE)
Co-stimulation blocker	CD28-CD80/86 (T-cell)	Abatacept (CTLA-4-IgG fusion protein)
Anti-IL-6 receptor	IL-6R (soluble + membrane)	Tocilizumab, Sarilumab
IL-1 receptor antagonist	IL-1 receptor	Anakinra (recombinant IL-1Ra)
Anti-IL-17A	IL-17A	Secukinumab (IgG1 κ), Ixekizumab (IgG4)
Anti-IL-12/23 (p40) / anti-IL-23 (p19)	Shared p40 / IL-23 p19	Ustekinumab (p40); Risankizumab, Mirikizumab (p19)
Anti-integrin (anti-trafficking)	$\alpha 4\beta 7$ / $\alpha 4$ integrin	Vedolizumab (gut-selective $\alpha 4\beta 7$), Natalizumab ($\alpha 4$)
Anti-BAFF / BlyS	B-cell activating factor	Belimumab
Anti-type I IFN receptor	IFNAR1	Anifrolumab
Complement C5a-receptor inhibitor	C5a receptor	Avacopan (small molecule, adjunct in AAV)

- ▶ **Nomenclature pearl:** the suffix encodes structure — *-mab* = monoclonal antibody (*-ximab* chimeric e.g. infliximab/rituximab; *-zumab* humanised e.g. tocilizumab; *-umab* fully human e.g. golimumab, adalimumab, ustekinumab), while *-cept* = receptor–Fc **fusion protein** (etanercept, abatacept).
- ▶ **Not biologics but commonly confused with them:** *targeted synthetic DMARDs* — the oral **JAK inhibitors** (tofacitinib JAK1/3; baricitinib JAK1/2; upadacitinib JAK1) and **voclosporin** (a calcineurin inhibitor used in lupus nephritis). They block intracellular signalling and offer an oral alternative to injectable biologics.

Mechanism-based pharmacology of the major classes

- ▶ **TNF- α inhibitors** — TNF- α is a critical upstream driver of synovitis; five “innovator” agents exist. **Infliximab** is a chimeric mAb; **adalimumab/golimumab** are human(ised) mAbs; **certolizumab** is a PEGylated Fab’ fragment; **etanercept** is a soluble TNF-receptor-2–IgG1-Fc fusion protein. All reduce signs/symptoms, **slow radiographic joint damage** and improve function in RA; used alone or with background **methotrexate (MTX)**. Effective also in psoriasis, psoriatic arthritis, ankylosing spondylitis and IBD.
- ▶ **B-cell depletion** — **Rituximab (anti-CD20)** depletes mature B cells, lowering autoantibody production, T-cell activation and cytokine output. Approved for **MTX-refractory / TNF-failure RA** (more effective in seropositive disease) and a cornerstone of **AAV** therapy.
- ▶ **Co-stimulation blockade** — **Abatacept (CTLA-4-Ig)** binds CD80/86 on antigen-presenting cells, blocking the CD28 “second signal” required for T-cell activation; slows radiographic progression in RA, usually with a conventional DMARD.
- ▶ **IL-6 receptor blockade** — **Tocilizumab / sarilumab** are mAbs against soluble and membrane IL-6R; IL-6 drives the acute-phase response, B-cell help and osteoclast activation. Effective as monotherapy or with MTX.
- ▶ **IL-1 blockade** — **Anakinra** is recombinant IL-1 receptor antagonist (limited use in RA; mainstay of autoinflammatory syndromes).
- ▶ **IL-17 / IL-23 axis** — **Secukinumab, ixekizumab (anti-IL-17A)** and **ustekinumab (anti-p40)/risankizumab (anti-IL-23 p19)** target the Th17 pathway central to **psoriasis, psoriatic arthritis, ankylosing spondylitis and Crohn’s disease**.
- ▶ **Anti-trafficking integrin blockers** — **Vedolizumab (gut-selective $\alpha 4\beta 7$)** and **natalizumab ($\alpha 4$)** prevent leucocyte homing to gut/CNS in IBD.
- ▶ **SLE-specific biologics** — **Belimumab (anti-BAFF/BLyS)** reduces B-cell survival; **anifrolumab (anti-type I IFN receptor)** blocks the interferon signature.

Disease-specific applications

Disease	Biologic(s) used	Key clinical role
Rheumatoid arthritis	TNF inhibitors, abatacept, tocilizumab/sarilumab, rituximab, anakinra	Step-up after inadequate MTX response ($\approx 3-6$ mo); rituximab for TNF failure, esp. seropositive disease
SLE / lupus nephritis	Belimumab (incl. lupus nephritis), anifrolumab; rituximab (off-label refractory disease, AIHA, severe thrombocytopenia, neuropsychiatric lupus)	Glucocorticoid-sparing; belimumab given with MMF or low-dose cyclophosphamide; obinutuzumab & CAR-T (anti-CD19) emerging
ANCA-associated vasculitis (GPA/MPA)	Rituximab (induction & maintenance), avacopan (C5a-R, steroid-sparing)	Rituximab $375 \text{ mg/m}^2/\text{week} \times 4 \approx$ cyclophosphamide for induction; superior in relapsing disease
IBD (Crohn / UC)	Anti-TNF (infliximab, adalimumab, golimumab, certolizumab), vedolizumab, ustekinumab, risankizumab, mirikizumab	Moderate-severe disease; vedolizumab/IL-23 agents favoured when TNF risk is high
Psoriasis / PsA / ankylosing spondylitis	TNF inhibitors, secukinumab, ixekizumab, ustekinumab	IL-17/IL-23 agents highly effective for skin and axial disease
Sjögren syndrome	Belimumab $\rightarrow$ rituximab sequential, ianalumab (investigational)	Promising composite outcomes

Pre-treatment screening and monitoring

- ▶ **Latent tuberculosis** — *mandatory before any TNF inhibitor (and most biologics)*: tuberculin skin test (PPD) or IFN- γ release assay (IGRA) + chest X-ray; if positive, treat LTBI for ≥ 1 month before starting the biologic.
- ▶ **Viral hepatitis panel** — HBsAg + anti-HCV before rituximab, TNF inhibitors and tocilizumab; risk of hepatitis B reactivation (esp. rituximab).
- ▶ **CBC, LFTs, renal function and lipids** at baseline and periodically (cytopenias with rituximab/tocilizumab; transaminitis and dyslipidaemia — raised LDL — with tocilizumab).
- ▶ **Vaccination** before initiation — *live vaccines are contraindicated* during therapy; rituximab markedly blunts vaccine responses (e.g. SARS-CoV-2).
- ▶ **Therapeutic drug monitoring** in IBD — target trough levels: infliximab $>7 \mu\text{g/mL}$, adalimumab $>7-10 \mu\text{g/mL}$, golimumab $>1 \mu\text{g/mL}$; scheduled maintenance or co-immunomodulator use reduces anti-drug antibody formation to $<10\%$.

Adverse effects and contraindications

- ▶ **Infection** (the dominant risk) — serious bacterial, opportunistic fungal and viral infections; **reactivation of latent TB** (TNF inhibitors), **HBV reactivation** (rituximab), and **Pneumocystis jirovecii** pneumonia with rituximab/cyclophosphamide in AAV (give TMP-SMX prophylaxis).
- ▶ **TNF inhibitors specifically contraindicated in:** active infection, hypersensitivity, **chronic hepatitis B**, and **NYHA class III/IV heart failure**; can precipitate **demyelinating/neurologic events** (avoid in multiple sclerosis), **drug-induced lupus** (anti-histone antibodies) and rarely lymphoma (controversial).
- ▶ **Rituximab** — infusion reactions (premedicate with methylprednisolone), cytopenias, hypogammaglobulinaemia with prolonged use, and rare **progressive multifocal leukoencephalopathy (PML)** ($\approx 1:25,000$ in RA).
- ▶ **Tocilizumab/sarilumab** — neutropenia, thrombocytopenia, raised LDL, raised LFTs, and **gastrointestinal perforation** (avoid with diverticulitis/recent peptic ulcer).
- ▶ **Natalizumab** — PML from JC virus; largely abandoned in Crohn's for this reason (vedolizumab's gut selectivity confers lower PML risk).
- ▶ **Abatacept** and rituximab blunt vaccine responses.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ “Cytokine and cell targets of biologics in the rheumatoid synovium” — central panel showing macrophage, T cell, B cell, synovial fibroblast and osteoclast. Label arrows for: TNF- α $\rightarrow$ infliximab/etanercept/adalimumab/golimumab/certolizumab; IL-6/IL-6R $\rightarrow$ tocilizumab/sarilumab; IL-1 $\rightarrow$ anakinra; CD20 (B cell) $\rightarrow$ rituximab; CD28-CD80/86 co-stimulation $\rightarrow$ abatacept (CTLA-4-Ig); JAK/STAT (intracellular) $\rightarrow$ tofacitinib (tsDMARD).
- ▶ “Site of action ladder by disease” — vertical bars labelled: *Skin/joints* $\rightarrow$ IL-17 (secukinumab), IL-23 (risankizumab); *Gut* $\rightarrow$ $\alpha 4\beta 7$ (vedolizumab); *SLE* $\rightarrow$ BAFF (belimumab), IFNAR (anifrolumab); *Vasculitis* $\rightarrow$ CD20 (rituximab) + C5aR (avacopan).

Clinical / Diagnostic significance

- ▶ **Treat-to-target / step-up strategy:** in RA, begin with MTX; if inadequate response after 3–6 months, **add a TNF or non-TNF biologic** — combination DMARD therapy is superior to MTX alone.
- ▶ **Choice is individualised:** seropositive RA and refractory disease favour rituximab; concomitant psoriatic arthritis favours ustekinumab/IL-17 agents; lupus nephritis favours belimumab/voclosporin-based combinations; relapsing AAV favours rituximab.
- ▶ **Steroid-sparing** is a key modern goal — belimumab/anifrolumab in SLE and avacopan in AAV all allow rapid glucocorticoid tapering.

- ▶ **Biosimilars** lower cost and improve access without loss of efficacy — important in the Indian/RGUHS context.

High-yield exam pointers

- ▶ **First biologic class = TNF inhibitors (1999)**; etanercept is a **fusion protein**, the rest are **monoclonal antibodies**; certolizumab is a **PEGylated Fab'**.
- ▶ **Always screen for latent TB and HBV** before TNF inhibitors; treat LTBI ≥ 1 month before starting.
- ▶ **Rituximab = anti-CD20**, key in **TNF-refractory seropositive RA** and **AAV induction** ($375 \text{ mg/m}^2 \times 4$); watch for **PML** and **HBV reactivation**.
- ▶ **Abatacept = CTLA-4-Ig** (co-stimulation blocker); **tocilizumab = anti-IL-6R** (raises LDL, risk of GI perforation); **anakinra = IL-1Ra**.
- ▶ **SLE biologics: belimumab (anti-BAFF)** and **anifrolumab (anti-IFNAR)**; belimumab also approved for **lupus nephritis** with MMF/cyclophosphamide.
- ▶ **IBD: anti-TNF**, **vedolizumab ($\alpha 4\beta 7$, gut-selective)**, **ustekinumab (IL-12/23 p40)**, **risankizumab (IL-23 p19)**.
- ▶ **Psoriasis/spondyloarthritis: IL-17 (secukinumab, ixekizumab)** and **IL-12/23 agents**.
- ▶ **TNF inhibitors contraindicated** in class III/IV CHF, chronic hepatitis B and demyelinating disease.
- ▶ **JAK inhibitors are oral targeted-synthetic DMARDs**, **NOT biologics** — carry boxed warnings for thrombosis, MACE and malignancy.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Rheumatoid Arthritis” (biologic DMARD classes, Table 370-2 doses/toxicities, TNF/IL-6/B-cell/co-stimulation mechanisms), “Autoimmunity and Autoimmune Diseases” (cytokine and B-cell targets in autoimmunity), “Systemic Lupus Erythematosus” (belimumab, anifrolumab, rituximab, voclosporin, obinutuzumab, CAR-T), “The Vasculitis Syndromes / Granulomatosis with Polyangiitis” (rituximab induction/maintenance, avacopan, failure of etanercept/abatacept/belimumab in AAV), “Inflammatory Bowel Disease” (anti-TNF, natalizumab/vedolizumab integrin blockers, ustekinumab/risankizumab, trough levels), and the psoriasis/spondyloarthritis chapters (IL-17 and IL-23 agents).
- ▶ **CMDT 2026** — “Rheumatologic, Immunologic, & Allergic Disorders” (abatacept, rituximab, tocilizumab/sarilumab, Sjögren and vasculitis biologics, drug-induced lupus) and “Gastrointestinal Disorders” (IBD anti-TNF and anti-IL agents, therapeutic drug monitoring).

- *Coverage note:* This corpus has **no single dedicated “biologics” chapter** (as the spec flags); the answer is synthesised from the disease-specific therapy sections across Harrison and CMDT. The *-mab/-cept* nomenclature framework is standard, universally accepted pharmacology added for exam completeness.

Calcium Pyrophosphate Deposition Disease

Asked in: Paper III May 2019 — RGUHS MD General Medicine

Definition / Introduction — Calcium pyrophosphate deposition disease (CPPD) is a crystal-induced arthropathy caused by the deposition of **calcium pyrophosphate (CPP) crystals** in articular hyaline cartilage and fibrocartilage, producing the radiographic hallmark of **chondrocalcinosis**. The acute inflammatory presentation was originally termed *pseudogout* by McCarty and colleagues because it mimics acute gout. CPPD is overwhelmingly a disease of the elderly, with prevalence in articular tissues roughly **doubling with each decade after 60 years** (reaching nearly 50% in those >85 years). It encompasses a spectrum from asymptomatic chondrocalcinosis through acute crystal arthritis to several chronic arthropathies.

Pathogenesis

- The central abnormality is an **increased concentration of inorganic pyrophosphate (PPi) in the cartilage matrix** — pathogenically analogous to hyperuricaemia in gout. PPi combines with calcium to form CPP crystals within **cartilage matrix vesicles** or on collagen fibres.
- Most matrix PPi derives from breakdown of **extracellular ATP**. ATP efflux (and hence PPi levels) is tightly regulated by a multipass membrane transport protein, **ANKH**; mutations in the *ANKH* gene (described in both familial and sporadic disease) increase elaboration and extracellular transport of pyrophosphate.
- PPi production is also augmented by enhanced activity of **ATP pyrophosphohydrolase** and **5'-nucleotidase** (which generate adenosine and pyrophosphate from ATP). **Decreased cartilage glycosaminoglycans** and **increased transglutaminase** activity further favour CPP crystal nucleation.
- Once shed into the joint space, CPP crystals are phagocytosed by **monocyte-macrophages and neutrophils**, which release chemotactic/inflammatory mediators and activate the **NLRP3 inflammasome**, driving **IL-1 β** -mediated acute synovitis (shared final pathway with gout).
- Biochemical changes of **ageing or diseased cartilage** are thought to favour crystal nucleation in the common sporadic (“idiopathic”) form, where the underlying aetiology remains uncertain.

Associated conditions (“the four H’s and beyond”)

- ▶ A minority of patients have an underlying metabolic or hereditary cause. **CPPD presenting in a patient aged <50 years** must prompt a search for a secondary cause and inherited disease.
- ▶ Endocrine-metabolic and other associations (Harrison Table 384-2):

Category	Associations
Degenerative / mechanical	Ageing, osteoarthritis, post-menisectomy or joint trauma
Hereditary	Familial-genetic CPPD (<i>ANKH</i> mutations)
Endocrine-metabolic	Primary hyperparathyroidism, Hemochromatosis, Hypophosphatasia, Hypomagnesemia
Renal-tubular / electrolyte	Gitelman's syndrome, X-linked hypophosphatemic rickets, familial hypocalciuric hypercalcemia, malabsorption
Drug-associated	Thiazide and loop diuretics; potentially proton-pump inhibitors
Other crystal	Coexistent gout

- ▶ *Useful screening mnemonic:* the classic remediable causes are **Hyperparathyroidism, Haemochromatosis, Hypophosphatasia and Hypomagnesaemia**.
- ▶ **Work-up of the young patient** should include serum **calcium, phosphorus, alkaline phosphatase, magnesium, iron and transferrin**, plus enquiry for familial aggregation.

Clinical manifestations

- ▶ **Acute CPP crystal arthritis (pseudogout)** — an acute, self-limiting mono- or oligoarthritis closely mimicking gout. Distinguishing clinical clues:
 - The **knee is the most commonly affected joint**, followed by the **wrist**; the first metatarsophalangeal joint (*podagra*) is **rarely** involved (in contrast to gout). Shoulder, ankle, elbow and hands may also be affected.
 - **Initial attacks tend to last longer than gout** — often weeks to months.
 - Frequently provoked by **trauma, severe medical illness, or surgery** — especially **parathyroidectomy**, which causes rapid fall in serum calcium and magnesium, leading to crystal dissolution and shedding. Pseudogout characteristically develops **24–48 h after major surgery**.
 - Systemic features (fever, chills, raised acute-phase reactants) occur; in up to **50%** there is low-grade fever, occasionally as high as **40°C (104°F)** — synovial fluid culture is then essential to exclude coexistent sepsis.
- ▶ **Chronic CPPD arthropathies** (several patterns):

- **Pseudo-osteoarthritis** — the *most common* chronic form; a degenerative arthropathy with unusually severe damage in joints atypical for primary OA (**metacarpophalangeal, wrist, elbow, shoulder, glenohumeral, ankle, patellofemoral**).
- **Pseudo-rheumatoid arthritis** — chronic symmetric synovitis affecting MCP joints and wrists, clinically resembling RA.
- **Pseudo-neuropathic (pseudo-Charcot)** — severe destructive disease that radiographically mimics neuropathic arthropathy.
- **Spinal disease** — intervertebral disk and ligament calcification with restricted spinal mobility; **spinal stenosis** (elderly); and the **crowned dens syndrome** — CPP deposition at the atlanto-axial junction with “crown-like” calcification around the odontoid, presenting with severe neck pain, rigidity and high fever that can mimic **meningitis or giant cell arteritis**.
- Rarely, **tumoral CPP deposits** in soft tissue.

Diagnosis

- ▶ **Synovial fluid crystal analysis is definitive.** Under compensated polarized light microscopy CPP crystals are **rhomboid or rod-shaped** and **weakly positively birefringent (or non-birefringent)** — contrasting with the needle-shaped, strongly **negatively birefringent** MSU crystals of gout. Crystals may be seen within neutrophils, tissue fragments and fibrin clots; they may coexist with MSU or apatite.
- ▶ **Synovial fluid is inflammatory** — leukocyte counts range from several thousand to **100,000 cells/ μ L** (mean $\sim$ 24,000/ μ L), predominantly **neutrophils**. Always **Gram stain and culture** to exclude septic arthritis (which can coexist).
- ▶ **Imaging — chondrocalcinosis:** plain radiographs or ultrasound show **punctate and/or linear radiodense deposits** within fibrocartilage (knee menisci, triangular fibrocartilage of the wrist, symphysis pubis) and hyaline articular cartilage. In the absence of a tappable effusion, **chondrocalcinosis is presumptive of CPPD** — a key exception being chondrocalcinosis from **calcium oxalate** in chronic renal failure. Radiographs in pseudo-OA also show asymmetric joint-space narrowing and osteophytes in atypical joints.
- ▶ The **2023 ACR/EULAR classification criteria for CPPD** provide a formal weighted scheme (incorporating crystal identification, imaging chondrocalcinosis and clinical features) for research/diagnostic standardisation.

Differential diagnosis

- ▶ **Gout** — distinguished by joint distribution (podagra), negatively birefringent needle-shaped MSU crystals, usually elevated serum urate, and erosions with overhanging edges rather than chondrocalcinosis.
- ▶ **Septic arthritis** — must always be excluded by synovial fluid Gram stain and culture, particularly when fever is present.

- ▶ **Rheumatoid arthritis** (vs pseudo-RA), **osteoarthritis** (vs pseudo-OA), **neuropathic joint** (vs pseudo-neuropathic), **apatite / basic calcium phosphate disease** (e.g. Milwaukee shoulder), and **calcium oxalate arthropathy** in dialysis patients.

Treatment

- ▶ **Acute pseudogout** (management largely adapted from acute gout):
 - **Joint aspiration plus intra-articular glucocorticoid** — e.g. *triamcinolone 10–40 mg* depending on joint size; effective and well tolerated for one or a few joints.
 - **NSAIDs** in full anti-inflammatory dose (with gastroprotection where required).
 - **Colchicine** — up to *1.8 mg orally in the first 24 h*, then *0.6 mg once or twice daily* until resolution.
 - **Systemic glucocorticoids** — *oral prednisone 30–50 mg/day tapered over 7–10 days*, useful in polyarticular attacks or where NSAIDs/colchicine are contraindicated.
 - **IL-1 β antagonists (anakinra, canakinumab)** for severe polyarticular attacks or when conventional therapy fails/is contraindicated.
 - Adjuncts: ice-pack application and rest of the involved joint.
- ▶ **Recurrent attacks (≥ 3 per year)** — prophylactic **low-dose colchicine 0.6 mg once or twice daily** reduces flare frequency.
- ▶ **Chronic CPPD arthritis** — there is **no agent that dissolves or removes CPP crystals** from cartilage (a crucial contrast with urate-lowering therapy in gout). Symptomatic options for chronic synovitis include NSAIDs, colchicine, low-dose glucocorticoids, **hydroxychloroquine** or **methotrexate**. **Treat any underlying metabolic cause** (e.g. iron depletion in haemochromatosis, magnesium repletion). Progressive destructive large-joint arthropathy may require **joint replacement**.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Compensated polarized-light comparison of CPP vs MSU crystals**: draw two adjacent panels. *Panel A (CPPD)* — short rhomboid/rod-shaped crystals, one lying intracellularly within a neutrophil; label “**weakly POSITIVELY birefringent — blue when parallel to compensator axis**”. *Panel B (gout)* — long needle-shaped crystals; label “**strongly NEGATIVELY birefringent — yellow when parallel**”. Add common axis label “slow axis of red compensator”.
- ▶ **Knee radiograph showing chondrocalcinosis**: outline the knee joint with **linear/punctate calcific deposits in the meniscal fibrocartilage** and a thin line of **hyaline articular cartilage calcification**. Labels: *menisci (fibrocartilage), hyaline articular cartilage, chondrocalcinosis, joint-space narrowing/osteophyte (pseudo-OA)*.

Clinical / Diagnostic significance

- ▶ CPPD is a leading cause of **acute monoarthritis in the elderly** and a key mimic of **gout and septic arthritis** — every acute hot joint warrants aspiration for crystals, Gram stain and culture.
- ▶ **Chondrocalcinosis on imaging in a patient <50 years** is a red flag mandating screening for **haemochromatosis, hyperparathyroidism, hypophosphatasia and hypomagnesaemia** — diagnosing these may avert systemic complications.
- ▶ The **crowned dens syndrome** is an important reversible cause of acute neck pain with fever and raised inflammatory markers that can be misdiagnosed as meningitis or giant cell arteritis.
- ▶ Recognising **pseudo-OA / pseudo-RA / pseudo-neuropathic** patterns prevents misdiagnosis and inappropriate therapy.

High-yield exam pointers

- ▶ CPP crystals = **rhomboid, weakly POSITIVELY birefringent**; MSU = **needle-shaped, strongly NEGATIVELY birefringent** (the single most-tested discriminator).
- ▶ **Knee** is the commonest joint in pseudogout; **podagra** is **characteristically rare** (unlike gout).
- ▶ **Chondrocalcinosis** = linear/punctate cartilage calcification; **presumptive of CPPD** when no effusion is obtainable.
- ▶ Secondary causes — **4 H's: Hyperparathyroidism, Haemochromatosis, Hypophosphatasia, Hypomagnesaemia** ($\pm$ thiazide/loop diuretics).
- ▶ **Parathyroidectomy** and **major surgery (24–48 h post-op)** are classic precipitants via abrupt falls in $\text{Ca}^{2+}/\text{Mg}^{2+}$.
- ▶ Central pathogenesis = **excess inorganic pyrophosphate** from ATP breakdown; **ANKH** gene mutation in familial/sporadic disease.
- ▶ Acute attacks: **aspiration + intra-articular steroid, NSAIDs, colchicine, prednisone**; refractory $\rightarrow$ **anakinra/canakinumab**.
- ▶ **No crystal-dissolving (urate-lowering equivalent) therapy** exists for CPPD — management is anti-inflammatory plus treatment of any underlying metabolic cause.
- ▶ Up to 50% have **fever** during attacks (up to 40°C) $\rightarrow$ always exclude **septic arthritis** by culture.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22nd edition** — “Gout and Other Crystal-Associated Arthropathies” (pathogenesis, **ANKH**/pyrophosphate mechanism, Table of associated conditions, clinical patterns, crystal morphology and treatment).

Classify the biological agents used in the treatment of rheumatoid arthritis. What are the adverse effects and contraindications to their use

Asked in: Paper I 06 Apr 2026 — RGUHS MD General Medicine

Definition / Introduction — Rheumatoid arthritis (RA) is a chronic, symmetric, erosive inflammatory polyarthritis driven by dysregulated cytokine and cellular immunity. **Biologic disease-modifying antirheumatic drugs (biologic DMARDs / bDMARDs)** are protein therapeutics engineered to target specific cytokines or cell-surface molecules in this inflammatory cascade. Introduced in 1999, they have revolutionised RA management by reducing signs and symptoms, retarding radiographic joint damage, and improving function. They are typically added when conventional synthetic DMARDs (especially methotrexate) fail to achieve low disease activity, and are usually given **in combination with background methotrexate** within a “treat-to-target” strategy.

Classification of biologic agents used in RA

Biologics are best classified by their molecular target and mechanism of action:

Class (target)	Agents	Molecular nature / mechanism
TNF- α inhibitors (5 innovators)	Infliximab; Adalimumab; Golimumab; Certolizumab pegol; Etanercept	Infliximab = chimeric (mouse-human) anti-TNF mAb; adalimumab & golimumab = human(ized) anti-TNF mAbs; certolizumab = PEGylated Fab' fragment of a humanized mAb; etanercept = soluble TNF-receptor-2-IgG1 Fc fusion protein . All neutralise TNF- α , a pivotal upstream cytokine of synovitis
T-cell co-stimulation blocker	Abatacept	Soluble fusion protein of extracellular CTLA-4 + modified human IgG Fc; blocks the CD28-CD80/86 second signal, inhibiting T-cell activation
B-cell depletion (anti-CD20)	Rituximab	Chimeric mAb against CD20 on mature B lymphocytes $\rightarrow$ B-cell depletion; approved for RA refractory to a TNF inhibitor; more effective in seropositive (RF/ACPA+) disease

Class (target)	Agents	Molecular nature / mechanism
IL-6 receptor inhibitors	Tocilizumab; Sarilumab	mAbs against membrane-bound and soluble IL-6 receptor; block acute-phase response, osteoclast activation
IL-1 receptor antagonist	Anakinra	Recombinant human IL-1 receptor antagonist; limited RA use owing to weaker efficacy than other bDMARDs

Biosimilars — agents with the same active properties as a licensed reference biologic (e.g. of infliximab, etanercept, adalimumab); demonstrate comparable efficacy and safety.

Related but distinct — **targeted synthetic DMARDs (tsDMARDs)**: The oral JAK inhibitors *tofacitinib* (JAK1/3), *baricitinib* (JAK1/2) and *upadacitinib* (selective JAK1) target intracellular signalling. They are **not biologics** (they are small molecules), but are often examined alongside them as the modern “targeted” therapy; their adverse-effect profile is summarised below for completeness.

Mechanism and standard adult dosing

Agent	Route & dose (Harrison Table 370-2)
Infliximab	3 mg/kg IV at weeks 0, 2, 6, then every 8 weeks (may ↑ to 10 mg/kg q4 weeks)
Etanercept	50 mg SC weekly (or 25 mg SC twice weekly)
Adalimumab	40 mg SC every other week
Golimumab	50 mg SC monthly
Certolizumab pegol	400 mg SC at weeks 0, 2, 4, then 200 mg every other week
Abatacept	Weight-based IV (<60 kg: 500 mg; 60–100 kg: 750 mg; >100 kg: 1000 mg) at weeks 0, 2, 4, then q4 weeks; OR 125 mg SC weekly
Rituximab	1000 mg IV × 2 (days 0 and 14); repeat course every ≥24 weeks; premedicate with methylprednisolone 100 mg
Tocilizumab	4–8 mg/kg IV monthly; OR 162 mg SC every other week (<100 kg) / weekly (≥100 kg)
Sarilumab	200 mg SC every other week
Anakinra	100 mg SC daily

Adverse effects

Common to all biologics — **increased infection risk** is the dominant class effect: serious bacterial infections, opportunistic fungal infection, and **reactivation of latent tuberculosis** (most marked with TNF inhibitors, which characteristically cause granulomatous/TB reactivation). Live-vaccine responses are blunted.

- ▶ **TNF- α inhibitors:** $\uparrow$ bacterial and fungal infections; **reactivation of latent TB**; infusion reactions (IV infliximab; rarely anaphylaxis) and injection-site reactions (SC agents); raised LFTs; **drug-induced lupus** (induction of anti-dsDNA antibodies); **demyelinating/neurologic deficits** resembling multiple sclerosis (rare); possible $\uparrow$ lymphoma risk (controversial — most observational data show no excess malignancy); worsening of moderate–severe heart failure.
- ▶ **Abatacept:** $\uparrow$ risk of bacterial and viral infection; can **blunt vaccine responses**.
- ▶ **Rituximab:** mild–moderate infusion reactions; $\uparrow$ infection; **hepatitis B reactivation**; cytopenias; rare **progressive multifocal leukoencephalopathy (PML)** ($\approx 1:25,000$, mostly with prior immunosuppression); markedly inhibits vaccine response (e.g. to SARS-CoV-2 vaccine).
- ▶ **IL-6 receptor inhibitors (tocilizumab, sarilumab):** $\uparrow$ infection; **neutropenia and thrombocytopenia** (reversible on stopping); **LFT elevation**; **dyslipidaemia** ($\uparrow$ LDL cholesterol); $\uparrow$ rate of **gastrointestinal perforation**.
- ▶ **Anakinra:** injection-site reactions; $\uparrow$ bacterial/viral infection; neutropenia.
- ▶ **JAK inhibitors (tsDMARDs):** $\uparrow$ infection including **herpes zoster**; raised transaminases; dyslipidaemia; neutropenia; **thrombosis/VTE**; **major adverse cardiovascular events (MACE)** and malignancy — these carry an **FDA black-box warning** (highest risk in the elderly, from the tofacitinib-vs-TNFi safety trial); $\uparrow$ creatinine and hypertension.

Contraindications & pre-treatment screening

- ▶ **Active infection** of any kind — a contraindication to starting (and reason to suspend) any biologic.
- ▶ **Untreated latent TB** — *all* candidates must be screened with a **tuberculin skin test** (Mantoux/PPD) or **interferon- γ release assay (IGRA)** before therapy; if positive, treat LTBI for at least 1 month before starting.
- ▶ **TNF- α inhibitors specifically:** contraindicated in **chronic/active hepatitis B**, **NYHA class III/IV congestive heart failure**, and prior **hypersensitivity**; use cautiously in demyelinating disease (relative).
- ▶ **Rituximab:** active hepatitis B (risk of reactivation) — **viral hepatitis screening** (HBsAg, anti-HBc, HCV antibody) **mandatory** before use.
- ▶ **IL-6 receptor inhibitors:** avoid where possible in **diverticulitis** or recent **gastric/duodenal ulcer** (GI perforation risk); pre-existing significant neutropenia/thrombocytopenia or transaminitis.
- ▶ **Pregnancy:** anti-TNF agents are generally regarded as acceptable but are **discontinued in the third trimester**; data are insufficient for abatacept, anti-IL-6, rituximab and JAK inhibitors, so

these are **stopped at conception**. (The teratogenic conventional DMARDs **methotrexate** and **leflunomide** are absolutely contraindicated in pregnancy, but are not biologics.)

- **General:** live vaccines should not be given during biologic therapy; combining two biologics is not recommended (no added efficacy, additive toxicity).

Baseline work-up before any biologic: TB screen (PPD/IGRA), viral hepatitis panel (especially for TNF inhibitors and rituximab), CBC and LFTs; with periodic monitoring of CBC, LFTs and lipids thereafter.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- **Diagram 1 — “Cytokine/cell targets of biologic DMARDs in the rheumatoid synovium”:**
Draw an antigen-presenting cell (APC) presenting via MHC-II/peptide-TCR to a CD4⁺ T cell, with the CD80/86-CD28 co-stimulation pair, a B cell/plasma cell producing RF/ACPA, and a macrophage/fibroblast secreting TNF- α , IL-1, IL-6, driving an osteoclast (RANKL). Label each biologic at its target: TNF inhibitors $\rightarrow$ TNF- α ; Abatacept $\rightarrow$ CD80/86-CD28; Rituximab $\rightarrow$ CD20 (B cell); Tocilizumab/Sarilumab $\rightarrow$ IL-6 receptor; Anakinra $\rightarrow$ IL-1 receptor; JAK inhibitors $\rightarrow$ intracellular JAK-STAT (label as tsDMARD).
- **Diagram 2 — “Treat-to-target ladder”:** NSAIDs/short glucocorticoid $\rightarrow$ Methotrexate (anchor) $\rightarrow$ +conventional combination (oral triple therapy) $\rightarrow$ add anti-TNF or non-TNF biologic $\pm$ MTX $\rightarrow$ switch biologic class / JAK inhibitor. Label the goal box: low disease activity / remission.

Clinical / Diagnostic significance

- **Sequencing:** methotrexate remains the **anchor/first-choice DMARD**; a biologic (usually anti-TNF) is added on inadequate response after 3–6 months. Combination of methotrexate + anti-TNF is superior to methotrexate alone for both symptoms and radiographic progression.
- **Switching:** patients failing one anti-TNF may respond to a **second anti-TNF** or to a **different mechanism** (abatacept, rituximab, IL-6 inhibitor); some evidence favours switching class (e.g. to abatacept) over a second anti-TNF.
- **Serostatus guides choice:** rituximab is more effective in RF/ACPA-positive disease.
- **Monitoring:** vigilance for infection (suspend during febrile illness), serial CBC/LFTs/lipids; IL-6 inhibitors mask CRP/ESR, so acute-phase reactants are unreliable for detecting infection.
- **Comorbidity steering:** avoid TNF inhibitors in advanced heart failure and hepatitis B; avoid IL-6 inhibitors in diverticular disease; reserve JAK inhibitors cautiously in the elderly and those with cardiovascular/thrombotic/malignancy risk.
- **Extra-articular disease:** rituximab is useful for RA-associated interstitial lung disease (with corticosteroids $\pm$ azathioprine/MMF).

High-yield exam pointers

- ▶ Five TNF inhibitors: **infliximab** (chimeric mAb), **adalimumab**, **golimumab** (human mAbs), **certolizumab pegol** (PEGylated Fab'), **etanercept** (TNFR2–Fc fusion protein).
- ▶ **Abatacept** = CTLA-4-Ig (co-stimulation block); **rituximab** = anti-CD20 (B-cell depletion); **tocilizumab/sarilumab** = anti-IL-6R; **anakinra** = IL-1Ra.
- ▶ **JAK inhibitors (tofacitinib, baricitinib, upadacitinib) are targeted synthetic DMARDs, NOT biologics — oral, JAK-STAT pathway, carry an FDA black-box warning* (MACE, malignancy, thrombosis, death).*
- ▶ Class hazard = **infection + latent TB reactivation** → screen with PPD/IGRA in all; treat LTBI before starting.
- ▶ TNF inhibitors are contraindicated in **chronic hepatitis B**, **NYHA III/IV heart failure**; can cause **drug-induced lupus** and **demyelination**.
- ▶ **Rituximab**: hepatitis B reactivation, rare PML; check viral hepatitis panel first.
- ▶ **IL-6 inhibitors**: dyslipidaemia, cytopenias, **GI perforation** (avoid in diverticulitis).
- ▶ **Live vaccines contraindicated**; do **not** combine two biologics; anti-TNF stopped in third trimester.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e — "Rheumatoid Arthritis"** (classification, molecular design, dosing Table 370-2, adverse effects and contraindications, treat-to-target approach).

Classify vasculitis based on the pathology. Give the ACR classification criteria for any one type of vasculitis

Asked in: Paper I May 2025 — RGUHS MD General Medicine

Definition / Introduction — Vasculitis is a clinicopathologic process characterised by **inflammation of and damage to blood vessel walls**, with luminal compromise leading to ischaemia of the tissues supplied. Because *any* type, size and location of vessel may be involved, the result is a broad, heterogeneous and overlapping group of syndromes that may be primary or secondary, single-organ or multisystem. Classification is anchored on the **dominant calibre of vessel involved** (the basis of the *Chapel Hill Consensus Conference, CHCC 2012* nomenclature), refined by the **immunopathological**

mechanism (immune-complex deposition, ANCA, or T-cell/granuloma formation) and by features such as granuloma, ANCA status and artery-vs-vein involvement.

Basis of pathological classification

- ▶ **Size of predominant vessel** — large, medium or small (the first and most important discriminator).
- ▶ **Type of vessel** — artery only, vein, or both.
- ▶ **Presence/absence of granulomatous inflammation** on biopsy.
- ▶ **Immune mechanism** — immune-complex (with vessel-wall immunoglobulin/complement deposition) versus *pauci-immune* (ANCA-associated, scant immunoglobulin) versus cell-mediated/granulomatous.
- ▶ **Demography & associations** — age, sex, ethnicity, smoking, and any underlying trigger (infection, drug, connective-tissue disease, malignancy).

Classification by vessel size (Chapel Hill Consensus Conference 2012)

Predominant vessel	Syndromes	Characteristic pathology
Large vessel (aorta + major branches)	Takayasu arteritis; Giant cell (temporal) arteritis	Granulomatous panarteritis, mononuclear infiltrate, giant cells, fragmentation of internal elastic lamina
Medium vessel (main visceral/muscular arteries)	Polyarteritis nodosa (PAN); Kawasaki disease	Necrotising arteritis, fibrinoid necrosis, micro-aneurysms; <i>no</i> glomerulonephritis or granuloma in PAN
Small vessel — ANCA-associated (pauci-immune)	Granulomatosis with polyangiitis (GPA); Microscopic polyangiitis (MPA); Eosinophilic granulomatosis with polyangiitis (EGPA, Churg-Strauss)	Necrotising vasculitis of capillaries/venules/arterioles with <i>few or no</i> immune deposits; granuloma in GPA & EGPA; eosinophilia in EGPA
Small vessel — immune-complex	IgA vasculitis (Henoch-Schönlein); Cryoglobulinaemic vasculitis; Hypocomplementaemic urticarial (anti-C1q) vasculitis; Anti-GBM disease	Vessel-wall immune-complex/immunoglobulin deposition (e.g. IgA, cryoglobulins)
Variable vessel	Behçet disease; Cogan syndrome	May affect small, medium and large vessels; arteries <i>and</i> veins
Single-organ	Cutaneous leukocytoclastic angiitis; cutaneous arteritis; primary CNS vasculitis; isolated aortitis	Confined to one organ without systemic spread

Predominant vessel	Syndromes	Characteristic pathology
Associated with systemic disease	Lupus, rheumatoid, sarcoid vasculitis	Secondary to a defined connective-tissue/systemic illness
Associated with probable aetiology	HBV-associated (PAN-like); HCV-associated cryoglobulinaemic; drug-induced; cancer-associated	Identifiable antigenic trigger

Classification by immunopathogenic mechanism (pathology of vessel injury)

Dominant mechanism	Representative syndromes
Pathogenic immune-complex formation / deposition	IgA vasculitis (HSP); lupus vasculitis; serum-sickness & cutaneous vasculitis; HCV cryoglobulinaemic; HBV-associated
ANCA production (pauci-immune)	GPA (PR3/cANCA), MPA (MPO/pANCA), EGPA (MPO)
Pathogenic T-lymphocyte response & granuloma formation	Giant cell arteritis; Takayasu arteritis; GPA; EGPA

- ▶ ANCA serology further subdivides small-vessel disease: *cANCA/anti-proteinase-3* in >90% of active GPA; *pANCA/anti-myeloperoxidase* in ~75% of MPA and ~48% of EGPA. Up to 20% of GPA may be ANCA-negative.
- ▶ Renal lesion of GPA/MPA is a **pauci-immune crescentic glomerulonephritis** (no immune-complex deposition), distinguishing it from immune-complex small-vessel disease.

ACR classification criteria — Giant Cell (Temporal) Arteritis (1990 ACR criteria — featured example)

Classification criteria are designed to define a homogeneous patient population for study (and to distinguish one vasculitis from another once vasculitis is established) — they are not strict diagnostic criteria.

#	Criterion	Definition
1	Age at onset ≥ 50 years	Development of symptoms/findings beginning at age 50 or older
2	New headache	New onset of, or new type of, localised pain in the head
3	Temporal artery abnormality	Temporal artery tenderness to palpation or decreased pulsation, unrelated to arteriosclerosis of cervical arteries

#	Criterion	Definition
4	Elevated ESR	Erythrocyte sedimentation rate ≥ 50 mm/h (Westergren method)
5	Abnormal artery biopsy	Vasculitis with a predominance of mononuclear-cell infiltration or granulomatous inflammation, usually with multinucleated giant cells

- **Classification** is satisfied when ≥ 3 of 5 criteria are present $\rightarrow$ sensitivity **93.5%**, specificity **91.2%**.
- *Alternative example — GPA (1990 ACR):* (1) nasal/oral inflammation (oral ulcers or purulent/bloody nasal discharge); (2) abnormal chest radiograph (nodules, fixed infiltrates or cavities); (3) abnormal urinary sediment (microhaematuria >5 RBC/hpf or red-cell casts); (4) granulomatous inflammation on biopsy. ≥ 2 of 4 $\rightarrow$ sensitivity $\sim 88\%$, specificity $\sim 92\%$.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- **Vessel-size “tree” of vasculitis** — three concentric/parallel columns labelled **Large, Medium, Small**; place under each: Large $\rightarrow$ *Takayasu, Giant cell arteritis*; Medium $\rightarrow$ *PAN, Kawasaki*; Small $\rightarrow$ split into *ANCA-associated (GPA, MPA, EGPA)* and *Immune-complex (IgA vasculitis, cryoglobulinaemic, anti-GBM, urticarial)*; side boxes for *Variable vessel (Behçet, Cogan)* and *Single-organ*. Label overlapping zone “small + medium overlap (ANCA disease, PAN).”
- **Cross-section of an inflamed artery** — label: *lumen, thrombus, fibrinoid necrosis of media, transmural mononuclear/neutrophil infiltrate, fragmented internal elastic lamina, multinucleated giant cell, granuloma, adventitia/vasa vasorum.*

Clinical / Diagnostic significance

- **Vessel size predicts the clinical picture:** large-vessel $\rightarrow$ limb claudication, asymmetric BP/absent pulses, bruits, aortic dilatation; medium-vessel $\rightarrow$ cutaneous nodules, livedo reticularis, digital gangrene, mononeuritis multiplex, micro-aneurysms; small-vessel $\rightarrow$ palpable purpura, glomerulonephritis/haematuria, alveolar haemorrhage, splinter haemorrhages, scleritis.
- **Workup sequence:** consider vasculitis in any unexplained multisystem illness (palpable purpura, pulmonary infiltrates + haematuria, chronic sinusitis, mononeuritis multiplex, glomerulonephritis); **first exclude mimics** (endocarditis, atrial myxoma, cholesterol emboli, antiphospholipid syndrome, drug toxicity e.g. cocaine/levamisole). Confirm by **biopsy of involved tissue**; use **catheter angiography** when PAN, Takayasu or primary CNS vasculitis is suspected (micro-aneurysms / stenoses).
- **Serology directs categorisation:** PR3-ANCA, MPO-ANCA, cryoglobulins, complement, hepatitis B & C serology, eosinophil count.

- ▶ **Treatment is category-driven:** GPA/MPA — induction with **cyclophosphamide 2 mg/kg/day** *or* **rituximab 375 mg/m²/week ×4** + glucocorticoids ± **avacopan** (C5a-receptor inhibitor), then azathioprine/methotrexate/rituximab maintenance; GCA — **prednisone 40–60 mg/day** (urgent, to prevent blindness) ± **tocilizumab** (IL-6R); EGPA — glucocorticoids ± **mepolizumab** (anti-IL-5). Always weigh relapse risk and immunosuppression toxicity.

High-yield exam pointers

- ▶ First step in classifying vasculitis = **size of the dominant vessel** (large / medium / small) — CHCC 2012.
- ▶ **Pauci-immune** = ANCA-associated (GPA, MPA, EGPA); **immune-complex** = IgA vasculitis, cryoglobulinaemic, anti-GBM, urticarial.
- ▶ **GPA** = upper + lower airway granulomatous vasculitis + glomerulonephritis; PR3-cANCA >90%; saddle-nose, subglottic stenosis.
- ▶ **PAN** = medium-vessel necrotising arteritis, **sparing the lungs**, no glomerulonephritis/granuloma, HBV-associated, renal micro-aneurysms; ANCA usually negative; consider **DADA2** in early-onset disease.
- ▶ **GCA** = age >50, new headache, jaw claudication, ESR ≥50, temporal artery biopsy giant cells; dreaded complication = **anterior ischaemic optic neuropathy / blindness** — treat *before* biopsy.
- ▶ **Takayasu** = “pulseless disease” of young women, aortic arch and branches.
- ▶ **ACR classification** criteria define study populations (homogeneity) — they are **not** diagnostic criteria; e.g. GCA 3 of 5, GPA 2 of 4.
- ▶ EGPA triad = **asthma + eosinophilia (>1000/μL) + vasculitis**; MPO-ANCA in ~48%.

SOURCE & COVERAGE

- ▶ **Harrison’s Principles of Internal Medicine, 22e** — “The Vasculitis Syndromes” (classification tables, pathogenic mechanisms — immune-complex / ANCA / T-cell granuloma; syndrome-by-syndrome pathology and treatment).
- ▶ **CMDT 2026** — “Vasculitis Syndromes / Rheumatologic, Immunologic & Allergic Disorders” (classification scheme by size of predominant vessel — Table 23–11; clinical manifestations by vessel size — Table 23–12; revised International Chapel Hill Consensus Conference nomenclature, Jennette et al. 2012; current management).
- ▶ **Coverage note:** The provided corpus (Harrison 22e, CMDT 2026) tabulates the **vessel-size/CHCC classification** and pathogenic mechanisms fully, and references the **2022 ACR/EULAR** classification criteria for GCA, Takayasu and GPA, but does **not** reproduce the older **1990 ACR item-level classification criteria** as a list. The 1990 ACR criteria for giant cell arteritis (and GPA) given above are **universally accepted standard internal medicine** (Hunder et al., *Arthritis Rheum* 1990) and are supplied to satisfy the “give the

ACR criteria” stem; the cut-offs and sensitivity/specificity quoted are the published ACR figures.

Behçet Syndrome — Clinical Features, Evaluation, and Treatment

Asked in: Paper III 15 Apr 2026 — RGUHS MD General Medicine

Definition / Introduction — Behçet syndrome is a chronic, relapsing **systemic vasculitis** of unknown cause, first described by the Turkish dermatologist *Hulusi Behçet*. It is unique among the vasculitides in being able to involve **vessels of all sizes (small, medium and large)** on **both the venous and arterial side** of the circulation. It is characterised clinically by **recurrent oral and genital aphthous ulcers**, skin lesions, **uveitis**, **arthritis**, **vascular thrombosis**, and **gastrointestinal and neurological involvement**, occurring in varying combinations and sequence over time. The diagnosis is purely **clinical** — there is no pathognomonic laboratory, imaging or histological test.

Epidemiology and Pathogenesis

- ▶ **Geographic distribution** — clusters along the ancient “*Silk Road*”: highest in the **Middle East, Mediterranean region and Far East**. Most prevalent in **Turkey** (≈ 1 in 250 adults).
- ▶ **Age/sex** — relatively rare before the late teens and after age 50. Males and females are affected equally, but **males generally have more severe disease and poorer outcomes**.
- ▶ **Regional variation in phenotype** — gastrointestinal involvement is rare in Turkey but common in Japan and is seen in $\sim 30\%$ of US patients.
- ▶ **Pathogenesis (unknown)** — a probable **genetic predisposition** with activation of both **innate and adaptive immunity**; **neutrophil hyperreactivity** is characteristic. **HLA-B*51** is positive in ~ 50 – 60% of patients (but in $\sim 20\%$ of the normal population, so it is *not* diagnostic).
- ▶ **Not a classic autoimmune disease** — typically **no autoantibodies**, and not associated with Raynaud’s phenomenon, Sjögren’s, thrombocytopenia, haemolytic anaemia, photosensitivity or serositis. It also differs from autoinflammatory disorders (e.g. familial Mediterranean fever) by its tendency to **abate with time** and absence of the relevant gene mutations.

Clinical Features (organ-system approach)

- ▶ **Mucocutaneous (the hallmark and usually the first manifestation)**
 - **Oral aphthous ulcers** — seen in *virtually all* patients ($\sim 98\%$); usually multiple, resemble canker sores, last ~ 10 days and recur; only the uncommon **major ulcers scar**.
 - **Genital ulcers** — the **most specific lesion** ($\sim 80\%$); on **scrotum or labia**, larger, deeper, slower to heal and **tend to scar**.

- **Skin lesions** — **papulopustular/acne-like** lesions (indistinguishable from acne vulgaris), **erythema nodosum**-like nodules (panniculitis), and **superficial thrombophlebitis**. Superficial thrombophlebitis occurs in men and flags a need to screen for deeper vascular involvement (including pulmonary artery aneurysms).
- ▶ **Ocular** — in ~half of patients (**up to ~70% of males**); typically a **bilateral panuveitis**. Hypopyon (layered pus in the anterior chamber) occurs in ~10% of those with eye disease and is **quite specific**. Posterior uveitis/retinal venulitis can silently destroy the retina. **Poor prognostic factors:** *male sex, posterior involvement, >3 attacks/year, dense vitreous opacity, macular oedema*.
- ▶ **Articular** — arthralgia/arthritis in about half (CMDT: up to two-thirds); usually a **non-erosive, non-deforming mono- or oligoarthritis** of the lower limbs (knees, ankles).
- ▶ **Vascular** — in up to 40%; intense, **relapsing thrombosis**. Venous lesions cluster: **superficial and deep-vein thrombosis, Budd-Chiari syndrome, inferior vena cava syndrome, intracardiac thrombosis, cerebral venous sinus thrombosis, and pulmonary artery aneurysms**. Pulmonary artery aneurysms carry a 5-year mortality of 20–25% and can cause fatal haemorrhage.
- ▶ **Neurological** (“neuro-Behçet”, ~5%) — two largely **mutually exclusive** forms:
 - **Parenchymal** (~three-quarters) — affects the **telencephalic–diencephalic junction, brainstem and spinal cord**; subacute severe headache, cranial-nerve palsy, dysarthria, ataxia, hemiparesis. May radiologically **mimic multiple sclerosis**.
 - **Non-parenchymal** — **cerebral venous sinus thrombosis** (headache, raised intracranial pressure). Sterile meningitis with lymphocytic pleocytosis may occur.
- ▶ **Gastrointestinal** — frequency varies widely (up to ~50% in the Far East, rare in the Middle East). Ulcers are usually **single or <5, confined to the ileocaecal region, deep, round and prone to perforation**; perianal/rectal disease is rare. **Difficult to distinguish from Crohn’s disease** unless extra-intestinal features are present.

Evaluation and Diagnosis

- ▶ **Diagnosis is clinical** — based on the constellation of features after *excluding mimics*. Some patients take months to years to evolve the full picture.
- ▶ **International Study Group (ISG) criteria** — most widely used; sensitivity ~95%, specificity ~96%:

Criterion	Frequency	Comments
Recurrent oral ulcers (<i>mandatory</i>)	~98%	At least 3 times in a 12-month period
<i>Plus two of the following four:</i>		
Recurrent genital ulcers	~80%	Usually scarring

Criterion	Frequency	Comments
Skin lesions	~80%	Erythema nodosum, pseudofolliculitis, papulopustular/acneiform nodules (post-adolescent, not on corticosteroids)
Eye lesions	~50%	Anterior or posterior uveitis, cells in vitreous, or retinal vasculitis
Positive pathergy test	~50%	Read at 24–48 h after dermal prick with a 20–21-gauge needle

- ▶ **Pathergy test** — non-specific cutaneous hyper-reactivity to trauma: a **papule/pustule develops at 24–48 h** after a needle prick. Rather unique to Behçet and part of the ISG criteria (positivity is higher in Mediterranean/Far-Eastern populations).
- ▶ **Laboratory** — *no pathognomonic test* and **no specific autoantibody**; acute-phase reactants (ESR/CRP) are often raised. **HLA-B51** supports but does not confirm the diagnosis.
- ▶ **Targeted work-up by organ involvement** — slit-lamp/ophthalmological assessment and fluorescein angiography for uveitis; **MRI brain/MR venography** for neuro-Behçet (and CSF showing lymphocytic pleocytosis); **CT/MR angiography or Doppler** for venous thrombosis and pulmonary artery aneurysms; **ileocolonoscopy** for GI ulcers (to differentiate from Crohn's).

Treatment

General principles: therapy is tailored to the **type and severity of organ involvement**, aiming to **prevent irreversible damage**. Most new manifestations appear within the **first 5 years**, and the natural course is one of diminishing activity toward potential remission; **glucocorticoids are tapered** once disease is controlled, while **immunosuppressants are continued ≥ 2 years** and tapering/stopping is attempted at 2–3 years. **Young male patients** warrant more aggressive treatment owing to worse prognosis.

Manifestation	Preferred management
Oral/genital ulcers & mucocutaneous	Topical glucocorticoids for mild/as-needed; colchicine (0.6 mg 1–3×/day) for nodular/genital lesions; if resistant — oral glucocorticoids, apremilast (PDE-4 inhibitor, <i>FDA-approved for oral ulcers</i>), azathioprine , or a TNF-α inhibitor (infliximab)
Ocular (uveitis)	Early, aggressive therapy — brief glucocorticoid courses + long-term immunosuppression; azathioprine is the usual first choice; infliximab or adalimumab (first-line monotherapy or with steroid + azathioprine); cyclosporine or interferon-α are alternatives

Manifestation	Preferred management
Gastrointestinal	Glucocorticoids plus an immunosuppressant (azathioprine alone or with infliximab)
Venous thrombosis	Treat the inflammation with immunosuppressants (azathioprine; cyclophosphamide for severe disease) rather than relying on anticoagulation. Standard anticoagulation may be added only if bleeding risk is low and there are no coexistent pulmonary artery aneurysms
CNS (neuro-Behçet)	Combination of azathioprine + a TNF inhibitor is usually first choice (glucocorticoids for acute attacks)
Severe/refractory systemic disease	Higher-dose glucocorticoids (prednisone ~1 mg/kg/day) plus cyclophosphamide or TNF inhibitor ; <i>Saadoun 2024 (NEJM Evid)</i> trial compared infliximab vs cyclophosphamide for severe disease

- **Key caveat:** anticoagulation is **contraindicated/avoided** when **pulmonary artery aneurysms** coexist because of the risk of fatal haemorrhage — immunosuppression is the cornerstone of vascular Behçet.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- “Clinical map of Behçet syndrome” — a central figure with labelled arrows to: *Oral aphthous ulcer (~98%), Genital ulcer (scrotum/labia — most specific), Skin: erythema nodosum / papulopustular / superficial thrombophlebitis, Eye: bilateral panuveitis with hypopyon, Joint: non-erosive lower-limb oligoarthritis, Vessel: DVT / Budd-Chiari / pulmonary artery aneurysm, CNS: brainstem parenchymal lesion / cerebral venous sinus thrombosis, Gut: ileocaecal deep round ulcers.*
- “ISG diagnostic criteria pyramid” — base = **mandatory recurrent oral ulcers (≥3×/12 months)**; second tier = **need 2 of 4: genital ulcers · skin lesions · eye lesions · positive pathergy**; with a side-box labelled *Pathergy: 20–21G needle prick → read papule/pustule at 24–48 h.*

Clinical / Diagnostic significance

- A **clinical diagnosis of exclusion** — investigations chiefly **rule out mimics** (ANCA-associated vasculitis, IBD/Crohn’s, celiac disease, HIV/histoplasmosis, complex aphthosis, pemphigus, lichen planus).
- **Hypopyon uveitis** and **positive pathergy** are the most specific bedside clues; HLA-B51 supports but never confirms.

- ▶ **Pulmonary artery aneurysm + thrombosis** is a feared, high-mortality combination — recognise that anticoagulation can be lethal here.
- ▶ **Neuro-Behçet** can masquerade as multiple sclerosis on MRI — differentiate by mucocutaneous/systemic features and CSF pattern.
- ▶ GI Behçet vs Crohn's is a recurring exam discriminator — **few (<5), deep, round, ileocaecal, perforation-prone** ulcers favour Behçet.

High-yield exam pointers

- ▶ Systemic vasculitis affecting ALL vessel sizes, both arterial and venous — the distinguishing one-liner.
- ▶ **ISG criteria:** recurrent oral ulcers ($\geq 3 \times / \text{yr}$) + 2 of 4 (genital ulcers, skin lesions, eye lesions, pathergy); sens ~95%, spec ~96%.
- ▶ **Genital ulcer = most specific lesion; hypopyon = highly specific eye sign; pathergy = read at 24–48 h.**
- ▶ HLA-B51 positive in ~50–60% of patients (not diagnostic).
- ▶ **Pulmonary artery aneurysm** → 5-year mortality 20–25%.
- ▶ Vascular/venous disease is treated with immunosuppression, not primarily anticoagulation; avoid anticoagulants if PA aneurysms coexist.
- ▶ **Apremilast** (PDE-4 inhibitor) is FDA-approved for oral ulcers; **azathioprine** is the workhorse immunosuppressant; **TNF inhibitors (infliximab/adalimumab)** for severe ocular, GI and CNS disease.
- ▶ Worse prognosis in **young males**; most manifestations appear in the **first 5 years** then tend to abate.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Behçet Syndrome” (epidemiology, pathogenesis, ISG criteria, organ-specific clinical features, and the treatment section continuing into the adjacent chapter file).
- ▶ **CMDT 2026** — “Behçet Disease” (Rheumatologic, Immunologic & Allergic Disorders) — current clinical findings, differential diagnosis, and drug regimens (colchicine, apremilast, prednisone 1 mg/kg/day, azathioprine 2 mg/kg/day, TNF inhibitors, cyclophosphamide; infliximab-vs-cyclophosphamide evidence).

Criteria for Systemic Lupus Erythematosus (SLE) diagnosis

Asked in: Paper III May 2022 — RGUHS MD General Medicine

Definition / Introduction — Systemic lupus erythematosus (SLE) is a chronic, multisystem autoimmune disease characterised by loss of immune tolerance, production of autoantibodies to nuclear antigens (especially nucleic acids and nuclear proteins), and immune-complex-mediated inflammation and tissue damage. There is **no single confirmatory test**; the diagnosis is clinical, integrating a compatible multi-organ presentation with serology and *exclusion of mimics*. Standardised **classification criteria** (2019 EULAR/ACR and 2012 SLICC) were devised to enrol homogeneous patients into clinical trials — they are widely used as a structured diagnostic framework but are **not** a substitute for individualised clinical judgement.

Classification vs diagnosis — the cardinal exam point

- ▶ Harrison stresses that classification criteria were **developed for enrolment into clinical trials, not for diagnosis**. For an individual patient, diagnosis is made on the totality of clinical and laboratory features after **excluding other disease entities**, and ultimately rests on **clinical judgement**.
- ▶ Two criteria sets are currently in use for trial enrolment: the **2019 EULAR/ACR** classification criteria and the **2012 SLICC** (Systemic Lupus International Collaborating Clinics) criteria.
- ▶ Important limitation: because EULAR/ACR criteria mandate ANA positivity, they **exclude the ~5% of SLE patients who are ANA-negative**, as well as patients with *incomplete lupus* — both groups still require clinical recognition and management.

Entry criterion — ANA is the gateway

- ▶ The **2019 EULAR/ACR** criteria use a positive **antinuclear antibody (ANA) titre of $\geq 1:80$** (on HEp-2 cells or equivalent) as a **mandatory entry criterion**. If ANA is negative (and was never positive), the patient cannot be classified as SLE by these criteria.
- ▶ ANA is present in **~95%** of SLE patients; a titre of **$\geq 1:80$ is considered positive** — highly **sensitive but not specific**. *Repeatedly negative ANA by immunofluorescence makes SLE unlikely*, though rare ANA-negative cases occur.
- ▶ Only after the entry criterion is satisfied are the **additive weighted clinical and immunological criteria** applied; a **patient requires ≥ 10 points** across the domains to be classified as SLE.

2019 EULAR/ACR additive weighted criteria

Criteria are grouped into **7 clinical** and **3 immunological** domains, each item carrying a weight. Scoring rules: a criterion is counted only if there is **no more likely explanation**; it need occur on **only one occasion**; **at least one clinical criterion** is required; and within each domain **only the single highest-weighted item** is counted. **Total ≥ 10 points (with ANA $\geq 1:80$) = classify as SLE.**

Domain	Representative criteria (highest weight in domain)	Weight
Constitutional	Fever	2
Hematologic	Leukopenia (3); Thrombocytopenia (4); Autoimmune haemolysis (4)	up to 4
Neuropsychiatric	Delirium (2); Psychosis (3); Seizure (5)	up to 5
Mucocutaneous	Non-scarring alopecia / oral ulcers (2); Subacute cutaneous or discoid lupus (4); Acute cutaneous lupus / malar rash (6)	up to 6
Serosal	Pleural/pericardial effusion (5); Acute pericarditis (6)	up to 6
Musculoskeletal	Joint involvement (≥ 2 joints synovitis / tenderness + stiffness)	6
Renal	Proteinuria >0.5 g/24 h (4); biopsy Class II/V LN (8); biopsy Class III/IV LN (10)	up to 10
Antiphospholipid antibodies	Anticardiolipin OR anti- $\beta 2$ - glycoprotein-1 OR lupus anticoagulant	2
Complement proteins	Low C3 OR low C4 (3); low C3 AND C4 (4)	up to 4
SLE-specific antibodies	Anti-dsDNA OR anti-Sm	6

- ▶ Harrison highlights the practically important rule: **no single value reaches 10 points except a renal biopsy showing Class III or IV lupus nephritis** — biopsy-proven proliferative nephritis (with a positive ANA) alone satisfies classification.
- ▶ **Anti-dsDNA and anti-Sm are the only ANA subtypes included** in the EULAR/ACR criteria, reflecting their high specificity.

Other criteria sets — SLICC 2012 and ACR 1997

- ▶ **SLICC 2012:** classify as SLE if ≥ 4 of 17 criteria (11 clinical + 6 immunological) are met, with at least one clinical AND one immunological criterion; OR biopsy-proven lupus nephritis in the presence of ANA or anti-dsDNA. SLICC improved sensitivity over the older ACR set and formally recognised biopsy-proven nephritis as a stand-alone pathway.
- ▶ **ACR 1997 (revised) criteria:** historically, ≥ 4 of 11 criteria (present serially or simultaneously) classify SLE. The 11 items (mnemonic SOAP BRAIN MD): Serositis, Oral ulcers, Arthritis,

Photosensitivity, Blood disorder (cytopenias), Renal disorder, ANA, Immunologic (anti-dsDNA/anti-Sm/antiphospholipid), Neurologic, Malar rash, Discoid rash.

Autoantibody profile supporting the diagnosis

The immunologic, renal and haematologic domains form the laboratory backbone. After a positive ANA, test anti-dsDNA and anti-Sm; if ANA-negative but the picture is highly suggestive, anti-Ro (SS-A) confers a high likelihood of SLE.

Antibody	Prevalence	Diagnostic value / association
ANA	~95%	Best screening test; sensitive, not specific; $\geq 1:80$ positive
Anti-dsDNA	~70%	Higher titres specific for SLE; correlate with activity and nephritis
Anti-Sm	~30%	Most specific autoantibody for SLE
Anti-RNP / U1-RNP	~25% / ~13%	Overlap syndromes; pulmonary hypertension; high IFN signature
Anti-Ro (SS-A)	~30%	Often positive in ANA-negative SLE; sicca, neonatal lupus, congenital heart block, SCLE
Anti-La (SS-B)	~20%	Associated with anti-Ro
Antiribosomal P	~15%	CNS lupus; specific but not sensitive
Antihistone	~70%	Drug-induced lupus
Antiphospholipid (aCL, anti- $\beta 2$ GP-1, lupus anticoagulant)	~50%	Arterial/venous thrombosis, pregnancy loss, thrombocytopenia, Libman-Sacks endocarditis

- ▶ **Low C3/C4** falls during high disease activity; **anti-dsDNA + low complement** indicates a propensity to lupus nephritis and is used to track activity.
- ▶ Baseline work-up: CBC (leukopenia, lymphopenia, thrombocytopenia, anaemia of chronic inflammation/haemolytic anaemia), eGFR, serum creatinine, and **urine protein-to-creatinine ratio (UPCr)**; **renal biopsy when UPCR exceeds 0.5** to exclude active nephritis. Lupus nephritis is graded by the **ISN/RPS classification** (Class I–VI; Class III focal proliferative, IV diffuse proliferative, V membranous).

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Flow algorithm** — “EULAR/ACR 2019 classification”: box 1 **Entry criterion**: ANA $\geq 1:80$ → if negative → not classified; if positive → box 2 **Apply additive weighted criteria** (label the 7 clinical domains: Constitutional, Hematologic, Neuropsychiatric, Mucocutaneous, Serosal, Musculoskeletal, Renal; and 3 immunology domains: Antiphospholipid, Complement, SLE-specific antibodies) → box 3 **Score (count only highest item per domain; ≥ 1 clinical required)** → decision diamond **Total ≥ 10 points?** → Classify as SLE.
- ▶ **Labelled face/hand sketch**: malar (“butterfly”) rash with **nasolabial sparing**; discoid plaques; Jaccoud arthropathy of the hand — label *malar rash, nasolabial sparing, discoid lesion, photosensitive distribution, Jaccoud deformity*.

Clinical / Diagnostic significance

- ▶ Criteria provide a **structured checklist** that improves diagnostic consistency, but a patient may be unequivocally diagnosed clinically **without** meeting classification points (e.g., early or ANA-negative disease) — never withhold treatment because a patient is “one point short.”
- ▶ **Biopsy-proven Class III/IV lupus nephritis** is diagnostically decisive (10 points) and dictates aggressive immunosuppression; renal involvement (~35% of patients) drives prognosis.
- ▶ **Drug-induced lupus (DIL)** is a key differential: ~6–12% of lupus cases; classic triggers **procainamide** (highest risk, up to 30%) and **hydralazine** (first described, 1954), plus isoniazid, minocycline, anti-TNF agents, etc.; **antihistone antibodies** typical, dsDNA usually absent; rarely affects kidney/brain; resolves on stopping the drug.
- ▶ Differentiate from RA (overlap = *rhupus*), mixed connective tissue disease (anti-U1-RNP), Sjögren’s (anti-Ro/La), and primary antiphospholipid syndrome.

High-yield exam pointers

- ▶ Classification criteria = **for trials, not diagnosis**; diagnosis = clinical + lab + exclusion + judgement.
- ▶ **EULAR/ACR 2019**: mandatory entry ANA $\geq 1:80$, then **additive weights, ≥ 10 points** to classify.
- ▶ **No single item = 10 points except renal biopsy Class III/IV LN.**
- ▶ **Anti-dsDNA and anti-Sm are the only ANA subtypes in EULAR/ACR criteria**; anti-Sm = most specific; anti-dsDNA tracks activity/nephritis.
- ▶ **SLICC 2012**: ≥ 4 of 17 (≥ 1 clinical + ≥ 1 immunologic) **OR** biopsy-proven LN with ANA/anti-dsDNA.
- ▶ **ACR 1997**: ≥ 4 of 11 — mnemonic *SOAP BRAIN MD*.
- ▶ ~5% of SLE is **ANA-negative** (anti-Ro often positive) and is excluded by EULAR/ACR.
- ▶ **Low C3/C4 + rising anti-dsDNA** = flag for active disease/nephritis.

SOURCE & COVERAGE

Harrison's Principles of Internal Medicine, 22e (2025) — Ch 368 "Systemic Lupus Erythematosus." Coverage note: the chapter explicitly supports the entry criterion (ANA $\geq 1:80$), the ≥ 10 -point threshold, the renal-biopsy Class III/IV = 10 points rule, the use of EULAR/ACR 2019 and SLICC 2012, autoantibody prevalences/associations (Table 368-2), and that anti-dsDNA/anti-Sm are the only included ANA subtypes. The detailed per-item point weights of the EULAR/ACR table, the full SLICC $\geq 4/17$ rule, and the ACR 1997 11-criteria list (SOAP BRAIN MD) are not enumerated in the provided chapter; they are added here as universally accepted, accurate standard rheumatology to satisfy the exam ask.

Diagnostic Criteria and Extra-Articular Manifestations of Rheumatoid Arthritis

Asked in: Paper III Jul 2020 — RGUHS MD General Medicine

Definition / Introduction — Rheumatoid arthritis (RA) is a chronic, systemic, immune-mediated inflammatory disease characterised by a **symmetric, erosive polyarthritis** of the small joints of the hands and feet, driven by synovial proliferation (pannus) that destroys cartilage and bone. Although joints dominate the picture, RA is a *systemic* disease: up to **40%** of patients develop extra-articular manifestations, sometimes preceding the arthritis. Anti-citrullinated protein antibodies (ACPA / anti-CCP) and rheumatoid factor (RF) are key diagnostic and prognostic biomarkers. Early, aggressive disease-modifying therapy before irreversible damage ensues is the modern standard of care.

Articular features that anchor the diagnosis

- ▶ **Inflammatory pattern:** early-morning stiffness lasting **>1 hour** easing with activity; insidious, symmetric, additive small-joint synovitis.
- ▶ **Joints involved:** wrists, **metacarpophalangeal (MCP)** and **proximal interphalangeal (PIP)** joints, and metatarsophalangeal (MTP) joints. DIP-sparing is typical (DIP disease usually = coexisting osteoarthritis). RA affects the **cervical spine** (atlantoaxial C1–C2) but spares the thoraco-lumbar spine and sacroiliac joints.
- ▶ **Deformities of established disease:** ulnar deviation (MCP subluxation), **swan-neck** (PIP hyperextension + DIP flexion), **boutonnière** (PIP flexion + DIP hyperextension), **Z-line thumb deformity**, *piano-key* sign of the distal ulna, and pes planovalgus.
- ▶ **Tenosynovitis:** flexor tendon involvement → trigger finger, reduced grip; rupture of the flexor pollicis longus.

Diagnostic criteria — 2010 ACR/EULAR classification

The 2010 American College of Rheumatology / European League Against Rheumatism (ACR/EULAR) criteria replaced the 1987 set to enable *earlier* diagnosis. They apply to a patient with ≥ 1 joint with definite clinical synovitis not better explained by another disease. Points are summed across four domains; a score of ≥ 6 of 10 = definite RA.

Domain	Item	Score
Joint involvement	1 large joint (shoulder, elbow, hip, knee, ankle)	0
	2–10 large joints	1
	1–3 small joints (MCP, PIP, thumb IP, MTP, wrists)	2
	4–10 small joints	3
	>10 joints (at least 1 small joint)	5
Serology	Negative RF <i>and</i> negative ACPA	0
	Low-positive RF <i>or</i> low-positive anti-CCP ($\leq 3 \times$ ULN)	2
	High-positive RF <i>or</i> high-positive anti-CCP ($> 3 \times$ ULN)	3
Acute-phase reactants	Normal CRP <i>and</i> normal ESR	0
	Abnormal CRP <i>or</i> abnormal ESR	1
Duration of symptoms	<6 weeks	0
	≥ 6 weeks	1

- **Key changes from 1987:** symptom duration > 6 weeks is no longer mandatory; ACPA (specificity $\approx 95\%$) is incorporated for the first time; nodules and radiographic erosions were dropped as they are rare in *early* RA.
- **Important caveat:** these are **classification** (not diagnostic) criteria — designed to identify early patients likely to progress to persistent, erosive disease for trials and early therapy. In established disease, radiographic erosions or subcutaneous nodules can also clinch the clinical diagnosis.
- (Historical 1987 ACR criteria — universally taught: ≥ 4 of 7 — morning stiffness ≥ 1 h, arthritis of ≥ 3 joint areas, arthritis of hand joints, symmetric arthritis, rheumatoid nodules, serum RF, radiographic changes; criteria 1–4 present for ≥ 6 weeks.)

Laboratory and imaging support for diagnosis

- **Rheumatoid factor (RF):** IgM RF positive in $\sim 75\%$; sensitive but *not* specific — also seen in Sjögren's, SLE, type II cryoglobulinaemia, SBE, hepatitis B/C, and 1–5% of healthy people; sensitivity only $\sim 50\%$ in *early* disease.

- ▶ **Anti-CCP / ACPA:** similar sensitivity to RF but **specificity ≈95%**; best predictor of erosive disease and worse outcome; testing **both** RF and anti-CCP adds incremental value. About three-fourths of RA is seropositive; one-fourth seronegative.
- ▶ **Other antibodies:** ANA positive in ~30%; p-ANCA may be present, but **anti-MPO / anti-PR3 are negative** (distinguishes from ANCA-associated vasculitis).
- ▶ **Acute-phase reactants:** ESR and CRP elevated in proportion to disease activity; normochromic-normocytic anaemia of chronic disease.
- ▶ **Synovial fluid:** inflammatory, WBC 5000–50,000/μL (neutrophil-predominant); analysis chiefly excludes septic and crystal arthritis.
- ▶ **Imaging:** plain x-ray shows **periarticular osteopenia** (earliest), symmetric joint-space narrowing, juxta-articular/marginal **erosions** (fifth MTP and ulnar styloid first). **MRI and power-Doppler ultrasound** are more sensitive, detecting synovitis, tenosynovitis, effusions, and **bone-marrow oedema** (predicts future erosions).

Extra-articular manifestations (systemic RA)

Extra-articular disease clusters in patients who are RF/ACPA-positive, smokers, shared-epitope carriers, and have high disease activity.

System	Manifestations
Constitutional	Fatigue, weight loss, low-grade fever, malaise, depression, cachexia (fever >38.3 °C suggests vasculitis/infection)
Skin / subcutaneous	Rheumatoid nodules (firm, non-tender, over pressure points — forearm, Achilles, sacrum), purpura, pyoderma gangrenosum , digital infarcts
Ocular	Keratoconjunctivitis sicca, episcleritis , scleritis , scleromalacia perforans, peripheral ulcerative keratitis
Oral / glandular	Secondary Sjögren's syndrome (~10%): xerostomia, xerophthalmia; periodontitis
Pulmonary	Pleuritis/exudative pleural effusion (commonest); interstitial lung disease (UIP & NSIP patterns; prevalence up to ~12%); pulmonary nodules; Caplan's syndrome (nodulosis + pneumoconiosis after silica exposure); bronchiectasis
Cardiac	Pericarditis (commonest; symptomatic in <10%, subclinical in ~half), myocarditis, cardiomyopathy, accelerated ischaemic heart disease , arrhythmia, valve disease

System	Manifestations
Vascular	Rheumatoid vasculitis (<1%, long-standing seropositive disease, hypocomplementaemia): nail-fold infarcts, leg ulcers, digital gangrene, mononeuritis multiplex
Neurologic	Cervical (atlantoaxial) myelopathy from C1–C2 subluxation; entrapment (carpal tunnel); sensorimotor neuropathy
Haematologic	Anaemia of chronic disease, thrombocytosis (acute-phase), Felty's syndrome , T-cell large granular lymphocyte (T-LGL) leukaemia, 2–4× increased lymphoma risk (diffuse large B-cell type)
Renal	Membranous nephropathy, secondary (AA) amyloidosis
Skeletal / endocrine	Osteoporosis ($\approx 2\times$ risk; fragility fractures), hypoandrogenism

- ▶ **Subcutaneous nodules** are the prototypic extra-articular lesion (reported in ~20–40%), strongly correlate with RF seropositivity; may enlarge with long-term methotrexate.
- ▶ **Cardiovascular disease is the leading cause of death** in RA, with coronary and carotid atherosclerosis exceeding that predicted by traditional risk factors — driven by systemic inflammation; overall **mortality is $\sim 2\times$ the general population**.

Felty's syndrome and related associations

- ▶ **Felty's syndrome** = clinical triad of **neutropenia + splenomegaly + nodular (severe, seropositive) RA**; <1% of patients, late in disease; declining with aggressive therapy. Must be distinguished from T-LGL leukaemia, which shares neutropenia/splenomegaly but may appear *early*.
- ▶ **Lymphoma**: risk rises with high disease activity and Felty's syndrome.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Diagram 1 — RA hand deformities**: outline of a hand labelling MCP swelling with ulnar deviation, swan-neck deformity (PIP hyperextension + DIP flexion), **boutonnière deformity** (PIP flexion + DIP hyperextension), **Z-thumb deformity**, wrist/ulnar-styloid subluxation (piano-key), and DIP-sparing.
- ▶ **Diagram 2 — Whole-body extra-articular map**: a body figure with labelled pointers — **Eye** (keratoconjunctivitis sicca, episcleritis, scleritis); **Lung** (pleural effusion, ILD–UIP/NSIP, pulmonary nodules, Caplan's); **Heart** (pericarditis, IHD, myocarditis); **Neuro** (cervical myelopathy, mononeuritis multiplex); **Haematologic** (anaemia, Felty's,

lymphoma); **Skin** (nodules, vasculitis, pyoderma gangrenosum); **Renal** (amyloidosis, membranous nephropathy); **Skeletal** (osteoporosis).

Clinical / Diagnostic significance

- ▶ A score $\geq 6/10$ on ACR/EULAR criteria in a patient with synovitis warrants **early DMARD therapy** — *treat-to-target* aiming for low disease activity/remission (assessed by DAS28, CDAI, SDAI, RAPID3).
- ▶ **Anti-CCP** is the most useful single test to distinguish RA from RF-positive mimics (hepatitis C arthropathy, Sjögren's, SLE) and predicts erosive, extra-articular disease.
- ▶ Atlantoaxial subluxation mandates **cervical-spine assessment before intubation/surgery** — risk of compressive myelopathy.
- ▶ Any RA patient with **one joint inflamed out of proportion** to the rest needs arthrocentesis to exclude **septic arthritis**.
- ▶ Management: **methotrexate** is the anchor DMARD (with folate); add sulfasalazine/hydroxychloroquine (*triple therapy*) or biologics (TNF inhibitors, **abatacept**, **rituximab**, **tocilizumab/sarilumab**) or **JAK inhibitors** (tofacitinib, baricitinib, upadacitinib). Screen for **latent TB and hepatitis B/C** before biologics/JAK inhibitors. High-dose steroids are reserved for severe extra-articular disease (ILD, necrotising scleritis, vasculitis).

High-yield exam pointers

- ▶ **2010 ACR/EULAR score $\geq 6/10$ = definite RA**; four domains — joints, serology, acute-phase reactants, duration.
- ▶ **Anti-CCP specificity $\approx 95\%$** , RF sensitivity $\approx 75\%$ but poorly specific; both positive = worse prognosis.
- ▶ These are **classification, not diagnostic, criteria** — designed for early disease.
- ▶ Commonest extra-articular lesion = **subcutaneous nodule**; commonest pulmonary lesion = **pleuritis/effusion** (exudative).
- ▶ **Felty's triad** = neutropenia + splenomegaly + nodular RA ($<1\%$).
- ▶ **Caplan's syndrome** = rheumatoid pulmonary nodules + pneumoconiosis (silica/coal).
- ▶ **Cervical myelopathy** from atlantoaxial subluxation; thoraco-lumbar spine spared.
- ▶ **Cardiovascular disease = commonest cause of death**; overall mortality $\sim 2\times$.
- ▶ RA carries a **2–4 $\times$ increased risk of lymphoma** (diffuse large B-cell).
- ▶ ANCA may be positive but **anti-MPO/anti-PR3 negative**.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e — "Rheumatoid Arthritis"** (ACR/EULAR 2010 classification criteria [Table 370-1], extra-articular manifestations [Fig. 370-2], laboratory/imaging features, Felty's syndrome, prognosis).
- ▶ **CMDT 2026 — "Rheumatoid Arthritis" (Rheumatologic, Immunologic & Allergic Disorders)** for the classification-criteria reproduction (Table 23-5), current treat-to-target management, DMARD/biologic/JAK-inhibitor regimens, and pre-biologic screening.
- ▶ *Coverage note:* The 1987 ACR seven-item criteria are not enumerated in the corpus (Harrison cites only that the 1987 set was "revised"); they are included as universally accepted standard internal-medicine knowledge and clearly labelled as historical.

Discuss the risk factors for disease flares in patients with SLE, how do you classify severity of flare

Asked in: Paper III May 2025 — RGUHS MD General Medicine

Definition / Introduction — Systemic lupus erythematosus (SLE) is a multisystem autoimmune disease driven by autoantibodies and immune-complex deposition, with a characteristically **relapsing–remitting course** — roughly 70% of patients follow a pattern of flares and remissions. A **flare** is a measurable increase in disease activity (clinical and/or serological) above the patient's prior stable state that warrants escalation or intensification of therapy. Recognising the triggers of a flare allows preventive counselling, while grading flare severity is the central decision node that dictates whether treatment is purely symptomatic, intensified with steroid-sparing immunosuppression, or escalated to high-dose/pulse glucocorticoids and aggressive immunosuppression.

What constitutes a "flare"

- ▶ An *increase* in disease activity over baseline — new organ involvement or worsening of existing involvement — sufficient to require a change in treatment, distinct from chronic irreversible **damage** (which does not respond to immunosuppression).
- ▶ Flares may be **clinical** (e.g., arthritis, rash, serositis, nephritis, cytopenia, neuropsychiatric) and/or **serological** (rising anti-dsDNA titre, falling C3/C4).
- ▶ Most SLE patients have active disease despite therapy or have frequent flares requiring treatment adjustment; the treatment goal is remission or a low disease-activity state on the least possible therapy.

Risk factors / triggers for disease flares

Grouped by mechanism (all faithful to the source corpus unless flagged):

Category	Specific risk factors
Environmental / physical	Ultraviolet (UV) light / sun exposure — induces apoptosis, self-stimulatory nucleic acids, keratinocyte activation and DNA-methylation change (photosensitive patients flare rapidly after first major UV exposure); crystalline silica ; toxins (mercury, diet)
Infections	Viral infection, especially Epstein–Barr virus (EBV) , induces the type-1 interferon response and can precipitate activity
Hormonal / reproductive	Pregnancy and the postpartum period — disease can flare in any trimester; oestrogen-containing contraceptives/HRT are avoided in active or moderate–severe SLE (thrombosis and flare risk); active disease at conception predicts more flares
Drug / treatment-related	Non-adherence to therapy; discontinuation of hydroxychloroquine (HCQ) ; too-rapid glucocorticoid tapering/withdrawal; drug-induced lupus activity from offending agents
Lifestyle	Cigarette smoking — causes autoantigen release, worsens disease and interferes with antimalarial efficacy
Serological / disease-intrinsic	Rising anti-dsDNA titres and falling C3/C4 complement herald impending activity, especially nephritis; high prior disease activity; persistently active disease despite therapy
Host factors	Non-White ethnicity and low socioeconomic status (worse/more severe disease and poorer access to care)

Key prevention pearls embedded in the corpus: **HCQ prevents flares**, prolongs survival and reduces flares during pregnancy and postpartum — hence it is recommended for *all* patients unless contraindicated; daily sunscreen, smoking cessation and adherence are foundational.

Serological predictors of an impending flare

- ▶ Anti-dsDNA antibodies are produced by short-lived plasmablasts and track disease activity; a rising titre signals reactivation.
- ▶ **C3 and C4** fall during high activity (consumed by immune-complex formation); the **anti-dsDNA↑ / complement↓** combination specifically predicts active lupus **nephritis**.
- ▶ Quarterly monitoring of UPCr/eGFR, CBC and complement/anti-dsDNA is advised because renal and haematological flares can be clinically *silent*.

- ▶ Caveat (well recognised): a subset of patients have persistently high anti-dsDNA and low complement without clinical flare (“serologically active, clinically quiescent”) — treat the patient, not the number alone.

Classification of flare / disease-activity severity

Severity is graded both by **validated composite indices** (for trials and longitudinal monitoring) and by a practical **categorical mild/moderate/severe** scheme that drives therapy.

A. Validated disease-activity instruments

- ▶ **SLEDAI / SLEDAI-2K** (SLE Disease Activity Index) — weighted score summing active manifestations across organ systems; underpins treat-to-target targets (LLDAS, DORIS remission).
- ▶ **BILAG** (British Isles Lupus Assessment Group) — an organ-by-organ “physician’s intention-to-treat” categorical index grading each system: **A = severe** activity (needs high-dose steroids/immunosuppression), **B = moderate**, **C = mild/stable**, **D = previously involved, now inactive**, **E = never involved**.
- ▶ **SELENA–SLEDAI Flare Index (SFI)** — purpose-built flare instrument that categorises flares as **mild/moderate vs severe** using the change in SLEDAI plus clinical descriptors and the Physician Global Assessment (see Coverage note).
- ▶ Composite trial endpoints derived from these: **SRI** (SLE Responder Index) and **BICLA** (BILAG-based Composite Lupus Assessment); **CLASI** for cutaneous activity; **SLICC/ACR Damage Index** measures accrued damage (not activity).

B. EULAR categorical severity (the bedside, therapy-driving classification)

Severity	Defining features	SLEDAI	BILAG	Typical first-line therapy
Mild	Constitutional symptoms; mild arthritis; rash $\leq 9\%$ BSA; platelets $50\text{--}100 \times 10^9/\text{L}$	≤ 6	BILAG C or ≤ 1 BILAG B	HCQ $\pm$ short low-dose glucocorticoid; NSAIDs; topicals
Moderate	Moderate–severe (“RA-like”) arthritis; rash $9\text{--}18\%$ BSA; platelets $20\text{--}50 \times 10^9/\text{L}$; serositis	$7\text{--}12$	≥ 2 BILAG B	HCQ + GC + steroid-sparing agent (MTX/AZA/MMF); belimumab/anifrolumab add-on
Severe	Major organ-threatening disease (cerebritis, myelitis,	>12	≥ 1 BILAG A	Pulse/high-dose GC (IV methylprednisolone $125\text{--}1000\text{ mg/day} \times 1\text{--}3\text{ d}$) + MMF or

Severity	Defining features	SLEDAI	BILAG	Typical first-line therapy
	pneumonitis, mesenteric vasculitis); platelets $<20 \times 10^9/L$; TTP-like / acute haemophagocytic syndrome; rash $>18\%$ BSA			cyclophosphamide $\pm$ rituximab

C. Treat-to-target reference states (the “no-flare” goals against which a flare is judged):

- ▶ **Low disease-activity state (LLDAS):** clinical SLEDAI ≤ 4 , on HCQ, stable immunosuppressive/biologic, with prednisone ≤ 5 mg/day.
- ▶ **DORIS remission:** clinical SLEDAI = 0, with prednisone ≤ 5 mg/day and stable maintenance therapy.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Flare risk-factor wheel:** central hub “SLE FLARE” with labelled spokes — *UV light/sun, EBV/infection, Pregnancy & postpartum, Non-adherence / HCQ withdrawal, Rapid steroid taper, Smoking, Oestrogen (OCP/HRT), Rising anti-dsDNA / falling C3–C4*. Annotate “HCQ + sunscreen + adherence = flare prevention”.
- ▶ **Severity ladder (3-tier bar):** three ascending blocks labelled **MILD** (SLEDAI ≤ 6 / BILAG C), **MODERATE** (SLEDAI 7–12 / ≥ 2 BILAG B), **SEVERE** (SLEDAI >12 / ≥ 1 BILAG A); side-label the matching platelet count, %BSA rash and first-line drug for each tier; add a baseline line for “LLDAS / DORIS remission”.

Clinical / Diagnostic significance

- ▶ **Distinguish flare from infection:** in active SLE the ESR rises but CRP is usually normal — a high CRP without serositis/arthritis should raise suspicion of **infection** (a major mimic in an immunosuppressed patient).
- ▶ **Distinguish flare from damage:** activity is reversible with immunosuppression; damage (e.g., glucocorticoid-induced cataract, avascular necrosis, ESRD) is not — escalating immunosuppression for damage only adds toxicity.
- ▶ **Renal flare** is often silent: a UPCr rising above 0.5 and/or falling eGFR with active sediment (haematuria, cellular casts) should prompt renal biopsy; class III/IV ($\pm V$) nephritis needs aggressive therapy.

- ▶ **Pregnancy planning:** conceive when disease is quiescent for ≥ 6 months, continue **HCQ**, use AZA/tacrolimus if immunosuppression is needed, and avoid MMF, methotrexate, cyclophosphamide and warfarin.
- ▶ **Severity grade determines therapy intensity:** mild $\rightarrow$ HCQ $\pm$ brief low-dose steroid; moderate $\rightarrow$ add a steroid-sparing agent $\pm$ biologic; severe/organ-threatening $\rightarrow$ pulse methylprednisolone plus MMF/cyclophosphamide $\pm$ rituximab, with the steroid tapered to ≤ 5 mg/day as fast as feasible.

High-yield exam pointers

- ▶ SLE is **relapsing–remitting** in $\sim 70\%$; a flare = increase in activity requiring treatment change, *not* fixed damage.
- ▶ **Top modifiable flare triggers:** UV light, infection (EBV), pregnancy/postpartum, **HCQ discontinuation / non-adherence**, smoking, oestrogens, rapid steroid taper.
- ▶ **HCQ prevents flares**, improves survival and is recommended for *all* SLE patients (≤ 5 mg/kg/day; annual retinal screening).
- ▶ **Anti-dsDNA $\uparrow$ + C3/C4 $\downarrow$** predicts a flare, especially **nephritis**.
- ▶ Severity is graded by **SLEDAI** (≤ 6 mild, 7–12 moderate, >12 severe) and **BILAG** (A severe, B moderate, C mild, D inactive, E never involved).
- ▶ **SELENA–SLEDAI Flare Index** grades flares as mild/moderate vs severe; **SRI/BICLA** are composite trial endpoints; **SLICC/ACR Damage Index** measures damage, not activity.
- ▶ **Severe flare = organ-threatening** (CNS, renal, pulmonary, mesenteric vasculitis, platelets $<20 \times 10^9/L$) $\rightarrow$ IV methylprednisolone pulse + MMF/cyclophosphamide $\pm$ rituximab.
- ▶ **Treat-to-target:** aim for **LLDAS** (SLEDAI ≤ 4 , prednisone ≤ 5 mg/day) or **DORIS remission** (SLEDAI 0).
- ▶ **CRP normal in pure lupus flare** — a raised CRP points to infection or serositis.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Systemic Lupus Erythematosus” (risk factors/environmental triggers, anti-dsDNA/complement monitoring, EULAR mild/moderate/severe activity figure, SLEDAI/BILAG/SRI/BICLA, LLDAS/DORIS targets, pregnancy and flare prevention with HCQ); “Antiphospholipid Syndrome” (flare-related triggers of catastrophic APS).
- ▶ **CMDT 2026** — “Rheumatologic, Immunologic, & Allergic Disorders: Systemic Lupus Erythematosus” (waxing–waning course, severity-matched therapy, CRP-vs-infection pearl, HCQ flare prevention, glucocorticoid dosing for mild vs severe disease).
- ▶ **Rook's Textbook of Dermatology, 10e** — “Lupus Erythematosus and Antiphospholipid Syndrome” (relapsing–remitting epidemiology, disease-activity indices)

SELENA/SLEDAI/SLEDAI-2K/BILAG/CLASI, UV- and smoking-induced flares, anti-dsDNA/complement as predictors).

Coverage note: The corpus names and uses the SLEDAI, BILAG, SELENA, SRI, BICLA, CLASI and SLICC/ACR indices and provides the EULAR categorical mild/moderate/severe activity cut-offs (used as the main severity table here), but it does **not** spell out the numeric thresholds of the *SELENA-SLEDAI Flare Index* (e.g., SLEDAI change >3 for mild/moderate vs >12 for a severe flare, with Physician Global Assessment descriptors) or the full BILAG-2004 organ glossary. The SFI mild/moderate-vs-severe framing and the BILAG A–E category meanings given above are standard, universally accepted rheumatology, included for completeness and flagged here as not detailed verbatim in the available chapters.

Disease-Modifying Antirheumatic Drugs

Asked in: Paper III Nov 2019 — RGUHS MD General Medicine

Definition / Introduction — Disease-modifying antirheumatic drugs (DMARDs) are agents that, unlike pure analgesics or NSAIDs, **slow or arrest the structural (radiographic) progression** of inflammatory arthritis in addition to relieving symptoms. They are the cornerstone of management of **rheumatoid arthritis (RA)** and are also used in other immune-mediated arthritides (psoriatic arthritis, SLE, vasculitis). They are conventionally divided into **conventional synthetic (csDMARDs)**, **biologic (bDMARDs)** and **targeted synthetic (tsDMARDs)** classes. They share a characteristically **delayed onset of action** (≈ 6 –12 weeks for csDMARDs) and require structured laboratory monitoring for toxicity.

Classification of DMARDs

Class	Sub-group	Representative agents
Conventional synthetic (csDMARD)	—	Methotrexate, Leflunomide, Sulfasalazine, Hydroxychloroquine
Biologic (bDMARD)	TNF- α inhibitors	Infliximab, Etanercept, Adalimumab, Golimumab, Certolizumab pegol
	IL-6 receptor blockers	Tocilizumab, Sarilumab
	IL-1 receptor antagonist	Anakinra
	T-cell co-stimulation blocker	Abatacept (CTLA-4-Ig)
	Anti-CD20 (B-cell depletion)	Rituximab

Class	Sub-group	Representative agents
Targeted synthetic (tsDMARD)	JAK inhibitors	Tofacitinib, Baricitinib, Upadacitinib

- ▶ **Biosimilars** — agents engineered to have the same active properties as a licensed reference biologic, with similar efficacy and toxicity (available for infliximab, etanercept, adalimumab); they reduce cost.
- ▶ *Methotrexate* is the **DMARD of first choice** and the “**anchor drug**” for most combination regimens.
- ▶ *Hydroxychloroquine*, although DMARD-like, has **not** been shown to delay radiographic progression and so is **not strictly a true DMARD**; it is used for early/mild disease or as an adjunct.

Conventional synthetic DMARDs (csDMARDs)

- ▶ **Methotrexate (MTX)** — a **folate antagonist (dihydrofolate reductase inhibitor)**; at the low *weekly* doses used in RA its anti-inflammatory action is mediated chiefly by **promoting adenosine release**. Onset 4–6 weeks; about one-third of patients reach low disease activity on monotherapy. Given **10–25 mg once weekly orally or subcutaneously** (CMDT: start 7.5–15 mg/week, titrate to a maximal oral dose of ~20 mg/week). **Folic acid 1 mg/day** (or weekly leucovorin) is co-prescribed to reduce stomatitis, cytopenias, GI and hepatic toxicity. SQ route is used when oral is poorly tolerated or absorption is limiting.
- ▶ **Leflunomide** — inhibits **dihydro-orotate dehydrogenase**, blocking *de novo* pyrimidine synthesis; efficacy similar to MTX as monotherapy or in combination. Dose **10–20 mg/day** orally. Very long half-life with active metabolite detectable for up to ~2 years (cholestyramine washout if rapid elimination needed, e.g., pregnancy planning).
- ▶ **Sulfasalazine** — reduces joint inflammation and **retards radiographic progression** (RCT-proven). Start **500 mg twice daily**, maintenance **1000–1500 mg twice daily**. Check G6PD before starting (haemolysis risk).
- ▶ **Hydroxychloroquine** — antimalarial, **not immunosuppressive**, low toxicity; **200–400 mg/day** (≤ 5 mg/kg) to limit retinal toxicity. Mainly used within “**oral triple therapy**” (MTX + sulfasalazine + hydroxychloroquine).

Biologic DMARDs (bDMARDs)

Biologics are **protein therapeutics** targeting cytokines or cell-surface molecules; the **TNF inhibitors** (first approved 1999) revolutionised RA care. Most are used **in combination with background methotrexate**, typically after an inadequate response to MTX.

Target / mechanism	Agent	Dosing (representative)
TNF- α — chimeric mAb	Infliximab	3 mg/kg IV at wk 0, 2, 6, then every 8 wk (up to 10 mg/kg q4wk)
TNF- α — soluble TNF-R2-Fc fusion	Etanercept	50 mg SQ weekly
TNF- α — humanized mAb	Adalimumab	40 mg SQ every other week
TNF- α — humanized mAb	Golimumab	50 mg SQ monthly
TNF- α — pegylated Fab' fragment	Certolizumab pegol	400 mg SQ wk 0, 2, 4 $\rightarrow$ 200 mg every other week
IL-6 receptor mAb	Tocilizumab / Sarilumab	Tocilizumab 4–8 mg/kg IV monthly <i>or</i> 162 mg SQ; Sarilumab 200 mg SQ every other week
IL-1 receptor antagonist	Anakinra	100 mg SQ daily (limited use; lower efficacy)
T-cell co-stimulation (CTLA-4-Ig blocks CD28–CD80/86)	Abatacept	Weight-based IV q4wk <i>or</i> 125 mg SQ weekly
CD20 B-cell depletion	Rituximab	1000 mg IV $\times$ 2 (days 0 and 14); repeat $\sim$ q24 weeks

- ▶ **TNF inhibitors** reduce signs/symptoms, **slow radiographic damage**, and improve function/quality of life.
- ▶ **Abatacept** blocks the CD28–CD80/86 co-stimulatory signal to T cells.
- ▶ **Rituximab** (anti-CD20) is approved for **refractory RA** (TNF-inhibitor failure) with MTX; **more effective in seropositive disease**. Rare risk of **progressive multifocal leukoencephalopathy (PML)** ($\sim$ 1:25,000) and blunting of vaccine response.
- ▶ **IL-6R blockers** are effective as monotherapy or with MTX; raise **LDL cholesterol** and carry a risk of **GI perforation** (avoid in diverticulitis/recent peptic ulcer).
- ▶ **Biologics should not be combined with one another** (additive infection risk without added benefit).

Targeted synthetic DMARDs — JAK inhibitors

- ▶ **Mechanism** — small oral molecules inhibiting Janus kinases (JAK1, JAK2, JAK3, Tyk2), which transduce intracellular signals from cytokine receptors (common γ -chain cytokines IL-2/-4/-7/-9/-15/-21, IFN- γ , IL-6, IL-12/-23) via the JAK–STAT pathway.
 - *Tofacitinib* — JAK1/JAK3 inhibitor; **5 mg twice daily** (or 11 mg XR daily).
 - *Baricitinib* — JAK1/JAK2 inhibitor; **2 mg daily**.

- *Upadacitinib* — selective JAK1 inhibitor; **15 mg daily**.
- ▶ Advantage: **oral** route; used as monotherapy or with MTX.
- ▶ **Safety signal** — an FDA **black-box warning** (from an RCT vs TNF inhibitors in MTX-treated patients) of increased **serious infection, herpes zoster, thrombosis/VTE, major adverse cardiovascular events (MACE), malignancy and death**, greatest in the **elderly**.

Adverse effects, screening and monitoring

Drug	Serious toxicity	Baseline screen	Monitoring
Methotrexate	Hepatotoxicity, myelosuppression, interstitial pneumonitis; teratogenic (Pregnancy category X)	CBC, LFTs, viral hepatitis panel, CXR	CBC, creatinine, LFTs every 2–3 months
Leflunomide	Hepatotoxicity, myelosuppression; teratogenic	CBC, LFTs, viral hepatitis panel	LFTs periodically
Sulfasalazine	Granulocytopenia, haemolysis (G6PD deficiency)	G6PD level , CBC, LFTs	CBC every 2–4 wk ×3 months, then q3 months
Hydroxychloroquine	Irreversible retinal damage , cardiotoxicity	Eye exam (esp. >40 y)	OCT + visual fields every 12 months
TNF inhibitors	Serious bacterial/fungal infection, reactivation of latent TB , demyelination, drug-induced lupus	TB screening (PPD or IGRA) , hepatitis panel	Monitor for infection/injection or infusion reactions
Rituximab	Infection, hepatitis B reactivation , PML, infusion reaction	Viral hepatitis panel, CBC	CBC at intervals
JAK inhibitors	Infection (zoster), thrombosis, MACE, malignancy, transaminitis, dyslipidaemia	TB screening, varicella vaccination	CBC, LFTs, lipids at intervals

- ▶ **Latent TB** must be screened (PPD/IGRA) before any biologic or JAK inhibitor; if positive, **treat LTBI for ≥1 month** before starting.
- ▶ TNF inhibitors are **contraindicated** in active infection, **chronic hepatitis B**, and NYHA class III/IV heart failure.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **DMARD molecular-target schematic of the rheumatoid synovium** — draw a synovial joint with infiltrating immune cells and arrows to each drug target. Labels: *TNF- α* (infliximab/etanercept/adalimumab/golimumab/certolizumab), *IL-6 / IL-6R* (tocilizumab/sarilumab), *IL-1 / IL-1Ra* (anakinra), *CD20 B cell* (rituximab), *T-cell co-stimulation CD28-CD80/86* (abatacept/CTLA-4-Ig), *intracellular JAK1/2/3-Tyk2* $\rightarrow$ *STAT* (tofacitinib/baricitinib/upadacitinib).
- ▶ **Treat-to-target algorithm** — flow boxes: *Early RA diagnosis* $\rightarrow$ *Methotrexate + folic acid (anchor)* $\pm$ *short glucocorticoid bridge* $\rightarrow$ *Reassess at 3–6 months (DAS28 / CDAI / SDAI)* $\rightarrow$ if target not met $\rightarrow$ *Triple csDMARD therapy or Add TNF inhibitor $\pm$ MTX or Non-TNF biologic $\pm$ MTX* $\rightarrow$ *Switch class / JAK inhibitor* $\rightarrow$ *Goal: low disease activity or remission.*

Clinical / Diagnostic significance

- ▶ **Treat-to-target (“T2T”)** — the guiding principle: aim for **low disease activity or clinical remission**, with **frequent reassessment** using composite indices (DAS28, SDAI, CDAI, RAPID3) and rapid step-up of therapy when targets are unmet. *ACR/EULAR provisional remission*: tender joints ≤ 1 , swollen joints ≤ 1 , CRP ≤ 1 mg/dL, patient global ≤ 1 — **or** SDAI ≤ 3.3 .
- ▶ **Sequencing** — begin with **methotrexate**; if inadequate at 3–6 months, escalate to a combination (**oral triple therapy** = MTX + sulfasalazine + hydroxychloroquine) **or** add a TNF / non-TNF biologic $\pm$ MTX. MTX + anti-TNF is superior to MTX alone for symptoms and for retarding structural damage. Triple therapy is **non-inferior to MTX + etanercept** and is economical.
- ▶ **Switching** — anti-TNF failure may respond to a **different mechanism** (abatacept, rituximab, IL-6R blocker, JAK inhibitor); evidence suggests switching to abatacept can beat a second anti-TNF.
- ▶ **Glucocorticoid bridging** — low–moderate dose prednisone (5–10 mg/day) gives rapid control until DMARDs act; chronic use is minimised (osteoporosis — consider bisphosphonate prophylaxis).
- ▶ **Pregnancy** — **methotrexate and leflunomide are contraindicated (teratogenic)**; **hydroxychloroquine and sulfasalazine are the safest**; anti-TNF agents are generally acceptable but usually stopped in the third trimester.
- ▶ **Comorbidity/mortality** — RA excess mortality is largely **cardiovascular**; controlling inflammation plus CV risk-factor management improves outcomes. In resource-limited settings, **TB and viral hepatitis reactivation** drive screening practice.

High-yield exam pointers

- ▶ DMARD = drug that **slows radiographic progression**, not just symptoms; csDMARDs act in 6–12 weeks.
- ▶ **Methotrexate = anchor/first-choice DMARD**; weekly dosing + **folic acid**; key toxicities = hepatotoxicity, cytopenias, **pneumonitis**, teratogenicity.

- ▶ **Hydroxychloroquine is not a true DMARD** (no radiographic benefit); main risk = **retinal toxicity** → annual OCT/visual fields, dose ≤ 5 mg/kg.
- ▶ **Oral triple therapy** = MTX + sulfasalazine + hydroxychloroquine.
- ▶ **Five TNF inhibitors**: infliximab, etanercept, adalimumab, golimumab, certolizumab; screen **latent TB** first; avoid in chronic HBV and **class III/IV heart failure**.
- ▶ **Abatacept** = CTLA-4-Ig (T-cell co-stimulation block); **Rituximab** = anti-CD20 (better in **seropositive RA**, risk of HBV reactivation/PML); **Tocilizumab/Sarilumab** = IL-6R (raise LDL, GI perforation).
- ▶ **JAK inhibitors** (tofacitinib, baricitinib, upadacitinib) are **oral tsDMARDs**; **black-box warning** for thrombosis, MACE, malignancy, infection.
- ▶ **Do not combine two biologics**; remission target = **SDAI ≤ 3.3** .

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Rheumatoid Arthritis” (Treatment section; Table 370-2 *DMARDs Used for the Treatment of Rheumatoid Arthritis*; Table 370-3 *ACR/EULAR Provisional Definition of Remission*).
- ▶ **CMDT 2026** — “Rheumatologic, Immunologic, & Allergic Disorders” (Rheumatoid Arthritis — synthetic and biologic DMARD dosing, monitoring, combination/triple therapy).
- ▶ Mechanistic notes for methotrexate (dihydrofolate reductase inhibition) and leflunomide (dihydro-orotate dehydrogenase inhibition) and the csDMARD/bDMARD/tsDMARD classification are universally accepted standard internal medicine, consistent with the cited chapters.

Drug-Induced Lupus

Asked in: Paper III Jul 2021 — RGUHS MD General Medicine

Definition / Introduction — *Drug-induced lupus (DIL)* is an autoimmune phenomenon in which a positive antinuclear antibody (ANA) and clinical features resembling systemic lupus erythematosus (SLE) arise as a consequence of continuous exposure to a particular drug, and characteristically resolve after the offending agent is withdrawn. It accounts for roughly **6–12% of all lupus cases**. Compared with idiopathic SLE it is generally milder, *rarely involves the kidney or brain*, lacks the strong female predominance, and is serologically dominated by **antihistone antibodies**. Recognising DIL is important because it is largely reversible — the single most effective “treatment” is to stop the culprit drug.

Epidemiology and offending drugs

- ▶ DIL was first described with **hydralazine** in 1954; since then **more than 100 drugs** have been implicated as potential triggers.
- ▶ The **highest incidence is with the antiarrhythmic procainamide**, where the risk has been reported to be as high as ~30%. With **hydralazine taken for a year or longer the incidence is ~5–8%**; for most other implicated drugs the risk is considerably **lower than 1%**.
- ▶ DIL has a **nearly equal sex ratio** (unlike the strong female predominance of SLE), and typically affects an **older age group**, reflecting the age at which the culprit cardiovascular/anti-infective drugs are prescribed.
- ▶ *Drugs with definite associations: hydralazine, procainamide, isoniazid, minocycline*, with methyl dopa and chlorpromazine less commonly.

Risk / drug class	Representative agents
High risk	Procainamide (~30%), hydralazine (~5–8% if ≥1 yr)
Antiarrhythmics / antihypertensives	Procainamide, quinidine, hydralazine, methyl dopa, ACE inhibitors, beta-blockers, hydrochlorothiazide
Anti-infectives	Isoniazid, minocycline, rifampin, nitrofurantoin
Anticonvulsants	Phenytoin, carbamazepine
Antithyroid	Propylthiouracil
Psychotropics	Chlorpromazine, lithium
Others	Sulfasalazine, proton-pump inhibitors, NSAIDs, oral contraceptives
Biologics	Anti-TNF- α agents (especially infliximab , etanercept), interferon- α

- ▶ **Drug-induced subacute cutaneous lupus erythematosus (SCLE)** is a related but distinct entity — *more than one-third* of SCLE is drug-induced; **hydrochlorothiazide** is a classic cause, with terbinafine, PPIs, calcium-channel blockers, ACE inhibitors and TNF inhibitors also implicated.

Pathogenesis

- ▶ Drug exposure provokes a **loss of self-tolerance**, generating ANA and SLE-like clinical features; in many cases simple **discontinuation of the drug is sufficient** for symptoms to abate.
- ▶ **Pharmacogenetic susceptibility** — the **slow-acetylator phenotype**: hydralazine, procainamide and isoniazid are metabolised by hepatic N-acetyltransferase 2 (NAT2). *Slow acetylators* accumulate the parent drug and develop DIL **earlier, more frequently and at lower cumulative doses** than fast acetylators (universally accepted internal-medicine teaching).
- ▶ Proposed mechanisms include drug-induced **disruption of central tolerance**, **impaired DNA methylation in T cells**, and **oxidative/reactive-metabolite modification of self chromatin** (the

histone–DNA complex), exposing cryptic antigens — explaining the dominance of **antihistone antibodies**.

- ▶ **Biologic-induced lupus** (anti-TNF, IFN- α) is mechanistically distinct: TNF inhibitors can induce **antibodies to dsDNA but usually not antihistone antibodies**, and clinically produce a lupus-like syndrome in only ~0.5–1%.

Clinical features

- ▶ Typically an **abrupt onset weeks to several months after starting the drug**, with constitutional and musculoskeletal/serosal symptoms predominating:
 - **Fever, arthralgia and myalgia, arthritis**
 - **Serositis** — pleuritis (pleuritic chest pain, effusion) and pericarditis
 - **Cutaneous rash** (including photosensitive eruptions; drug-induced SCLE as a variant)
- ▶ **Severe organ involvement is characteristically absent** — *renal* (nephritis) and *CNS/neuropsychiatric* disease are rare, distinguishing DIL from SLE.
- ▶ **Cytopenias** may occur but are typically **mild**.
- ▶ Symptoms **resolve within several weeks to a few months of stopping the offending agent**.

Feature	Drug-induced lupus	Idiopathic SLE
Sex ratio	Nearly equal	Strong female predominance
Typical age	Older (drug-exposed)	Younger (15–45 yr)
Renal / CNS disease	Rare	Common, prognosis-defining
Severity	Generally milder	Variable, can be severe
ANA	Positive (often before symptoms)	Positive ($\geq 95\%$)
ANA pattern	Usually homogeneous	Variable (often speckled/homogeneous)
Antihistone Ab	Positive in ~75–95%	~70% (not specific)
Anti-dsDNA / anti-Sm	Usually absent (dsDNA may occur with anti-TNF)	dsDNA & Sm characteristic
Complement (C3/C4)	Usually normal	Often low in active disease
Course on drug withdrawal	Resolves	Persists (chronic)

Investigations and serology

- ▶ ANA is **positive in essentially all symptomatic patients**, characteristically in a **homogeneous** pattern, and the ANA frequently **appears before symptoms**.

- ▶ **Antihistone antibodies** are the serologic hallmark — present in ~75% (Harrison) up to ~95% (CMDT) of DIL. *Important caveat:* antihistone antibodies are also seen in the majority of idiopathic SLE, so by themselves they **do not distinguish** DIL from SLE.
- ▶ **Antibodies to dsDNA, Sm, RNP, SS-A (Ro) and SS-B (La)** are characteristically rare in DIL — their presence should raise suspicion for true SLE. *Exception:* **TNF inhibitors can induce anti-dsDNA antibodies.**
- ▶ **Complement levels are usually normal;** mild cytopenias may be present.
- ▶ Many of the same drugs induce a **positive ANA in asymptomatic patients who never develop DIL**, so a positive ANA alone does not mandate stopping the drug — the laboratory tests must be interpreted alongside the clinical picture.
- ▶ *Skin biopsy* in DIL may be **indistinguishable from SLE** and is not by itself discriminatory.

Diagnosis and differential diagnosis

- ▶ DIL is a **clinical-temporal diagnosis** requiring: (1) **exposure to an implicated drug**, (2) compatible SLE-like features developing **during** that exposure, (3) supportive serology (ANA ± antihistone, absence of SLE-specific antibodies, normal complement), and (4) **resolution of symptoms after discontinuation** — the latter is the strongest confirmatory feature.
- ▶ *Differential diagnosis:* idiopathic SLE, rheumatoid arthritis, systemic and ANCA-associated vasculitis, primary antiphospholipid syndrome, viral arthralgia, and acute drug reactions.
- ▶ **Related drug-induced autoimmune syndrome — drug-induced ANCA vasculitis:** propylthiouracil, hydralazine, minocycline, allopurinol, penicillamine and sulfasalazine can induce a systemic vasculitis with **high-titre p-ANCA (anti-MPO)** and features of microscopic polyangiitis — a useful contrast point in the exam.

Management

- ▶ **Withdraw the offending drug** — this is the definitive intervention; constitutional, articular and serosal symptoms typically remit over weeks to months.
- ▶ For symptomatic relief while the syndrome settles: **NSAIDs** for arthralgia/serositis and a **short course of low-dose corticosteroids** for more troublesome serositis or persistent arthritis (standard supportive practice).
- ▶ **Hydroxychloroquine** may be used for persistent cutaneous/articular symptoms, particularly in drug-induced SCLE.
- ▶ The patient (and treating physicians) should be advised to **avoid re-challenge** with the culprit agent.
- ▶ Note that the **ANA may persist for months to years** after clinical recovery and does not require treatment — clinical, not serologic, resolution guides management.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Venn / comparison diagram “DIL vs SLE”:** two overlapping circles. *DIL circle labels* — drug exposure, equal sex ratio, antihistone antibody, homogeneous ANA, normal complement, no renal/CNS disease, resolves on stopping drug. *SLE circle labels* — female predominance, anti-dsDNA & anti-Sm, low C3/C4, nephritis & neuropsychiatric disease, chronic course. *Overlap labels* — positive ANA, fever, arthritis, serositis, rash, antihistone positivity.
- ▶ **Schematic of pathogenesis:** Drug → (slow acetylator / NAT2) → reactive metabolite modifies **histone–DNA (chromatin)** → loss of self-tolerance → **antihistone antibodies + ANA** → SLE-like illness → *drug withdrawal* → resolution. Labels: Culprit drug, NAT2 / slow acetylator, Histone–DNA complex, Antihistone Ab, Homogeneous ANA, Reversibility.

Clinical / Diagnostic significance

- ▶ A new **lupus-like illness in an older patient on procainamide, hydralazine, isoniazid or minocycline** should trigger DIL workup before labelling idiopathic SLE.
- ▶ **Antihistone positivity with absent anti-dsDNA/Sm and normal complement** strongly favours DIL; conversely, low complement, anti-dsDNA, nephritis or neuropsychiatric disease points to true SLE.
- ▶ An **anti-TNF-treated patient** developing arthralgia, rash and serositis with **anti-dsDNA but negative antihistone** is the classic biologic-induced lupus pattern.
- ▶ **Hydrochlorothiazide-associated photosensitive annular/papulosquamous rash** with anti-Ro positivity suggests **drug-induced SCLE**.
- ▶ Distinguish DIL (reversible, organ-sparing) from **drug-induced ANCA vasculitis** (PTU/hydralazine/minocycline; p-ANCA, can cause glomerulonephritis), which needs immunosuppression, not just drug withdrawal.

High-yield exam pointers

- ▶ DIL = 6–12% of all lupus; first agent described was **hydralazine (1954)**; **>100 drugs** implicated.
- ▶ **Highest risk: procainamide (~30%)**; hydralazine 5–8% if used ≥1 year; most others <1%.
- ▶ **Antihistone antibody** is the serologic hallmark (75–95%) but is **NOT specific** (also in SLE); **homogeneous ANA**.
- ▶ **Anti-dsDNA, anti-Sm absent and complement normal** in classic DIL — their presence argues for true SLE.
- ▶ **Renal and CNS involvement are rare; sex ratio is nearly equal**; disease is **milder** than SLE.
- ▶ **Slow acetylators (NAT2)** develop hydralazine/procainamide/isoniazid DIL earlier and more often.

- ▶ **TNF inhibitors** (infliximab, etanercept) induce **anti-dsDNA** but **usually not antihistone** — exception to the rule.
- ▶ **Treatment** = **stop the drug**; NSAIDs ± short steroids for symptoms; resolves in **weeks to months**; ANA may persist.
- ▶ **Drug-induced SCLE** — think **hydrochlorothiazide**, terbinafine, PPIs, CCBs, ACE inhibitors.
- ▶ **Drug-induced ANCA vasculitis** — PTU, hydralazine, minocycline, allopurinol, penicillamine, sulfasalazine (high-titre p-ANCA).

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “**Systemic Lupus Erythematosus**” (Drug-Induced Lupus section; Table 368-2, Autoantibodies in SLE; Drug-Induced Autoimmunity).
- ▶ **CMDT 2026** — “**Rheumatologic, Immunologic, & Allergic Disorders**” (Drug-Induced Lupus; SLE serology and differential diagnosis; drug-induced SCLE and drug-induced ANCA vasculitis).
- ▶ **Bologna, Dermatology** — “**Drug Interactions**” (slow-acetylator / pharmacogenetic risk factor) for the acetylator phenotype point.
- ▶ *Coverage note:* The corpus covers DIL well within the SLE chapters. The **NAT2 slow-acetylator** mechanism and the specific roles of **NSAIDs/short-course corticosteroids/hydroxychloroquine** for residual symptoms are standard, universally accepted internal-medicine teaching corroborated in the corpus only in part (acetylator phenotype via Bologna); they are included as established facts, not from a dedicated DIL management trial.

Takayasu Arteritis — Clinical Manifestations and Diagnosis

Asked in: Paper III May 2025 — RGUHS MD General Medicine

Definition / Introduction — **Takayasu arteritis (TAK)** is an idiopathic, chronic, granulomatous **large-vessel vasculitis** with a strong predilection for the **aorta, its major branches, and the pulmonary arteries**. It produces a *panarteritis* that leads to **stenosis, occlusion, post-stenotic dilatation and aneurysm formation**, the clinical hallmark being **absent or diminished pulses** (hence the eponym “*pulseless disease*” / *aortic arch syndrome*). It is an uncommon disease (annual incidence **1.2–2.6 per million**), most prevalent in **adolescent girls and young women**, and although commoner in Asia it is neither racially nor geographically restricted.

Pathology and Pathogenesis (basis of the clinical picture)

- ▶ **Vessels involved:** large elastic arteries — aortic arch and its branches; the pulmonary artery may also be involved. Involvement of the major branches is **much more marked at their origin than distally**, explaining the bruits and pulse loss at vessel ostia.
- ▶ **Histology:** a **panarteritis** with inflammatory **mononuclear-cell infiltrates** and occasionally **giant cells**; marked **intimal proliferation and fibrosis**, scarring and vascularisation of the media, and **disruption/degeneration of the elastic lamina**. The **vasa vasorum** are frequently involved.
- ▶ **Consequences:** luminal **narrowing with or without thrombosis** → tissue ischaemia; weakening of the wall → **aneurysm**. Organ pathology reflects reduced blood flow through stenoses.
- ▶ **Immunopathogenesis** is uncertain; circulating immune complexes have been demonstrated but their significance is unclear.

Clinical Manifestations

TAK is a **systemic disease** with both *generalised (constitutional)* and *vascular (ischaemic)* features, classically evolving through overlapping phases:

- ▶ **Systemic / “pre-pulseless” phase:** malaise, fever, night sweats, **arthralgias**, anorexia and **weight loss** — may precede overt vessel involvement by months.
- ▶ **Vascular / occlusive phase:** symptoms and signs of organ ischaemia as constitutional features merge into vascular compromise.
- ▶ **Cardinal physical signs:** pulses are commonly absent in involved vessels (especially the subclavian), an **inter-arm blood-pressure discrepancy**, **arterial bruits** (carotid, subclavian, abdominal), **carotidynia** (tenderness over the carotid arteries) and **limb claudication**.
- ▶ **Hypertension occurs in 32–93%** of patients (frequently from renal-artery stenosis) and is a major driver of **renal, cardiac and cerebral injury**.

Pattern of arterial involvement (Harrison Table 375-7) — frequency of arteriographic abnormality and resulting clinical features:

Artery	Arteriographic involvement	Clinical manifestation
Subclavian	93%	Arm claudication, Raynaud's phenomenon
Common carotid	58%	Visual changes, syncope, TIA, stroke
Abdominal aorta	47%	Abdominal pain, nausea, vomiting
Renal	38%	Hypertension , renal failure
Aortic arch / root	35%	Aortic insufficiency , congestive heart failure

Artery	Arteriographic involvement	Clinical manifestation
Vertebral	35%	Visual changes, dizziness
Coeliac axis	18%	Abdominal pain, nausea, vomiting
Superior mesenteric	18%	Abdominal pain, nausea, vomiting
Iliac	17%	Leg claudication
Pulmonary	10–40%	Atypical chest pain, dyspnoea
Coronary	<10%	Chest pain, myocardial infarction

- ▶ **Ophthalmic/CNS:** carotid and vertebral disease → visual changes, dizziness, syncope, TIA, stroke; **retinopathy** may be seen.
- ▶ **Cardiac:** aortic-root dilatation → **aortic regurgitation and heart failure**; coronary ostial disease → angina/MI; hypertensive heart disease.
- ▶ **Renovascular:** renal-artery stenosis → **renovascular hypertension** and renal failure.

Laboratory Findings

- ▶ **Acute-phase reactants:** elevated ESR and/or CRP — raised in most active cases and useful for monitoring (but neither sensitive nor specific, and may be normal in “burnt-out” disease).
- ▶ **Mild anaemia** and **elevated immunoglobulin levels**.
- ▶ **No specific autoantibody** exists; ANCA is characteristically negative — distinguishing TAK from ANCA-associated small-vessel vasculitides.

Diagnosis

- ▶ **Clinical suspicion:** the diagnosis should be **strongly suspected** in a **young woman** who develops a **decrease or absence of peripheral pulses**, a **discrepancy in blood pressure between the arms**, or **arterial bruits**.
- ▶ **Confirmatory imaging** — **angiography is the cornerstone**. Characteristic findings: **irregular vessel walls**, **stenosis**, **post-stenotic dilatation**, **aneurysm formation**, **occlusion**, and **increased collateral circulation**.
- ▶ **Whole-aorta imaging is mandatory** because lesions are widely distributed: **MR or CT arteriography** of the aorta and its major branches should be obtained to delineate the full distribution and severity. **MRI** also detects **inflammatory mural thickening** (early/active disease); **CT angiography** best shows the stenoses, occlusions and dilatations.
- ▶ **¹⁸F-FDG-PET** can demonstrate large-vessel wall metabolic activity and help assess disease activity (emerging role).

- ▶ Tissue is rarely available or necessary; biopsy is obtained only if vascular surgery is performed, because the affected vessels are large.
- ▶ Classification criteria (aids, not for clinical diagnosis): the 1990 ACR criteria (≥ 3 of 6 $\rightarrow$ classification): age at onset ≤ 40 y, limb claudication, decreased brachial pulse, **>10 mmHg inter-arm systolic BP difference**, bruit over subclavian arteries/aorta, and arteriographic abnormality. These have been updated by the 2022 ACR/EULAR classification criteria, which formally incorporate imaging.

Differential Diagnosis

- ▶ Giant cell arteritis (GCA): the other large-vessel granulomatous arteritis, but affects patients >50 years (TAK typically <40); shares aortic/branch involvement and raised ESR/CRP.
- ▶ IgG4-related disease (aortitis/periaortitis): histologically distinguished by a dense lymphoplasmacytic infiltrate rich in IgG4-positive plasma cells, storiform fibrosis and obliterative phlebitis.
- ▶ Atherosclerosis, fibromuscular dysplasia, congenital coarctation, syphilitic/infective aortitis, and connective-tissue aortopathies (e.g., Behçet's, Cogan's) when aortic disease is present.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ Aortic tree schematic (front view): label ascending aorta, aortic arch, brachiocephalic trunk, right & left common carotid, right & left subclavian (mark “93% — pulseless”), vertebral arteries, descending thoracic aorta, abdominal aorta, coeliac axis, superior mesenteric artery, renal arteries (mark “renovascular HTN”), iliac arteries, pulmonary artery; shade stenosis, post-stenotic dilatation and an aneurysm to depict the lesion types.
- ▶ Cross-section of an affected artery: label intimal proliferation/fibrosis, thickened scarred media with giant cells, disrupted elastic lamina, involved vasa vasorum, narrowed lumen $\pm$ thrombus — illustrating the “panarteritis”.

Clinical / Diagnostic significance

- ▶ Four-limb BP and bilateral pulse examination with auscultation for bruits is the single most important bedside screen; central aortic pressure may be needed when both arms are affected.
- ▶ Whole-aorta MR/CT angiography both confirms the diagnosis and maps lesions for management; serial imaging plus ESR/CRP guide activity monitoring.
- ▶ Management (for context): glucocorticoids (prednisone 40–60 mg/d, or ~ 1 mg/kg/d, then taper) are first-line; steroid-sparing/refractory options include methotrexate (up to 25 mg/week), azathioprine, mycophenolate mofetil and TNF inhibitors (CMDT lists TNF inhibitors as first-line adjunct); tocilizumab and tofacitinib have limited data. Antiplatelet therapy is advised in active disease or critical cranial/vertebrobasilar involvement.

- ▶ **Revascularisation** (surgery/angioplasty) is reserved for established critical stenoses and is best performed when **inflammation is medically controlled**.
- ▶ **Prognosis**: chronic, relapsing-remitting; overall survival $\geq 94\%$ in North-American series though 5-year mortality has ranged 0–35%; death is usually from **heart failure, stroke, MI, aneurysm rupture or renal failure**.

High-yield exam pointers

- ▶ **TAK = large-vessel granulomatous vasculitis of aorta + branches**; “*pulseless disease*” of young Asian women.
- ▶ **Subclavian artery is the most commonly involved (93%)** → arm claudication + absent pulse.
- ▶ **Triad to suspect**: absent/diminished pulses, **inter-arm BP discrepancy**, and **arterial bruits** in a young woman.
- ▶ **Hypertension (32–93%)** is common and often **renovascular** — always measure BP carefully (may underestimate central pressure if subclavians are stenosed).
- ▶ **Raised ESR/CRP, mild anaemia, raised immunoglobulins; ANCA-negative, no specific autoantibody**.
- ▶ **Diagnosis is by imaging**: whole-aorta MR/CT angiography (stenosis, post-stenotic dilatation, aneurysm, occlusion, collaterals); **biopsy rarely needed**.
- ▶ **Differentiate from GCA (>50 y)** and **IgG4-related aortitis** (IgG4+ plasma cells, storiform fibrosis, obliterative phlebitis).
- ▶ **1990 ACR criteria**: ≥ 3 of 6 (age ≤ 40 , claudication, $\downarrow$ brachial pulse, > 10 mmHg inter-arm BP difference, subclavian/aortic bruit, arteriographic abnormality).

SOURCE & COVERAGE

- ▶ **Harrison’s Principles of Internal Medicine, 22e** — “*The Vasculitis Syndromes*” (Takayasu Arteritis: definition, epidemiology, pathology/pathogenesis, Table 375-7 frequency of arteriographic abnormalities and clinical manifestations, clinical/laboratory features, diagnosis, IgG4-related disease differential, treatment and prognosis).
- ▶ **CMDT 2026** — “*Rheumatologic, Immunologic, & Allergic Disorders*” (Takayasu arteritis: carotidynia and bedside signs, MRI/CT-angiography, 2022 ACR/EULAR classification criteria reference, and current management — corticosteroids, methotrexate/azathioprine/MMF/TNF inhibitors, antiplatelet therapy).
- ▶ **Coverage note**: The corpus (Harrison ch. on the Vasculitis Syndromes + CMDT 2026) does not enumerate the individual **1990 ACR criteria items** or the **Numano/Hata angiographic types (I–V)**; these are included as universally-accepted standard internal-medicine teaching, and the 2022 ACR/EULAR criteria are cited by CMDT only as a reference (items not listed in the text). The constitutional → vascular → fibrotic “triphasic

course,” the *pulseless disease/aortic arch syndrome* eponym, and the GCA age cut-off (>50 y) are standard textbook points reinforcing the sourced material.

Extra-glandular Manifestations and Treatment of Primary Sjögren’s Syndrome

Asked in: Paper III Jul 2020 — RGUHS MD General Medicine

Definition / Introduction — Sjögren’s disease (syndrome) is a prototype systemic autoimmune disorder characterised by lymphocytic infiltration of the exocrine glands producing **xerostomia** and **keratoconjunctivitis sicca**, together with profound **B-cell hyperactivity**. It occurs alone (*primary* Sjögren’s) or with another rheumatic disease (*secondary* — most often rheumatoid arthritis, SLE, limited scleroderma). It predominantly affects middle-aged women (F:M 9–20:1), has a prevalence of ~0.5–1%, and carries the **highest risk of lymphoma among all autoimmune diseases**. Although the glandular sicca complex dominates, roughly **one-third of patients develop extra-glandular (systemic) manifestations**, which determine prognosis and guide treatment.

Classification of extra-glandular manifestations

Extra-glandular disease is best grouped by its **pathogenic mechanism** into four categories — *nonspecific*, *periepithelial* (lymphocytes surrounding parenchymal epithelium — Moutsopoulos’ concept of **autoimmune epithelitis**), *immune-complex-mediated* (vasculitic), and *lymphoma*.

Manifestation	Approx. %	Mechanism / Remark
Fatigability / myalgias	25	Nonspecific; overlaps fibromyalgia
Arthralgias / arthritis	60	Nonspecific; non-erosive , may give <i>Jaccoud’s arthropathy</i>
Raynaud’s phenomenon	37	Nonspecific; precedes sicca in one-third
Lung involvement	14	Periepithelial; small-airway disease / lymphocytic interstitial pneumonitis
Kidney involvement	9	Periepithelial; interstitial nephritis, often asymptomatic
Liver involvement	6	Periepithelial; primary biliary cholangitis (stage I)
Small-vessel vasculitis	9	Immune-complex; purpura, urticarial lesions

Manifestation	Approx. %	Mechanism / Remark
Peripheral neuropathy	2	Immune-complex; sensory or sensorimotor polyneuropathy
Glomerulonephritis	2	Immune-complex; membranoproliferative
Lymphoma	6	Glandular MALT lymphoma most common

Nonspecific & musculoskeletal manifestations

- ▶ **Constitutional:** fatigability, low-grade fever, myalgias — frequently with a coexistent fibromyalgia phenotype.
- ▶ **Arthritis/arthralgia (≈60%):** the commonest systemic feature; characteristically **non-erosive**. Reducible deformities (*Jaccoud's arthropathy*) may occur, but bony erosions are absent in primary disease (their presence suggests overlapping RA).
- ▶ **Raynaud's phenomenon (≈37%):** present in a third of patients and may *precede* the sicca symptoms by years; unlike scleroderma it is usually not associated with digital ulceration.

Periepithelial (autoimmune epithelitis) manifestations

Periepithelial lymphocytic accumulation around the epithelium of parenchymal organs explains the visceral disease:

- ▶ **Lung (≈14%):** usually a dry cough, rarely dyspnoea. Pathology = peribronchial infiltrates (**bronchitis sicca**), small-airway disease and **interstitial pneumonitis** (including lymphocytic interstitial pneumonitis).
- ▶ **Kidney (≈9%):** **interstitial nephritis** producing hyposthenuria and renal tubular dysfunction, classically **distal (type I) renal tubular acidosis** (in up to ~20% per CMDT). Untreated acidosis can cause **nephrocalcinosis**; chronic interstitial nephritis may impair GFR.
- ▶ **Liver (≈6%):** autoimmune cholangitis / **primary biliary cholangitis (stage I)** — suggested by antimitochondrial antibodies.
- ▶ **Other exocrine epithelia:** xerotrachea, oesophageal dysmotility, atrophic gastritis, dyspareunia from genital dryness, and dry skin.

Immune-complex-mediated (vasculitic) manifestations

Driven by circulating immune complexes and **cryoglobulins**:

- ▶ **Cutaneous small-vessel vasculitis (≈9%):** **palpable purpura** (most typical), urticarial lesions, and skin ulceration — often with mixed **type II or III cryoglobulinaemia** and **low C4**.
- ▶ **Peripheral nervous system:** sensory or sensorimotor **polyneuropathy** and **mononeuritis multiplex**; *anti-calponin-3* antibodies have been linked to peripheral neuropathy.

- ▶ **Renal: membranoproliferative glomerulonephritis** associated with cryoglobulinaemia (distinct from the periepipithelial interstitial nephritis above).
- ▶ **Central nervous system (rare):** occasionally myelitis with anti-aquaporin-4 antibodies (neuromyelitis optica spectrum); CMDT also notes dysautonomia.
- ▶ **Cardiovascular:** like RA and SLE, an increased risk of cardiovascular disease.

Lymphoma — the most feared complication

- ▶ Sjögren's carries the **highest lymphoma risk of any autoimmune disease**; lifetime incidence $\approx$ 5–10% of the cohort.
- ▶ Most are **extranodal, low-grade, marginal-zone B-cell (MALT) lymphomas**, often detected incidentally on labial salivary-gland biopsy; affected nodes are typically peripheral.
- ▶ **Risk factors (Fig. 373-2):** *clinical* — persistent **parotid/major salivary gland enlargement**, severe tongue atrophy, **palpable purpura**; *haematologic/serologic* — leukopenia, autoantibodies (RF, anti-Ro/SSA, anti-La/SSB), **low C4, monoclonal gammopathy, cryoglobulins**; *histopathologic* — **germinal-centre formation** and heavy focal lymphocytic infiltrates in salivary tissue.
- ▶ **Worse survival** with B symptoms, nodal mass >7 cm, and high/intermediate histologic grade. FDG-PET/CT helps exclude transformation when lymphoma is suspected.
- ▶ Pathogenically, chronic B-cell stimulation driven by elevated **BAFF (B-cell activating factor)** under type I/II interferon signalling, germinal-centre formation and cryoglobulin-producing clones (carrying mutations seen in B-cell malignancies) underlie the malignant evolution — this rationalises the **anti-BAFF/anti-CD20** therapeutic targets.

Treatment of primary Sjögren's

Management is twofold — **symptomatic relief of sicca** (substitution and stimulation of secretions) and **immunomodulation for systemic disease**.

Target	First-line / agents
Dry eyes	Artificial tears (hydroxypropyl methylcellulose, polyvinyl alcohol, 0.5% methylcellulose); topical cyclosporine 0.05% or lifitegrast 5% ; corneal ulcer → eye patching + boric-acid ointment
Dry mouth	Water (best replacement); sugar-free gum/hard candy; secretagogues — pilocarpine 5 mg TID or cevimeline 30 mg TID ; strict oral hygiene + fluoride to prevent caries
Arthralgia / mild arthritis	Hydroxychloroquine 200–400 mg/day and/or methotrexate 0.2–0.3 mg/kg/week
Distal RTA	Oral sodium bicarbonate 0.5–2 mmol/kg/day in 4 divided doses

Target	First-line / agents
Systemic / vasculitic disease	Glucocorticoids + rituximab (anti-CD20) — especially purpura and persistent arthritis
Refractory / emerging	Sequential belimumab → rituximab; ianalumab (anti-BAFF-R); anti-CD40L/CD40; nipocalimab (FcRn blocker, FDA Breakthrough 2024)
Vaginal dryness	Propionic-acid gels / lubricants

- ▶ **Avoid** drugs that worsen dryness — diuretics, antihypertensives, **anticholinergics**, antidepressants/decongestants.
- ▶ **Lymphoma** is managed per standard lymphoma protocols for the general population; low-grade localised MALT lymphoma may be watched or treated with rituximab-based therapy.
- ▶ **General principles:** there is no proven disease-modifying therapy that reverses glandular destruction, so treatment is largely organ-directed — escalate from local/symptomatic measures, to hydroxychloroquine for musculoskeletal disease, to glucocorticoids ± rituximab for organ-threatening vasculitic, neurologic, pulmonary or renal involvement. Patient-reported activity (ESSPRI) and systemic activity (ESSDAI) indices guide intensity.
- ▶ Formal management recommendations have been issued by EULAR and the British Society for Rheumatology.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Mechanism-based classification wheel:** central circle “Extra-glandular Sjögren’s” with four spokes labelled **Nonspecific** (fatigue, arthralgia, Raynaud’s), **Periepithelial / autoimmune epithelitis** (lung, kidney–RTA, liver–PBC), **Immune-complex / vasculitic** (purpura, cryoglobulinaemia, neuropathy, MPGN), **Lymphoma** (MALT).
- ▶ **Lymphoma risk-factor triangle (Fig. 373-2):** three sides labelled *Clinical* (parotid enlargement, tongue atrophy, palpable purpura), *Haematologic/Serologic* (leukopenia, RF/anti-Ro/anti-La, low C4, monoclonal gammopathy, cryoglobulins), *Histopathologic* (germinal centres, focal lymphocytic infiltrates) → apex “MALT lymphoma”.

Clinical / Diagnostic significance

- ▶ Suspect primary Sjögren’s when sicca is accompanied by **major salivary-gland enlargement, palpable purpura, Raynaud’s, or RTA**.
- ▶ **Investigations:** Schirmer’s I test (≤ 5 mm/5 min), ocular staining (lissamine green/Rose Bengal; ocular staining score ≥ 5 or van Bijsterveld ≥ 4), unstimulated whole-saliva flow ≤ 0.1 mL/min, salivary-gland ultrasound, **labial minor salivary-gland biopsy (focus score ≥ 1)**, anti-Ro/SSA, anti-La/SSB, RF, ANA, C4, cryoglobulins and serum protein electrophoresis. The **2016 ACR–EULAR criteria** weight biopsy focal sialadenitis and anti-Ro most heavily.

- ▶ **Exclude mimics:** hepatitis C, HIV (CD8 diffuse infiltration), sarcoidosis (non-caseating granulomas), amyloidosis, **IgG4-related disease**, prior head-and-neck radiation, GVHD.
- ▶ **Monitor** persistent parotid swelling, falling C4, new monoclonal band or cryoglobulins, and B symptoms — red flags for lymphoma warranting biopsy/FDG-PET.

High-yield exam pointers

- ▶ Extra-glandular disease affects ~1/3 of patients; classify as **nonspecific, periepithelial, immune-complex, lymphoma**.
- ▶ Arthritis is **non-erosive** (→ *Jaccoud's*); erosions imply overlap RA.
- ▶ **Distal (type I) RTA** from interstitial nephritis is the classic renal lesion → treat with oral bicarbonate; MPGN is cryoglobulin-driven.
- ▶ **Palpable purpura + low C4 + cryoglobulins** = vasculitic Sjögren's and a **lymphoma risk marker**.
- ▶ Highest lymphoma risk of any autoimmune disease; commonest = **extranodal marginal-zone (MALT) lymphoma** of salivary gland.
- ▶ Secretagogues = **pilocarpine 5 mg TID / cevimeline 30 mg TID**; both are muscarinic agonists — avoid in uncontrolled asthma/narrow-angle glaucoma.
- ▶ Systemic/vasculitic disease → **glucocorticoids + rituximab**; emerging B-cell/BAFF/FcRn agents (belimumab→rituximab, ianalumab, nipocalimab).
- ▶ **Anti-aquaporin-4 myelitis** is a rare CNS manifestation.

SOURCE & COVERAGE

- ▶ Harrison's Principles of Internal Medicine, 22e — "Sjögren's Disease" (Table 373-1 prevalence of extra-glandular manifestations; Fig. 373-2 lymphoma risk factors; Fig. 373-3 / 2016 ACR-EULAR criteria; treatment section).
- ▶ CMDT 2026 — "Sjögren Disease" (Chapter 23, Rheumatologic, Immunologic & Allergic Disorders) for current symptomatic and biologic management (topical cyclosporine 0.05%/lifitegrast 5%, ianalumab, nipocalimab) and distal RTA frequency.

Extra-articular manifestations of rheumatoid arthritis

Asked in: Paper III Dec 2023 — RGUHS MD General Medicine

Definition / Introduction — Rheumatoid arthritis (RA) is a chronic systemic inflammatory disease whose dominant manifestation is symmetric erosive polyarthritis, but it is not confined to joints. Extra-articular manifestations are non-synovial organ-system features caused by systemic inflammation, immune-complex disease, vasculitis, nodulosis, treatment complications, and comorbidity clustering. They may occur in up to 40% of patients, may rarely precede arthritis, and are most likely in smokers,

patients with early severe disability, and patients positive for **rheumatoid factor (RF)** or **anti-citrullinated protein antibodies (ACPA/anti-CCP)**.

Predisposition and broad classification

- ▶ Extra-articular RA usually indicates **high inflammatory burden**, **seropositive disease**, long disease duration, nodular/erosive phenotype, or poor functional status.
- ▶ Frequently observed extra-articular features include **subcutaneous nodules**, **secondary Sjogren disease**, **interstitial lung disease (ILD)**, **pulmonary nodules**, and **anemia of chronic disease**.
- ▶ Severe systemic variants such as **rheumatoid vasculitis** and **Felty syndrome** have become less common with earlier and more aggressive disease-modifying therapy.
- ▶ Fever, weight loss, fatigue, malaise, depression, and cachexia reflect systemic inflammation; fever $>38.3^{\circ}\text{C}$ during RA should prompt search for **infection** or **systemic vasculitis**, not be dismissed as arthritis activity.

System	Important extra-articular manifestations
Constitutional	Fatigue, fever, weight loss, malaise, depression, cachexia
Skin/subcutaneous	Rheumatoid nodules, purpura, digital infarcts, gangrene, leg ulcers, pyoderma gangrenosum
Eye/oral	Keratoconjunctivitis sicca, xerostomia, episcleritis, scleritis, peripheral ulcerative keratitis, periodontitis
Lung/pleura	Pleuritis, exudative pleural effusion, pulmonary nodules, ILD, pulmonary vasculitis, organizing pneumonia, bronchiectasis, bronchiolitis
Heart/vessels	Pericarditis, pericardial effusion, ischemic heart disease, myocarditis, cardiomyopathy, arrhythmia, mitral regurgitation
Neurologic	Cervical myelopathy from C1-C2 disease; mononeuritis multiplex in vasculitis; entrapment neuropathy
Hematologic/immune	Anemia of chronic disease, thrombocytosis, neutropenia, splenomegaly, Felty syndrome, T-cell large granular lymphocyte disorder, lymphoma
Renal/skeletal	Membranous nephropathy, secondary amyloidosis, osteoporosis and fragility fracture

Constitutional, cutaneous, ocular and sicca manifestations

- ▶ **Constitutional symptoms** may precede joint symptoms and are useful bedside markers of active systemic inflammation. Cachexia and persistent fever suggest severe disease or an alternative diagnosis such as infection, occult malignancy, or vasculitis.
- ▶ **Rheumatoid nodules** occur classically in seropositive, erosive, high-activity RA. Harrison reports nodules in 30-40% historically, while CMDT emphasizes about 20% in current clinical practice.
- ▶ Nodules are firm, usually nontender, and often adherent to periosteum, tendon, or bursa. Common sites are pressure areas: **extensor forearm/elbow**, sacral prominences, Achilles tendon, bursae, and tendon sheaths.
- ▶ Nodules may also occur in **lung, pleura, pericardium, peritoneum, sclera**, and other tissues. Complications include ulceration, infection, and gangrene; accelerated nodulosis can occur during long-term methotrexate therapy.
- ▶ **Secondary Sjogren disease** occurs in about 10% of RA patients and presents with **keratoconjunctivitis sicca** and/or **xerostomia**. It may cause dry eye, burning foreign-body sensation, photophobia, dental caries, oral discomfort, and mucosal dryness.
- ▶ Ocular disease includes **episcleritis, scleritis, scleromalacia from scleral nodules**, and **peripheral ulcerative keratitis**. Scleritis is deeper and more serious than episcleritis: it causes severe ocular tenderness, pain, violaceous discoloration, and may threaten vision.
- ▶ **Pyoderma gangrenosum** and palpable purpura are important skin associations. Palpable purpura, livedo reticularis, nail-fold infarcts, and digital ischemia should suggest rheumatoid vasculitis.

Pulmonary and upper-airway manifestations

- ▶ **Pleuritis** is the most common pulmonary manifestation of RA. It causes pleuritic chest pain, dyspnea, pleural rub, and radiographic pleural effusion. Pleural effusions are usually **exudative** with increased monocytes and neutrophils; pleural fluid pH may be low and can mimic complicated parapneumonic or malignant effusions.
- ▶ **RA-associated ILD** presents with dry cough and progressive exertional dyspnea. It is associated with smoking, high RA disease activity, and seropositive disease, and may rarely be detected before joint symptoms.
- ▶ Harrison reports overall RA-ILD prevalence as high as 12%; CMDT notes clinically significant ILD in about 10%. ILD confers poor prognosis and contributes substantially to excess mortality in RA.
- ▶ Diagnosis is by **high-resolution CT (HRCT)** and **pulmonary function tests**. HRCT shows peripheral infiltrative or ground-glass opacification. PFTs typically show a **restrictive pattern** with reduced total lung capacity and reduced DLCO.
- ▶ The two main RA-ILD patterns are **usual interstitial pneumonia (UIP)** and **nonspecific interstitial pneumonia (NSIP)**. UIP produces progressive lower-zone/peripheral fibrosis with

honeycombing; NSIP produces more symmetric bilateral ground-glass opacities, fine reticulation, volume loss, and traction bronchiectasis.

- ▶ **Pulmonary nodules** may be solitary or multiple. *Caplan syndrome* is pulmonary nodulosis with pneumoconiosis after silica exposure.
- ▶ Less common respiratory manifestations are **pulmonary vasculitis**, organizing pneumonia, bronchiectasis, constrictive bronchiolitis, follicular bronchiolitis, and respiratory bronchiolitis.
- ▶ **Cricoarytenoid arthritis** in advanced RA may cause hoarseness, throat pain, stridor, or vocal fold immobility; acute airway compromise requires urgent specialist assessment.

Cardiovascular, vasculitic and neurologic manifestations

- ▶ The **pericardium** is the most frequent site of cardiac involvement. Symptomatic pericarditis occurs in <10%, but pericardial involvement may be detectable by echocardiography or autopsy in nearly half of patients; up to 20% have asymptomatic pericardial effusion on echocardiography.
- ▶ RA pericarditis presents like other inflammatory pericarditis: pleuritic/postural chest pain, pericardial rub, widespread ST elevation or PR depression, and/or new or worsening pericardial effusion.
- ▶ Other cardiac manifestations include **myocarditis**, cardiomyopathy from necrotizing or granulomatous inflammation, diastolic dysfunction, ischemic heart disease, arrhythmia, mitral regurgitation, and rarely myocardial nodules or amyloid infiltration.
- ▶ **Cardiovascular disease is the commonest cause of death in RA.** Coronary artery disease, carotid atherosclerosis, and heart failure occur more often than expected from traditional risk factors alone; systemic inflammation adds to risk.
- ▶ **Rheumatoid vasculitis** is now uncommon, with overall incidence <1%. It typically occurs in long-standing, severe, seropositive RA with RF/ACPA positivity and hypocomplementemia.
- ▶ Cutaneous vasculitis ranges from petechiae, purpura, nail-fold or pulp infarcts and livedo reticularis to digital gangrene and large painful lower-limb ulcers. Ulcers may resemble venous disease but require recognition as systemic vasculitis.
- ▶ Neurologic vasculitis causes **sensorimotor neuropathy** or **mononeuritis multiplex**, presenting with new numbness, paresthesias, foot/wrist drop, or focal weakness.
- ▶ **Atlantoaxial involvement** is not purely extra-articular but is clinically crucial: C1-C2 instability may cause compressive myelopathy and neurologic dysfunction; current prevalence is reported as <10%.

Hematologic, renal, skeletal and malignant associations

- ▶ **Normocytic normochromic anemia of chronic disease** is the commonest hematologic abnormality. Severity generally parallels inflammation and correlates with ESR/CRP.

- ▶ Reactive **thrombocytosis** may accompany active inflammation. Immune thrombocytopenia is rare.
- ▶ **Felty syndrome** is the triad of **seropositive nodular RA**, **splenomegaly**, and **neutropenia**. It is now seen in <1%, usually in late severe destructive RA.
- ▶ Felty syndrome must be distinguished from **T-cell large granular lymphocyte (T-LGL) disorder**, which can also cause neutropenia and splenomegaly in RA and may occur earlier in the RA course.
- ▶ Clinically important neutropenia predisposes to bacterial and fungal infections; repeated bacterial infections may require myeloid growth factor therapy, and older teaching includes splenectomy for selected recurrent infection.
- ▶ **Lymphoma risk is increased two- to fourfold** in RA. Diffuse large B-cell lymphoma is the commonest histology, and risk is higher with high disease activity and Felty syndrome.
- ▶ Renal manifestations include **membranous nephropathy** and **secondary amyloidosis**. Always also consider drug nephrotoxicity, chronic inflammation, hypertension, and comorbid kidney disease.
- ▶ **Osteoporosis** is common in RA and affects both trabecular and cortical bone. Risk is increased by systemic inflammation, immobility, disability, postmenopausal status, and chronic glucocorticoids; fragility fractures increase disability and mortality.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Organ-system map of extra-articular RA**: central box “Seropositive/severe RA” with labelled branches to skin nodules/vasculitis, eye sicca/scleritis, lung pleuritis-ILD-nodules, heart pericarditis-CAD, blood anemia-Felty-lymphoma, renal amyloid/membranous nephropathy, bone osteoporosis, nervous system cervical myelopathy/mononeuritis multiplex.
- ▶ **RA lung disease panel**: pleura labelled “exudative effusion”; parenchyma labelled “UIP honeycombing, NSIP ground glass”; rounded lesions labelled “rheumatoid nodules/Caplan”; airways labelled “bronchiectasis/bronchiolitis”.

Clinical / Diagnostic significance

- ▶ Extra-articular disease is a **prognostic marker**: it identifies patients with more severe systemic inflammation, higher disability, and higher mortality from respiratory disease, cardiovascular disease, and infection.
- ▶ Evaluate every RA patient for systemic disease by history and examination: fever/weight loss, nodules, sicca symptoms, red painful eye, cough/dyspnea, chest pain, neuropathic symptoms, ulcers, splenomegaly, and fracture risk.

- ▶ Useful investigations include **CBC with differential**, ESR/CRP, RF and anti-CCP, renal function and urinalysis/proteinuria, chest radiograph, **HRCT chest**, PFT with DLCO, ECG/echocardiography when cardiac disease is suspected, ophthalmology slit-lamp examination for scleritis/keratitis, and biopsy when vasculitis, nodules, renal disease, or lymphoma is uncertain.
- ▶ Management principle: treat the underlying RA aggressively to low disease activity/remission with DMARDs, stop smoking, vaccinate appropriately, and minimize chronic glucocorticoid exposure.
- ▶ Serious extra-articular disease, such as ILD flare, necrotizing scleritis, pericarditis, vasculitis, or mononeuritis multiplex, may require high-dose glucocorticoids and specialist-directed immunosuppression; always exclude infection before escalating therapy.
- ▶ Cardiovascular risk factors require active treatment: blood pressure, diabetes, obesity, lipids, smoking, physical inactivity, and persistent RA inflammation.

High-yield exam pointers

- ▶ Write early: extra-articular RA occurs in **up to 40%** and correlates with **smoking, severe disability, RF/ACPA positivity**, and erosive/nodular disease.
- ▶ The five most frequent examples to list are **nodules, secondary Sjogren disease, ILD, pulmonary nodules, and anemia**.
- ▶ **Pleuritis** is the commonest pulmonary manifestation; **pericardium** is the commonest cardiac site.
- ▶ RA-ILD: symptoms are dry cough and progressive dyspnea; HRCT plus PFT/DLCO confirms; patterns are **UIP** and **NSIP**.
- ▶ **Felty syndrome** = **neutropenia + splenomegaly + nodular seropositive RA**; differentiate from T-LGL disorder.
- ▶ **Rheumatoid vasculitis** is rare now, <1%, but classically occurs in long-standing seropositive RA with hypocomplementemia.
- ▶ Red painful eye in RA is not trivial: **scleritis/peripheral ulcerative keratitis** can threaten vision.
- ▶ Excess mortality in RA is driven largely by **cardiovascular disease**, respiratory disease, and infection.
- ▶ Do not attribute high fever to RA until **infection and systemic vasculitis** have been excluded.

Extrapulmonary manifestations of sarcoidosis

Asked in: Paper III Nov 2021 — RGUHS MD General Medicine

Definition / Introduction — Sarcoidosis is a systemic inflammatory disease of unknown cause characterised by **nonnecrotizing (noncaseating) granulomatous inflammation**. Although the lung is affected in >90% of cases, sarcoidosis can afflict almost **any other organ system**, and about **half of all patients have extrapulmonary involvement** at some point. The disease was first described by *Jonathan Hutchinson* as a skin malady (later termed *lupus pernio*); the term “sarkoid” was coined by *Caesar Boeck*. Extrapulmonary disease drives much of the morbidity, disfigurement and mortality (cardiac and neurological involvement in particular), and serious extrapulmonary disease (cardiac, CNS, hepatic) is present in 4–7% at presentation.

Frequency of organ involvement and characteristic acute syndromes

- ▶ Almost every organ can be involved; approximate frequencies at presentation (Baughman cohort, Harrison Fig. 379-3):

Organ system	Frequency	Organ system	Frequency
Lungs	95%	Spleen	7%
Skin	16%	Neurologic	5%
Peripheral lymph nodes	15%	Salivary/parotid	4%
Eyes	12%	Hypercalcaemia (↑Ca)	4%
Liver	12%	Ear/nose/throat	3%
Heart (clinical)	2%	Bones/joints/muscles	1%
Kidneys	1%		

- ▶ ***Löfgren syndrome** (*acute, up to 10% of cases*): *fever + erythema nodosum + ankle arthralgias + bilateral hilar lymphadenopathy**. Excellent prognosis with spontaneous remission in up to 80%; commonest in Caucasians (20–30%), rare in Asians/African Americans (<5%).
- ▶ ***Heerfordt syndrome** (*uveoparotid fever; less common*): *facial (cranial) nerve palsy + fever + anterior uveitis + bilateral parotid gland enlargement**. Also has an excellent prognosis.
- ▶ These compelling presentations (along with lupus pernio) may allow diagnosis without biopsy.

Cutaneous and ocular sarcoidosis

Skin (~16%; often the most accessible biopsy site):

- ▶ **Maculopapular eruptions, nodules and plaques** are the commonest *granulomatous* (specific) lesions; also infiltration of **old scars or tattoos**, hypo-/hyperpigmentation, annular lesions, ulcers and subcutaneous nodules. Lesions are usually non-painful and non-pruritic.

- ▶ **Erythema nodosum** — a *nonspecific, nongranulomatous* reactive lesion: tender, raised, erythematous nodules over the **anterior legs**; a hallmark of Löfgren syndrome; commoner in Europeans and women.
- ▶ ***Lupus pernio** — *distinctive chronic lesion of indurated plaques and violaceous discoloration of the nose, cheeks, lips and ears, often involving the nasal mucosa*; *commonest in African-American women*; an *adverse prognostic marker** associated with bone cysts, pulmonary fibrosis and prolonged disease.
- ▶ Treat with topical/intralesional corticosteroids; disfiguring or symptomatic lesions need systemic therapy.

Eye (~12%; ophthalmologic exam recommended in all patients to detect clinically silent disease):

- ▶ **Uveitis** (anterior, posterior or panuveitis) is the **commonest** ocular manifestation, often **bilateral**. Chronic uveitis → **synechiae, glaucoma, cataract, cystoid macular oedema and blindness**.
- ▶ **Optic neuropathy** can cause **sudden permanent vision loss** and is an **emergency** requiring immediate immunosuppression.
- ▶ Other: conjunctival/eyelid granulomas (biopsiable), lacrimal gland enlargement, keratoconjunctivitis sicca, dacryocystitis, retinal vasculitis, periorbital swelling.

Cardiac and pulmonary-vascular sarcoidosis

Heart — granulomas may infiltrate any part, causing **rhythm disturbances, heart failure, pericardial effusion and sudden death**. Clinically evident in <5% of US patients but 23% of Japanese (subclinical rate higher at autopsy).

- ▶ A significant cause of **new-onset AV block, cardiomyopathy and ventricular dysrhythmias in younger patients**.
- ▶ **Sudden cardiac death** is the commonest cause of death in cardiac sarcoidosis and may be the initial presentation; **ventricular tachycardia** is the commonest tachyarrhythmia. Predictors of sudden death: severity of heart failure, LV end-diastolic diameter and sustained VT.
- ▶ **Diagnosis:** ECG in every patient (conduction block, ST-T changes, Q waves, frequent PVCs); **cardiac MRI** is the preferred imaging modality (high sensitivity for early myocardial involvement); cardiac PET/CT detects active inflammation; thallium/sestamibi scans show *reverse redistribution*. Endomyocardial biopsy has low sensitivity (patchy granulomas).
- ▶ **Management:** immunosuppression + antiarrhythmics/heart-failure therapy; ICD in those with arrhythmia; **heart transplantation** for refractory disease.

Pulmonary hypertension — a **WHO group 5** cause of PH; due to granulomatous vasculitis, nodal arterial compression, vascular bed destruction, venous occlusion or left-heart dysfunction. Suspect

when symptoms/low DLCO are disproportionate to parenchymal disease; right-heart catheterisation is the gold standard.

Neurosarcoidosis

- ▶ Highly associated with systemic disease but can occur in isolation; has a **predilection for the base of the brain**.
- ▶ **Cranial neuropathy** is the commonest manifestation — especially the **facial (VII) and optic nerves** — from granulomatous basal meningitis or direct nerve involvement. **Facial nerve palsy** carries a **good prognosis**.
- ▶ **Hypothalamic/pituitary** involvement → neuroendocrine deficits (e.g., diabetes insipidus) that may persist after treatment.
- ▶ Other: space-occupying masses, acute/chronic aseptic meningitis, peripheral neuropathy, **small-fibre neuropathy** (pain, autonomic dysfunction), spinal cord disease; rarely seizures or neuropsychiatric features.
- ▶ **Investigations:** **gadolinium-enhanced MRI** (leptomeningeal/parenchymal enhancement, periventricular white-matter lesions); **CSF** shows mononuclear pleocytosis, raised protein, raised CSF ACE, high soluble IL-2 receptor, raised lysozyme, low glucose, oligoclonal bands (supportive, not diagnostic; important to exclude infection).

Hepatosplenic, lymphoreticular, musculoskeletal, renal–metabolic and other systems

System	Key extrapulmonary features (Harrison Ch 379)
Liver	Granulomas very common (up to 80% at autopsy) but clinically significant in $\leq 15\%$; LFTs abnormal in up to one-third, raised alkaline phosphatase most common; hepatomegaly; may progress to cholestasis, portal hypertension, Budd-Chiari syndrome or cirrhosis
Lymph nodes	Peripheral lymphadenopathy may be the presenting sign — cervical, axillary, epitrochlear, inguinal nodes; discrete, mobile, non-tender, non-ulcerating
Spleen	Splenomegaly common but usually clinically silent ; hypodense nodules on imaging; rarely needs splenectomy
Parotid/salivary	$\sim 4\%$; part of Heerfordt syndrome ; painful swollen glands or xerostomia; may mimic Sjögren's syndrome
Musculoskeletal	Acute arthritis (Löfgren) common — ankles, knees, elbows, wrists, small joints ; chronic arthritis rarer;

System	Key extrapulmonary features (Harrison Ch 379)
	lacy reticular osteolytic bone lesions; myopathy/myositis/muscle nodules (commoner in women, may be sole presentation)
Hypercalcaemia/Renal	Hypercalcaemia in 10–20%, hypercalciuria in up to 50%; due to unregulated 1α-hydroxylation (CYP27B1) of vitamin D to calcitriol by macrophages despite low PTH $\rightarrow$ $\uparrow$ gut absorption + bone resorption; leads to nephrocalcinosis ; renal disease usually from hypercalcaemia, occasionally granulomatous interstitial nephritis (sterile pyuria, mild proteinuria)
GI / reproductive / ENT	GI rare (stomach commonest — dysphagia, bleeding, obstruction); reproductive granulomas (uterus, epididymis — exclude malignancy); upper-airway (larynx, pharynx, sinus) involvement signals chronic severe disease

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ “Sarcoidosis homunculus” — frequency of organ involvement: a body outline with labelled arrows to each organ and its percentage — Lungs 95%, Skin 16%, Peripheral lymph nodes 15%, Eyes 12%, Liver 12%, Spleen 7%, Neurologic 5%, Salivary/parotid 4%, Hypercalcaemia 4%, ENT 3%, Heart 2%, Bones/joints/muscles 1%, Kidneys 1%.
- ▶ **Calcium dysregulation flow diagram:** Activated macrophage/granuloma $\rightarrow$ unregulated 1 α -hydroxylase (CYP27B1) $\rightarrow$ 25-OH vitamin D $\rightarrow$ 1,25-(OH)₂ vitamin D (calcitriol) $\rightarrow$ $\uparrow$ intestinal Ca absorption + $\uparrow$ bone resorption $\rightarrow$ hypercalcaemia/hypercalciuria $\rightarrow$ nephrocalcinosis (label: low/suppressed PTH).

Clinical / Diagnostic significance

- ▶ **Baseline screening for occult extrapulmonary disease in every patient:** ophthalmologic exam (silent uveitis), ECG (silent conduction disease), serum **calcium**, alkaline phosphatase, creatinine, CBC, and 25-/1,25-vitamin D where indicated.
- ▶ **Diagnosis** rests on a compatible clinical picture + nonnecrotizing granulomas on biopsy + **exclusion of mimics** (TB, atypical mycobacteria, fungi, berylliosis, lymphoma, drug/checkpoint-inhibitor reactions). Biopsy the most accessible site (skin, conjunctival nodule, peripheral node).
- ▶ **Serum ACE** (macrophage-derived) is **not** a reliable diagnostic/prognostic test (low sensitivity) but roughly tracks granuloma burden for activity monitoring.
- ▶ **Adverse prognostic markers** are largely extrapulmonary: **lupus pernio**, **chronic uveitis**, **chronic hypercalcaemia**, **nephrocalcinosis**, **neurosarcoidosis**, **cardiac involvement**, **sinus involvement**,

cystic bone lesions (plus older age, African origin, pulmonary hypertension, fibrotic lung disease).

- ▶ **Treatment:** corticosteroids (prednisone ~0.5 mg/kg/day or 20–40 mg/day, tapered to <10 mg/day) are first-line when organs are threatened; **methotrexate** is the preferred steroid-sparing agent (others: azathioprine, leflunomide, mycophenolate, **hydroxychloroquine** — useful for skin/hypercalcaemia, **infliximab/adalimumab** for refractory disease). Organ-/life-threatening sites (CNS, sight-threatening eye, myocardium) warrant aggressive immunosuppression.

High-yield exam pointers

- ▶ **Noncaseating (necrotizing) granuloma** is the histological hallmark; inclusions include **asteroid bodies**, **Schaumann bodies** and **Hamazaki-Wesenberg bodies**.
- ▶ **Löfgren** = fever + erythema nodosum + ankle arthralgia + **bilateral hilar lymphadenopathy** (good prognosis, ~80% remit).
- ▶ **Heerfordt (uveoparotid fever)** = **parotid enlargement** + **anterior uveitis** + fever + **facial nerve palsy**.
- ▶ **Lupus pernio** = chronic violaceous nasal/facial plaques → marker of severe, chronic disease (≠ erythema nodosum, which is acute and reactive).
- ▶ **Uveitis** is the commonest eye lesion; **optic neuropathy** is a sight-threatening emergency.
- ▶ **Cardiac sarcoidosis:** sudden death + VT + AV block; **cardiac MRI/PET** preferred; consider ICD.
- ▶ **Neurosarcoidosis:** **CN VII palsy** commonest; **basal meningitis**; gadolinium MRI + CSF.
- ▶ **Hypercalcaemia** is from **macrophage 1 α -hydroxylase–driven calcitriol** with low PTH → **nephrocalcinosis**.
- ▶ **Hepatic granulomas** are very common ($\uparrow$ ALP) but usually clinically silent; splenomegaly likewise.

SOURCE & COVERAGE

Harrison's Principles of Internal Medicine, 22e — **Ch 379 "Sarcoidosis"** (Alicia K. Gerke). All organ-specific data, frequencies, eponymous syndromes and the vitamin-D/calcium mechanism are taken directly from this chapter. *Coverage note:* the synonym *uveoparotid fever* for Heerfordt syndrome and *diabetes insipidus* as an example of hypothalamic-pituitary dysfunction are universally accepted standard internal medicine added for completeness; the chapter names the syndrome and the neuroendocrine abnormality but not these exact terms.

Familial Mediterranean Fever

Asked in: Paper III 09/2025 — RGUHS MD General Medicine

Definition / Introduction — Familial Mediterranean fever (FMF) is the prototype of the hereditary recurrent (periodic) fevers — a group of monogenic **autoinflammatory** diseases driven by dysregulated *innate* immunity (myeloid effector cells and germline pattern-recognition receptors) rather than by high-titre autoantibodies or antigen-specific T cells. It is characterised by recurrent, self-limited episodes of fever accompanied by **serosal (peritoneal/pleural), synovial or cutaneous inflammation**, and, if untreated, the eventual development of systemic **AA amyloidosis**. It is caused by gain-of-function mutations in the *MEFV* gene encoding **pyrin**, and is exquisitely responsive to lifelong oral colchicine.

Epidemiology and Genetics

- ▶ **Populations:** First recognised among **Armenians, Arabs, Turks, and non-Ashkenazi (North African, Iraqi) Jews**; with genetic testing now documented in Ashkenazi Jews, Italians and other Mediterranean/Middle-Eastern groups, and occasionally in those without known Mediterranean ancestry.
- ▶ **Gene:** *MEFV* on chromosome **16p13.3**; product is a **781-amino-acid, ~95-kDa protein, pyrin** (marennostin), expressed in granulocytes, eosinophils, monocytes, dendritic cells, and synovial/peritoneal fibroblasts.
- ▶ **Inheritance:** Classically **autosomal recessive**, but clear-cut clinical cases occur with only a *single* demonstrable mutation, and certain rare mutations show **dominant** inheritance. Only ~70% of clinically typical patients have two identifiable mutations *in trans* (gain-of-function with a gene-dosage effect).
- ▶ **Carrier frequency** is as high as **1:10** in affected populations — a selective advantage is postulated, with population-genetic evidence implicating **bubonic plague pandemics** in selecting for founder mutations that arose in the Middle East in Biblical times.
- ▶ A positive **family history** is elicited in only ~50% of cases (small families).
- ▶ **Genotype–phenotype:** Most severe disease-associated mutations lie in **exon 10. M694V homozygosity** (especially in non-Ashkenazi Jews) → earlier onset and higher frequency of arthritis, erysipeloid rash and amyloidosis. The **E148Q** variant (exon 2), common in Asian populations, more often raises overall inflammation than causes overt FMF and may increase penetrance of an exon-10 mutation when present *in cis*.

Pathophysiology — the pyrin inflammasome

- ▶ Pyrin's N-terminal 92 amino acids form the **PYRIN domain (PYD)**, a homotypic protein–interaction motif also found in **cryopyrin (NLRP3)**.
- ▶ Via an intermediary adaptor (ASC), pyrin nucleates a macromolecular **pyrin inflammasome** that activates **caspase-1** (IL-1 β –converting enzyme), driving secretion of **IL-1 β and IL-18** and **gasdermin-D–mediated pyroptotic cell death**.

- ▶ Physiologically, bacterial toxins that inactivate **RhoA GTPase** (blocking cytoskeletal assembly) trigger pyrin inflammasome activation as host defence; FMF mutations are **gain-of-function**, lowering the activation threshold and producing sterile, IL-1 β -driven inflammation.
- ▶ (CMDT additionally notes deficiency of a serosal protease that normally inactivates IL-8 and complement C5a, contributing to the neutrophil-rich serositis.)

Clinical features — the acute attack

- ▶ **Onset:** Often in early infancy; **90% have had their first attack by age 20**. In infants, fever (even febrile seizures/hyperpyrexia) may be the sole manifestation.
- ▶ **Duration:** Typical episodes last **24–72 h** (arthritis somewhat longer); frequency varies from every few days to remissions of years. Triggers include physical exertion, emotional stress and menses; pregnancy is often associated with remission.

Site	Manifestation
Fever	Nearly always present; abrupt, high-grade
Abdomen (>90%)	Sterile peritonitis — pain, guarding, rebound, absent bowel sounds, air–fluid levels; neutrophil-rich exudate at laparotomy; <i>ascites rare</i> ; mimics surgical acute abdomen → “needless laparotomy”
Pleura	Unilateral, sharp, stabbing chest pain; exudative neutrophilic effusion; pleural thickening after repeated attacks
Joints	Acute monoarthritis of knee/ankle/hip; large sterile neutrophil-rich effusion <i>without</i> commensurate erythema/warmth; radiographic change rare; chronic hip/knee arthritis (~5% pre-colchicine); chronic sacroiliitis can occur irrespective of HLA-B27
Skin	Erysipelas-like erythema — raised, tender, on dorsum of foot/ankle/lower leg (most often in M694V homozygotes)
Muscle	Exercise-induced (non-febrile) myalgia common; rare protracted febrile myalgia lasting weeks
Other	Acute unilateral scrotal inflammation (prepubertal boys); rare pericarditis; aseptic meningitis (controversial)

- ▶ **Associations:** Increased frequency of IgA vasculitis (**Henoch-Schönlein purpura**) and **polyarteritis nodosa**; the M694V mutation is a risk factor for **Behçet’s syndrome** and **ankylosing spondylitis**.

- ▶ **Laboratory (during attacks):** Elevated ESR, CRP, leukocytosis, thrombocytosis (in children), raised fibrinogen, haptoglobin and immunoglobulins; transient albuminuria/haematuria.

AA (secondary) amyloidosis — the major long-term threat

- ▶ Caused by tissue deposition of a fragment of **serum amyloid A (SAA)**, an acute-phase reactant, in **kidneys, adrenals, intestine, spleen, lung and testes**; the kidney is affected first → nephrotic-range proteinuria and progressive renal failure.
- ▶ **Suspect when proteinuria persists between attacks; confirm by renal or rectal biopsy** (Congo-red apple-green birefringence).
- ▶ **Risk factors:** M694V homozygosity, positive family history (independent of mutation status), SAA1 genotype, male sex, **non-compliance with colchicine/IL-1 inhibitor**, and national origin (amyloid risk parallels infant-mortality rate).
- ▶ Now largely *preventable* with adherent colchicine prophylaxis.

The hereditary recurrent fevers — differentiation (exam table)

Feature	FMF	TRAPS	HIDS / MKD	CAPS (FCAS / MWS / NOMID)
Gene / protein	MEFV / pyrin	TNFRSF1A / p55 TNF receptor	MVK / mevalonate kinase	NLRP3 / cryopyrin
Inheritance	Recessive (or dominant)	Dominant	Recessive	Dominant (NOMID often <i>de novo</i> /mosaic)
Attack length	1–3 days	Often >7 days	3–7 days	Minutes–3 days (NOMID continuous)
Distinctive clue	Erysipeloid erythema; serositis	Migratory myalgia + overlying erythema; periorbital oedema/conjunctivitis	Cervical adenopathy, oral ulcers, palm/sole rash; ↑urinary mevalonate	Cold-induced urticarial rash (FCAS); sensorineural deafness (MWS); aseptic meningitis (NOMID)
Treatment	Colchicine ; IL-1 inhibitors if refractory	Glucocorticoids, IL-1 inhibitors, etanercept	IL-1 inhibitors; NSAIDs for fever	IL-1 inhibitors (anakinra/canakinumab/rilonacept)

(TRAPS = *TNF-receptor-associated periodic syndrome / familial Hibernian fever*; HIDS/MKD = *hyperimmunoglobulinaemia D / mevalonate kinase deficiency*; CAPS = *cryopyrin-associated periodic syndromes*.)

Diagnosis

- ▶ **Largely clinical** in experienced hands; validated clinical criteria sets perform well where pre-test probability is high. Core features: recurrent short (<72 h) febrile serositis episodes in an at-risk ethnic group, family history, and a **therapeutic response to colchicine**.
- ▶ **Genetic testing** (*MEFV* sequencing) is a useful adjunct in ambiguous cases; the expert-curated **Infevers** registry catalogues pathogenic mutations vs benign polymorphisms. Note: a single or no mutation does **not** exclude FMF.
- ▶ **Differential diagnosis**: other hereditary recurrent fevers; **PFAPA** (periodic fever, aphthous stomatitis, pharyngitis, cervical adenitis — commonest periodic fever of childhood); systemic-onset JIA / adult Still's disease; porphyria; **hereditary angio-oedema**; inflammatory bowel disease; and gynaecological disorders in women.

Treatment

- ▶ **Daily oral colchicine is first-line** — it reduces attack frequency/severity and **prevents amyloidosis** in compliant patients; intermittent dosing at attack onset is *inferior* and unproven for amyloid prevention.
- ▶ **Adult dose 1.2–1.8 mg/day** (CMDT: 0.6 mg 2–3 times daily): substantial benefit in ~two-thirds, some improvement in >90%; children need lower (non-weight-proportional) doses.
- ▶ **Side effects**: bloating, cramps, **lactose intolerance**, **diarrhoea** — minimised by low starting dose, dose-splitting, simethicone and dairy avoidance. In **renal insufficiency/elderly**, watch for **colchicine myoneuropathy** (proximal weakness, raised CK).
- ▶ **Cautions**: **never give IV colchicine to a patient already on oral colchicine** (fatal toxicity); **cyclosporine** blocks hepatic colchicine excretion via the **MDR1** transporter (toxicity post renal transplant). Colchicine is **continued in pregnancy** (FMF-attack miscarriage risk outweighs fetal risk) though it may marginally raise trisomy-21 risk if taken at conception.
- ▶ **Colchicine-resistant/intolerant disease** → **IL-1 inhibitors**: **canakinumab** (anti-IL-1 β monoclonal, monthly SC; FDA-approved for FMF on phase-3 data), **rilonacept** (IL-1 receptor fusion protein, weekly SC), **anakinra** (recombinant IL-1 receptor antagonist, daily SC; may also reduce established amyloid). Bone-marrow transplantation has an unacceptable risk–benefit ratio.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Pyrin inflammasome cascade**: *MEFV* mutation → mutant pyrin (PYD) + adaptor ASC → assembled **pyrin inflammasome** → **caspase-1** activation → **IL-1 β / IL-18** secretion + **gasdermin-D** → **pyroptosis** → recurrent sterile serositis/fever. Side-label the trigger: bacterial toxin → **RhoA GTPase inactivation**. Show colchicine and anti-IL-1 agents (anakinra/canakinumab/rilonacept) as the therapeutic blockade points.

- ▶ “Spot map” of FMF organ involvement: stick-figure with labels — *Serosa* (peritonitis, pleurisy), *Joint* (acute monoarthritis – knee/ankle), *Skin* (erysipeloid erythema – dorsum of foot), *Scrotum* (acute scrotal inflammation), and *Kidney* → AA amyloidosis (proteinuria) as the long-term complication.

Clinical / Diagnostic significance

- ▶ Consider FMF in any patient of Mediterranean/Middle-Eastern origin with **recurrent self-limited fever + serositis** and unexplained acute abdomens — early diagnosis prevents repeated negative laparotomies.
- ▶ **Persistent inter-attack proteinuria mandates work-up for AA amyloidosis** (renal/rectal biopsy); it is the leading cause of morbidity/mortality and is preventable.
- ▶ A **colchicine therapeutic trial** can be diagnostically confirmatory when genetics are equivocal.
- ▶ Lifelong adherence is the single most important determinant of outcome; counsel that colchicine is continued through pregnancy.

High-yield exam pointers

- ▶ *MEFV* gene (16p13.3) → **pyrin** → gain-of-function → over-active **pyrin inflammasome** → IL-1 β .
- ▶ Autosomal **recessive** (mostly); carrier frequency up to **1:10**; **90% present before age 20**.
- ▶ Attack = **24–72 h** of fever + **sterile peritonitis/pleuritis, monoarthritis, erysipeloid erythema**; resolves spontaneously.
- ▶ **M694V homozygote** = severe phenotype → arthritis, rash, **amyloidosis**.
- ▶ Main complication = **AA amyloidosis** (SAA deposition, renal-first, nephrotic proteinuria) — preventable by colchicine.
- ▶ **Colchicine 1.2–1.8 mg/day** is first-line and *amyloid-protective*; **IL-1 inhibitors** (canakinumab/anakinra/rilonacept) for refractory cases.
- ▶ **Never give IV colchicine to a patient on oral colchicine.**
- ▶ Differential: TRAPS, HIDS/MKD, CAPS, PFAPA, adult Still’s, hereditary angio-oedema.

SOURCE & COVERAGE

- ▶ **Harrison’s Principles of Internal Medicine, 22e** — “Familial Mediterranean Fever and Other Hereditary Autoinflammatory Diseases” (Kastner); and “Amyloidosis” (AA amyloidosis / SAA, colchicine).
- ▶ **CMDT 2026** — “Gastrointestinal Disorders” (Familial Mediterranean fever; ascites differential) and “Amyloidosis” management note.

Fibromyalgia

Asked in: Paper III Nov 2021 — RGUHS MD General Medicine

Definition / Introduction — Fibromyalgia (FM) is characterised by **chronic widespread musculoskeletal pain and tenderness**. Although defined primarily as a *pain syndrome*, patients also commonly report associated **neuropsychological symptoms** — fatigue, unrefreshing sleep, cognitive dysfunction, anxiety, and depression. Available evidence implicates the **central nervous system (CNS)** as key to maintaining the pain and other core symptoms. FM belongs to a group of **chronic primary / chronic overlapping pain conditions** and carries substantial negative consequences for physical and social functioning.

Epidemiology and risk factors

- ▶ **Worldwide prevalence** ~2% — approximately 4% in women and <1% in men; data are similar across world regions and socioeconomic classes.
- ▶ **Sex ratio:** in clinical settings women >> men at ~8:1; in population studies the ratio is closer to 3:1 (subjective criteria applied to populations raise prevalence and shift the sex ratio).
- ▶ Markedly higher in **rheumatic disease** — up to 30% of patients with rheumatoid arthritis or SLE have comorbid FM; FM occurs in ~10–30% of patients with degenerative or inflammatory rheumatic disorders (these act as peripheral pain generators).
- ▶ **Additional risk factors:** sleep disturbances, physical inactivity, and overweight or obesity.

Clinical manifestations

- ▶ **Pain and tenderness:** patients classically report “*pain all over*.” Widespread pain is operationalised as being present **above and below the waist, on both sides of the body, and involving the axial skeleton** (neck, back, or chest). The pain is poorly localised, difficult to ignore, severe, and reduces functional capacity.
- ▶ **Duration:** pain present **most of the day on most days for at least 3 months**.
- ▶ **Evoked pain sensitivity (hyperalgesia/allodynia):** elevated sensitivity may be detected clinically by pain from a **blood-pressure cuff** or **skin-roll tenderness**. Formal **tender-point examination** uses the thumbnail to exert ~4 kg/m² pressure (the amount producing blanching of the thumbnail tip) over defined musculotendinous sites; the older **ACR criteria required 11 of 18 tender points**. Tenderness is a continuous variable, so a strict categorical threshold is not essential.
- ▶ **Peripheral pain generators / triggers:** arthritis, bursitis, tendinitis, neuropathies; more subtle ones include **joint hypermobility** and **scoliosis**. Myalgias may be triggered by infectious, metabolic, or psychiatric conditions.
- ▶ **Neuropsychological symptoms:** fatigue (highly prevalent), stiffness, **non-restorative sleep** (difficulty falling/staying asleep, early-morning awakening, waking unrefreshed; may include

restless legs syndrome, sleep-disordered breathing, frank sleep apnea), and cognitive dysfunction (“fibro-fog” — impaired attention/concentration, word-retrieval difficulty, short-term memory loss with age-appropriate processing speed). Lifetime prevalence of mood disorders approaches 80% — screen for depression by querying depressed mood and anhedonia (depression is neither necessary nor sufficient for diagnosis).

- **Overlapping syndromes (chronic overlapping pain conditions):** myalgic encephalitis/chronic fatigue syndrome, temporomandibular disorder, chronic headaches, irritable bowel syndrome, interstitial cystitis/painful bladder syndrome, and other pelvic pain syndromes.
- **Psychosocial:** onset and exacerbation often during perceived stress; high prevalence of prior interpersonal violence — consider PTSD.

Diagnostic criteria (2016, after Wolfe et al.)

The newer criteria eliminate tender-point counting and rely on patient-reported widespread pain and symptom burden, using the Widespread Pain Index (WPI, 0–19) and Symptom Severity Score (SSS, 0–12).

Component	Detail
WPI (0–19)	Number of body regions with pain/tenderness over the past week
SSS (0–12)	Fatigue + trouble thinking/remembering + waking unrefreshed (each 0–3); plus abdominal pain/cramps, depression, headache over 6 months (each 0/1)
Threshold	WPI ≥ 7 and SSS ≥ 5 OR WPI 4–6 and SSS ≥ 9
Generalised pain	Pain in ≥ 4 of 5 regions (jaw, chest, and abdomen not counted)
Chronicity	Symptoms present at a similar level for ≥ 3 months

Differential diagnosis and investigations

Because musculoskeletal pain is so common, the differential is broad; inflammatory causes are identifiable by specific history, examination, and laboratory/radiographic tests.

Category	Conditions to exclude
Inflammatory	Polymyalgia rheumatica; inflammatory arthritis (RA, spondyloarthritis); connective tissue disease (SLE, Sjögren’s)
Infectious	Hepatitis C, HIV, Lyme disease, parvovirus B19, Epstein-Barr virus

Category	Conditions to exclude
Non-inflammatory	Degenerative joint/spine/disk disease; myofascial pain syndromes; bursitis, tendinitis, repetitive strain injuries
Endocrine	Hypo-/hyperthyroidism, hyperparathyroidism
Neurologic	Multiple sclerosis, neuropathic pain syndromes
Psychiatric	Major depressive disorder
Drugs	Statins, aromatase inhibitors

- ▶ **Routine labs and radiographs are normal** in uncomplicated FM; testing aims to identify alternative diagnoses, pain generators, or comorbidities.
- ▶ **Routine screen:** ESR or CRP, CBC, TSH.
- ▶ **Guided by history/examination:** complete metabolic panel, ANA, anti-SSA/anti-SSB, rheumatoid factor and anti-CCP, CPK, viral (hepatitis C, HIV) and bacterial (Lyme) serologies, spine/joint radiographs.
- ▶ Use radiography **very sparingly** (only for suspected inflammatory arthritis); **avoid repeat testing**, and particularly **discourage MRI of the spine** unless there are features of inflammatory spine disease or neurologic symptoms.

Pathophysiology and genetics

- ▶ **Polygenic vulnerability** — multiple genes in pathways controlling **pain and stress responses**; notably genes for **metabolism, transport, and receptors of serotonin and other monoamines**, shared with mood disorders and other chronic pain conditions.
- ▶ **Central pain amplification:** psychophysical testing shows **altered sensory afferent pain processing and impaired descending noxious inhibitory control**, producing **hyperalgesia and allodynia**. Functional MRI demonstrates activation of brain pain regions to stimuli that are innocuous in healthy controls.
- ▶ Pain perception is modulated by **emotional and cognitive factors** (catastrophising, perceived loss of control) — the rationale for cognitive-behavioural treatment.
- ▶ Some patients have a **small-fibre neuropathy**; early reports suggest a possible **autoimmune** contribution and altered peripheral-blood gene/metabolic signatures (not yet diagnostic).

Treatment

Optimal management requires prompt diagnosis, assessment of pain/function/psychosocial context, patient education, and a goal of **improved function and quality of life rather than elimination of pain**. Illness behaviours (e.g., frequent visits) are discouraged.

Non-pharmacologic (first-line):

- ▶ **Physical conditioning / aerobic exercise** — the most consistently helpful strategy; begin at low intensity and advance slowly. Physically inactive patients do best with **supervised or water-based** programs; add **strength training** after aerobic goals are met.
- ▶ **FDA-approved devices**: a **laser therapy** device and a **TENS** device — an RCT showed TENS reduces movement-evoked pain and fatigue.
- ▶ **Meditative movement therapies** — qigong, yoga, Tai Chi; also consider acupuncture and hydrotherapy.
- ▶ **Cognitive-behavioural strategies** to improve sleep hygiene and reduce illness behaviour.

Pharmacologic — target afferent or descending pain pathways; use single agents that cover multiple symptom domains.

Drug class	Examples	Best symptom target
Muscle relaxant	Cyclobenzaprine	Pain + sleep disturbance
Sedating tricyclic antidepressant	Amitriptyline	Pain + sleep disturbance
$\alpha 2$ - δ ligands	Gabapentin, Pregabalin	Pain + sleep disturbance
SNRIs	Duloxetine, Milnacipran	Pain + fatigue/anxiety/depression

- ▶ **Treat any comorbid triggering condition.** Glucocorticoids and NSAIDs help inflammatory triggers but are **not effective against FM symptoms**.
- ▶ **Avoid strong opioids** — no demonstrated efficacy and adverse effects worsen both symptoms and function. **Tramadol** (an opioid with mild serotonin-noradrenaline reuptake inhibitor activity) shows some efficacy but is **generally discouraged** because of opioid-related adverse effects.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Body manikin for the Widespread Pain Index** — front-and-back human outline with the 19 WPI sites labelled: right/left jaw, neck, upper back, lower back, chest, right/left shoulder, right/left upper arm, right/left lower arm, right/left hip (buttock), right/left upper leg, right/left lower leg, plus abdomen — and the **5 generalised-pain regions** (Region 1 upper-left, Region 2 upper-right, Region 3 lower-left, Region 4 lower-right, Region 5 axial). Annotate threshold: **WPI ≥ 7 + SSS ≥ 5 OR WPI 4–6 + SSS ≥ 9 ; $\geq 4/5$ regions; ≥ 3 months.**
- ▶ **Schematic of central pain amplification** — labels: *peripheral pain generator* → *increased ascending afferent input* → *impaired descending noxious inhibitory control* → *CNS amplification* → *hyperalgesia & allodynia*, with side-boxes for *genetic/serotonin-monoamine vulnerability* and *stress / catastrophising*.

Clinical / Diagnostic significance

- ▶ FM is a **clinical diagnosis of central sensitisation**, not a diagnosis of exclusion requiring extensive imaging — over-investigation reinforces illness behaviour.
- ▶ **Recognise FM superimposed on rheumatic disease (RA, SLE)**: when pain extends beyond what the inflammatory disease explains, with neuropsychological symptoms and diffuse tenderness, treat **central pain** rather than escalating anti-inflammatory therapy.
- ▶ **Screen for and treat mood disorders, non-restorative sleep, and sleep apnea** — they drive disability and respond to dual-action agents.
- ▶ A **multimodal plan (education + exercise + a single rationally chosen drug + CBT)** outperforms drug monotherapy and is the examiner-favoured management answer.

High-yield exam pointers

- ▶ FM = **chronic widespread pain + tenderness ≥ 3 months**, with fatigue, unrefreshing sleep, cognitive (“fibro-fog”), anxiety/depression; a **CNS central-sensitisation disorder**.
- ▶ Prevalence $\sim 2\%$ ($\approx 4\%$ women, $< 1\%$ men); clinical F:M $\sim 8:1$; up to **30%** comorbidity with RA/SLE.
- ▶ **2016 criteria** use **WPI (0–19) + SSS (0–12)**; **tender points (11/18, 4 kg/m²)** are the **OLD ACR criteria**.
- ▶ Mechanism: **impaired descending inhibition + augmented afferent processing** $\rightarrow$ **hyperalgesia and allodynia**; serotonin/monoamine genes; some have **small-fibre neuropathy**.
- ▶ **Routine labs normal**; order ESR/CRP, CBC, TSH; avoid repeat testing and spine MRI.
- ▶ First-line is **non-pharmacologic** — **aerobic exercise is the single most helpful intervention**; TENS and a laser device are FDA-approved.
- ▶ Effective drugs: **pregabalin/gabapentin, duloxetine/milnacipran, amitriptyline, cyclobenzaprine**.
- ▶ **Avoid strong opioids; tramadol discouraged; glucocorticoids/NSAIDs ineffective for FM pain**.

SOURCE & COVERAGE

Harrison 22e — Ch 385 “Fibromyalgia” (L.J. Crofford). 2016 diagnostic criteria per Fig. 385-1 (Wolfe et al., *Semin Arthritis Rheum* 2016); differential diagnosis from Table 385-1; investigations from Table 385-2; drug classes from Table 385-3.

Coverage note: The plain-text extract reproduces the *names/classes* of effective drugs (Table 385-3) but not their **doses**; specific milligram regimens (e.g., pregabalin 300–450 mg/day, duloxetine 60 mg/day, milnacipran 50 mg BID, low-dose amitriptyline at night) and the statement that **pregabalin, duloxetine and milnacipran are the three FDA-approved agents for FM** are standard, universally accepted internal medicine added for completeness and are not verbatim in the provided chapter text. The WPI/SSS scoring breakdown is drawn from Fig. 385-1.

Gout

Asked in: Paper III Nov 2021 — RGUHS MD General Medicine

Definition / Introduction — Gout is a hyperuricemic metabolic disorder typically manifesting as **episodic inflammatory arthritis** with disabling pain, most often in middle-aged to elderly men and postmenopausal women. It arises from an **increased body pool of urate** due to chronic hyperuricemia, leading to supersaturation and crystallisation of **monosodium urate (MSU)** within joints and connective tissue, with subsequent inflammatory reactions to the crystals. Although chronic hyperuricemia is a prerequisite, only a minority of hyperuricemic individuals develop gout; additional pathophysiologic factors govern crystallisation and the inflammatory response. Humans are the only mammals to develop gout spontaneously, owing to evolutionary species-wide **loss of uricase** (which converts urate to highly soluble allantoin).

Urate metabolism and pathogenesis

- ▶ At physiologic pH, uric acid exists largely as **urate**, its ionised form, reflecting its weak acidity (**pKa 5.8**). Systemic urate reflects a balance of dietary intake, endogenous synthesis, and excretion.
- ▶ Supersaturation threshold: serum urate **>~6.85 mg/dL** favours MSU crystallisation, crystal growth, and tissue deposition.
- ▶ **Overproduction vs under-excretion** — hyperuricemia arises predominantly from **impaired renal urate excretion (90%)** or, less commonly, **overproduction (10%)**, with many cases involving both.
- ▶ **Renal handling**: ~two-thirds of daily urate is eliminated renally, one-third via the GI tract. In the proximal tubule, apical reabsorption is **sodium-dependent** via **URAT1** and **OAT10**; basolateral efflux is via the **GLUT9** transporter (the target of anti-uricosurics like *pyrazinoate (PZA)* and *nicotinate*). Intestinal urate efflux occurs through **ABCG2**, followed by degradation by gut bacteria (**intestinal uricolysis**).
- ▶ **Crystal-induced inflammation**: triggered crystal shedding from synovial tophi → phagocytosis of MSU by neutrophils; activation of resident synovial macrophages, mast cells, and the **NLRP3 inflammasome** → generation of **pro-IL-1 / IL-1β**, plus IL-6, IL-8, and TNF-α. Neutrophils mount a **respiratory burst** releasing lysosomal enzymes, superoxide anion, **leukotriene B4**, and IL-1.
- ▶ Untreated, gout progresses to **chronic gouty arthritis** with low-grade persistent synovitis, erosive deformities, and **tophi** (MSU deposits surrounded by granulomatous inflammation in proteoglycan-rich joints and tendons).

Etiology / classification of hyperuricemia

Mechanism	Causes (per Harrison)
Under-excretion (~90%)	Idiopathic; CKD/renal insufficiency; diuretics (thiazide, loop); low-dose aspirin; insulin-resistance syndrome
Overproduction (~10%)	Increased cell turnover with purine salvage — hematologic malignancies, psoriasis; chemotherapy; tissue hypoxia
Inherited metabolic (subset of overproduction)	PRPP synthetase superactivity (X-linked) → ↑PRPP, purine nucleotides, urate; HPRT deficiency — <i>Lesch-Nyhan syndrome</i> and variants (X-linked)

- ▶ **PRPP synthetase overactivity**: accelerated production of PRPP, purine nucleotides, and urate → gout and urate nephrolithiasis.
- ▶ **HPRT deficiency**: hypoxanthine cannot be recycled and is converted exclusively to urate; reduced IMP/GMP further drives hyperuricemia via loss of feedback inhibition of de-novo purine synthesis. The HPRT gene is on the **X chromosome** (>250 described mutations); homozygous males are affected, carrier (esp. postmenopausal) females may develop gout/stones.
Hyperuricemia in prepubertal boys should prompt consideration of these enzyme defects.
- ▶ **Modifiable risk factors**: obesity, Western diet, alcohol, fructose-rich foods/beverages, sedentary lifestyle, and diuretics.
- ▶ **Comorbidity cluster** (part of the insulin-resistance syndrome): obesity, hypertension, type 2 diabetes, myocardial infarction, stroke, CKD, and urate nephrolithiasis.

Clinical manifestations and stages

- ▶ **Acute gout flare**: usually **monoarticular** initially. The **1st metatarsophalangeal joint (podagra)** is involved in **70–90%** of cases, followed by tarsal joints, ankles, and knees; finger/wrist/elbow involvement is later (elderly, advanced disease). Oligo- and polyarticular flares develop over time.
- ▶ Flares characteristically begin at **night to early morning** and are among the most painful human conditions: the joint becomes warm, red, tender, and swollen, often mimicking cellulitis (**pseudocellulitis**). Untreated flares subside spontaneously within **1–2 weeks**.
- ▶ **Intercritical gout**: symptom-free intervals of varying length between flares.
- ▶ **Triggers**: purine-rich food, alcohol, diuretic use, **initiation of urate-lowering therapy (ULT)**, local trauma, and medical illness (congestive heart failure, respiratory/hypoxic conditions).
- ▶ **Chronic gouty arthritis** (after years of untreated flares): ongoing synovitis, **subcutaneous tophi**, deformity, and bony destruction; rarely gout manifests only as tophi or only as chronic arthritis.
- ▶ **Women** account for only **5–20%** of gout patients — usually postmenopausal/elderly, often with OA, hypertension, mild renal insufficiency, and diuretic use; premenopausal gout is rare.

Diagnosis

- ▶ **Definitive** = needle aspiration of joint or tophus with **polarising light microscopy**: MSU crystals are **needle/rod-shaped**, seen both intracellularly and extracellularly during flares, showing **strong negative birefringence** under compensated polarised light.
- ▶ **Synovial fluid**: cloudy/inflammatory with leukocytes typically **5000–75,000/μL**; may be thick, pasty, chalky. Always **Gram-stain and culture** to exclude septic arthritis, which can coexist with crystals. MSU crystals are demonstrable in the 1st MTP and clinically quiet knees, so **inter-critical arthrocentesis** is diagnostically useful.
- ▶ **Serum urate**: can be normal or low *during* an acute flare (inflammatory cytokines, e.g. IL-6, are uricosuric and lower urate ~2 mg/dL) — so seek **historical or post-flare** values; urate is almost always elevated at some point. Baseline workup: serum creatinine, LFTs, hemoglobin, WBC, HbA1c, and serum lipids (comorbidity screen and treatment monitoring).
- ▶ **Imaging**: musculoskeletal ultrasound shows the **double-contour sign** over articular cartilage (MSU deposition); **dual-energy CT** identifies MSU by chemical composition. Plain radiographs in advanced tophaceous gout show **cystic changes, well-defined erosions with sclerotic margins and overhanging bony edges**, and soft-tissue masses (absent in early disease).

Management

A. Acute flare — mainstay is early anti-inflammatory therapy (ice and rest are adjuncts); choice depends on comorbidities, concurrent drugs, and prior response.

Drug	Regimen (per Harrison)	Key caution
Colchicine	Low-dose: 1.2 mg at first sign, then 0.6 mg in 1 h, with subsequent-day dosing by response	Eliminated via P-glycoprotein (MDR1) and CYP3A4; reduce dose in renal disease, hepatorenal impairment, or with inhibitors (<i>clarithromycin, tacrolimus</i>)
NSAIDs	Indomethacin 25–50 mg tid; naproxen 500 mg bid; ibuprofen 800 mg tid; celecoxib 800 mg then 400 mg at 12 h, then 400 mg bid	Avoid in significant comorbidity (renal/GI/cardiac)
Glucocorticoids	Prednisone 30–50 mg/d initial, tapered; IM injection; intra-articular for one/few joints	Effective even in polyarticular gout
IL-1β blockade	Anakinra or canakinumab	When other options contraindicated or failed

B. Urate-lowering therapy (ULT) — corrects the central cause (chronic hyperuricemia); usually lifelong. **Target serum urate <5–6 mg/dL (300–360 μmol/L)**, a sub-saturation point, to prevent flares and dissolve tophi.

- **Indications:** ≥ 2 flares/year, severe/prolonged flares, or patient commitment; *always* if subcutaneous tophi, chronic gouty arthritis, or known uric-acid nephrolithiasis.
- **Allopurinol** (xanthine oxidase inhibitor) — **first-line**; single morning dose starting **100 mg/day or less**, titrating up to **800 mg/day**. In CKD start lower (e.g. **50 mg/day** if $\text{eGFR} < 30 \text{ mL/min}$) and titrate slowly. Risk of SCARs (**Stevens-Johnson syndrome, toxic epidermal necrolysis**) — risk factors are CKD, higher initial dose, and **HLA-B5801* carriage. **Screen for HLA-B5801*** before starting in Southeast Asian (except Japanese descent), Pacific Islander/Native Hawaiian, and Black patients; if positive, use an alternative agent. Mild cutaneous reactions in $\sim 2\%$.
- **Febuxostat** (xanthine oxidase inhibitor) — hepatic metabolism (glucuronidation/oxidation), **no dose adjustment in moderate–severe CKD**; usable in HLA-B*5801 carriers.
- **Uricosurics** — **probenecid** (second-line): 250 mg bid up to 3 g/day; needs good renal function (ineffective if creatinine $> 2 \text{ mg/dL}$ [$177 \mu\text{mol/L}$]). *Benzbromarone* (not in the US) is more effective in CKD.
- **Pegloticase** — pegylated uricase for refractory/intolerant patients; given with **methotrexate** to reduce immunogenicity (which causes loss of efficacy and infusion reactions).
- **Comorbidity drugs that also lower urate:** losartan, amlodipine, fenofibrate, and SGLT2 inhibitors (added cardiometabolic-renal benefit).
- **Flare prophylaxis at ULT initiation:** do not start ULT during an active flare; begin in the resolution phase with **colchicine 0.6 mg once–twice daily** or **naproxen 250 mg bid**, continued until normouricemic and flare-free for **3–6 months** or tophi resolve. Rapid urate lowering shedding MSU from tophi causes paradoxical flares.

Differential — Pseudogout (CPPD) vs Gout

Feature	Gout (MSU)	Pseudogout / CPPD
Crystal	Needle/rod-shaped, strongly negatively birefringent	Rhomboid/rod-shaped, weakly positively or non-birefringent
Typical joint	1st MTP (podagra), tarsus, ankle, knee	Knee (commonest), then wrist; podagra rarely
Radiograph clue	Erosions with overhanging edges, tophi	Chondrocalcinosis (linear/punctate cartilage calcification)
Key associations	Insulin-resistance syndrome, CKD, diuretics	Aging, OA, hyperparathyroidism , hemochromatosis , hypophosphatasia , hypomagnesemia ; <i>ANKH</i> gene

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

Feature	Gout (MSU)	Pseudogout / CPPD
	▶ Pathogenesis-and-targets schematic (Fig. 384-1): boxes/arrows — <i>Risk factors</i> (obesity/insulin resistance, diet/alcohol, genes, diuretics & low-dose aspirin) → Chronic hyperuricemia / increased urate pool → $SU > \sim 6.85 \text{ mg/dL}$ → MSU crystallisation, crystal growth, tissue deposition → Recurrent acute crystal-induced flares → Chronic gouty arthritis (tophi). Annotate two therapeutic targets: Urate-lowering therapy (allopurinol, febuxostat, probenecid, uricase; target $< 5\text{--}6 \text{ mg/dL}$) acting on the urate pool, and Anti-inflammatory therapy (NSAIDs, colchicine, glucocorticoids) acting on the flare. Labels: <i>Risk factors, Chronic hyperuricemia, MSU crystallisation/deposition, Acute flare, Chronic tophaceous gout, ULT target $< 5\text{--}6 \text{ mg/dL}$, Anti-inflammatory therapy.</i> ▶ MSU crystal under compensated polarised light: draw needle-shaped crystal inside a neutrophil; label <i>intracellular MSU crystal, needle-shaped, strongly negative birefringence, leukocyte 5000–75,000/μL.</i>	

Clinical / Diagnostic significance

- ▶ Crystal-proven diagnosis (synovial fluid microscopy) is the gold standard and simultaneously **excludes septic arthritis**, which may coexist — never assume crystals exclude infection.
- ▶ Serum urate is unreliable *during* a flare; use historical/post-flare values for diagnosis and as the **ULT target** ($< 5\text{--}6 \text{ mg/dL}$).
- ▶ Treat-to-target ULT dissolves tophi and prevents flares but must be paired with **flare prophylaxis** and started outside active flares.
- ▶ Gout is a marker of **cardiometabolic-renal disease** — screen for and manage obesity, hypertension, diabetes, dyslipidemia, and CKD; favour agents with dual benefit (losartan, fenofibrate, SGLT2i).
- ▶ **HLA-B5801 pharmacogenomic screening*** before allopurinol in high-risk ethnicities prevents life-threatening SCARs.

High-yield exam pointers

- ▶ Hyperuricemia = **90% under-excretion, 10% overproduction**; supersaturation threshold $\sim 6.85 \text{ mg/dL}$; urate pKa 5.8.
- ▶ Renal transporters: reabsorption via **URAT1/OAT10** (apical, Na-dependent), efflux via **GLUT9**; gut efflux via **ABCG2**.
- ▶ **NLRP3 inflammasome** → **IL-1 β** drives the acute flare (rationale for anakinra/canakinumab).
- ▶ **Podagra (1st MTP)** in **70–90%**; flares nocturnal, self-limited in **1–2 weeks**; intercritical periods between attacks.

- ▶ Crystals: **needle-shaped, strongly negatively birefringent**, intra- and extracellular; synovial WBC 5000–75,000/ μ L.
- ▶ **Allopurinol first-line** (start 100 mg/d, up to 800 mg/d; 50 mg/d if eGFR <30); **febuxostat** safe in CKD and HLA-B*5801 carriers.
- ▶ Lesch-Nyhan = **HPRT deficiency** (X-linked); **PRPP synthetase superactivity** = X-linked overproduction.
- ▶ ULT prophylaxis: **colchicine 0.6 mg od–bid** continued until urate-normal and flare-free 3–6 months / tophi resolve.
- ▶ **Pseudogout** = CPPD, knee, weakly positive birefringence, chondrocalcinosis; check Ca/PO4/Mg/iron in patients <50 y.

SOURCE & COVERAGE

Harrison's Principles of Internal Medicine, 22e — Ch 384 "Gout and Other Crystal-Associated Arthropathies" (Hyon K. Choi). Coverage note: All specifics above (drug doses, transporters, crystal morphology, HLA-B*5801, targets) are taken from this chapter; the gout topic is fully covered. The CPPD/pseudogout differential is drawn from the same chapter as supporting context for the differential diagnosis.

Granulomatosis with Polyangiitis (Wegener's Granulomatosis)

Asked in: Paper III Jul 2020 — RGUHS MD General Medicine

Definition / Introduction — Granulomatosis with polyangiitis (GPA, formerly *Wegener's granulomatosis*) is a distinct clinicopathologic entity characterised by **necrotising granulomatous vasculitis of the upper and lower respiratory tracts together with glomerulonephritis**, with variable disseminated small-vessel vasculitis involving both small arteries and veins. It is one of the three **antineutrophil cytoplasmic antibody (ANCA)–associated vasculitides** (with microscopic polyangiitis and eosinophilic granulomatosis with polyangiitis) and is strongly linked to **cytoplasmic ANCA against proteinase-3 (PR3-ANCA/c-ANCA)**. Untreated generalised disease is almost uniformly fatal within ~1 year.

Epidemiology & nosology

- ▶ **Prevalence ~3 per 100,000** (Harrison); estimated incidence ~12 cases per million per year (CMDT). Extremely rare in Black compared with White patients.
- ▶ **Male : female = 1:1**; mean age of onset **40–60 years** (4th–5th decade), but ~15% of patients are <19 years; onset before adolescence is rare.

- ▶ Belongs to the **ANCA-associated vasculitides (AAV)** — small-vessel vasculitis group. Distinguished from microscopic polyangiitis by **granulomatous inflammation and upper-airway/pulmonary-nodular disease**.
- ▶ Classification frameworks: the **1992/2012 Chapel Hill Consensus Conference nomenclature** (renamed Wegener's → GPA) and the **2022 ACR/EULAR classification criteria (DCVAS)** used to classify, not diagnose.

Pathology & pathogenesis

- ▶ **Histopathologic triad of hallmarks:** (1) **necrotising vasculitis** of small arteries and veins; (2) **granuloma formation** (intra- or extravascular) — palisading histiocytes and giant cells around *geographic necrosis*; (3) **pauci-immune crescentic glomerulonephritis**.
- ▶ **Renal lesion:** earliest is a focal, segmental glomerulitis evolving into **rapidly progressive crescentic GN**; immunofluorescence shows scant immunoglobulin/complement — *pauci-immune* — differentiating it from immune-complex and anti-GBM disease. Granulomas are *rarely* seen on renal biopsy.
- ▶ **Lung:** multiple, bilateral, nodular or **cavitary** infiltrates; biopsy reveals necrotising granulomatous vasculitis (highest diagnostic yield, ideally thorascopic).
- ▶ **Immunopathogenesis:** aberrant **TH1-type** cell-mediated response ($\uparrow$ IFN- γ , $\uparrow$ TNF- α , $\uparrow$ IL-12) to an airway antigen; suggested role of **ANCA** — when neutrophils/monocytes are primed by TNF- α /IL-1, PR3 and myeloperoxidase translocate to the cell surface, bind circulating ANCA, and trigger **degranulation, reactive-oxygen-species release, and endothelial injury**. Chronic nasal carriage of *Staphylococcus aureus* is associated with higher relapse rates (causal role unproven).

ANCA serology

Feature	c-ANCA (PR3-ANCA)	p-ANCA (MPO-ANCA)
Antigen	Proteinase-3 (29-kDa serine proteinase, azurophilic granule)	Myeloperoxidase
Immunofluorescence	Diffuse granular cytoplasmic staining	Perinuclear staining
Association in GPA	>90% of active GPA ; specificity >90%	~10–25% of classic GPA
Caveats	Sensitivity falls to ~60–70% in inactive disease; up to 20% of GPA are ANCA-negative ("limited"/sinonasal disease)	Predominant in microscopic polyangiitis & EGPA

- ▶ Positive immunofluorescence should be **confirmed by antigen-specific enzyme immunoassay** for anti-PR3 or anti-MPO.

- ▶ **ANCA titres correlate poorly with disease activity** — a rising titre alone is *not* a harbinger of relapse (only ~43% relapse within 1 year of an ANCA rise) and should **not** by itself trigger escalation of immunosuppression.

Clinical manifestations (frequencies through disease course)

- ▶ **Upper airway (~95%)**: paranasal sinus pain/drainage, purulent or bloody nasal discharge, nasal mucosal ulceration → nasal septal perforation → ***saddle-nose deformity**; *serous otitis media (eustachian blockage)*; *subglottic stenosis (~16%)** causing airway obstruction.
- ▶ **Lung (85–90%)**: cough, haemoptysis, dyspnoea, pleuritic pain; up to 30% asymptomatic; endobronchial disease with atelectasis; **diffuse alveolar haemorrhage** (severe).
- ▶ **Renal (~77%)**: glomerulitis with proteinuria, haematuria, **red-cell casts** → rapidly progressive renal failure if untreated; dominates prognosis.
- ▶ **Eye (~52%)**: conjunctivitis, episcleritis, **scleritis**, granulomatous sclerouveitis, **retro-orbital mass** → **proptosis** (orbital pseudotumour).
- ▶ **Skin (~46%)**: palpable purpura, papules, vesicles, ulcers, subcutaneous nodules.
- ▶ **Nervous system (~23%)**: **mononeuritis multiplex**, cranial neuritis; rarely cerebral vasculitis/granuloma.
- ▶ **Cardiac (~8%)**: pericarditis, coronary vasculitis, rarely cardiomyopathy.
- ▶ **Constitutional**: fever, malaise, arthralgia, anorexia, weight loss; **migratory oligoarthritis** of large joints. *Newly acquired hypertension is rare* (unlike PAN). Increased risk of **venous thromboembolism (DVT/PE)**.

Investigations & diagnosis

- ▶ **Labs**: elevated ESR/CRP, normochromic anaemia, leukocytosis, mild hypergammaglobulinaemia, thrombocytosis (acute-phase); urinalysis with dysmorphic RBCs and **red-cell casts**.
- ▶ **ANCA (PR3/c-ANCA)**: predictive value ~90% with active glomerulonephritis, but only 30–60% with isolated sinus/lung disease — so biopsy is needed there to exclude infection/malignancy.
- ▶ **Imaging**: chest CT (more sensitive than CXR) — bilateral nodules, masses, **cavitation**, infiltrates; extensive sinusitis with bony erosion.
- ▶ **Tissue biopsy is the diagnostic gold standard**: necrotising granulomatous vasculitis. **Lung** offers highest yield; **renal** biopsy confirms pauci-immune GN; **nasal** biopsy often shows only inflammation.
- ▶ **Differential diagnosis**: microscopic polyangiitis, EGPA, anti-GBM (Goodpasture) disease, SLE, relapsing polychondritis, **cocaine/levamisole-induced midline destruction** (anti-elastase ANCA, granulocytopenia, facial skin erosion), extranodal NK/T-cell lymphoma (nasal type),

lymphomatoid granulomatosis, infections (histoplasmosis, endocarditis, rhinoscleroma, mucocutaneous leishmaniasis). *Midline lesions in GPA are never irradiated.*

Treatment (induction → maintenance, severity-stratified)

- ▶ **Principle:** two phases — **induction** of remission, then **maintenance**. *Severe* = organ/life-threatening (active GN is *always* severe even with normal creatinine; alveolar haemorrhage); *non-severe* = no immediate organ threat.
- ▶ **Glucocorticoids:** historically prednisone 1 mg/kg/day then taper; reduced-dose regimens are **non-inferior with fewer serious infections**; IV methylprednisolone 1000 mg/day × 3 days for fulminant/life-threatening disease.

Setting	Induction	Maintenance
Severe disease	Rituximab 375 mg/m ² weekly × 4 or cyclophosphamide (oral 2 mg/kg/day; or IV 15 mg/kg q2wk × 3, then q3wk) + glucocorticoids ± avacopan	Rituximab (e.g. 500 mg × 2 then 500 mg q6mo, or 1000 mg q4mo), azathioprine 2 mg/kg/day, methotrexate 20–25 mg/week, or mycophenolate mofetil — usually ≥2 years
Non-severe disease	Methotrexate (15 → 20–25 mg/week) or mycophenolate mofetil + glucocorticoids; rituximab optional	Same agent continued

- ▶ **Avacopan** — oral C5a-receptor inhibitor; FDA-approved add-on; achieved higher sustained remission than prednisone and allows rapid steroid withdrawal.
- ▶ **Cyclophosphamide** is renally cleared (dose-reduce in renal impairment); stop at **3–6 months** and switch to a maintenance agent; bladder toxicity and infertility risk (rituximab avoids these).
- ▶ **Plasma exchange (PLEX):** PEXIVAS showed **no benefit** for the composite of ESRD/death — *not routine*; reserve for **co-existing anti-GBM antibody** (and possibly severe creatinine >5.7 mg/dL or fulminant pulmonary haemorrhage). When used with rituximab, separate by ≥48 h.
- ▶ **Infection prophylaxis:** trimethoprim-sulfamethoxazole for *Pneumocystis jirovecii* with cyclophosphamide/rituximab; TMP-SMX may help isolated sinonasal disease but **never as sole therapy** for multiorgan GPA. **Subglottic stenosis** responds to mechanical dilation + intralesional glucocorticoid, not systemic immunosuppression alone.
- ▶ **Avoid:** etanercept (no benefit, increased solid tumours), belimumab and abatacept (no benefit on relapse).

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **“Organ map of GPA”** — head-to-kidney schematic with labels: *Sinusitis, Nasal septal perforation, Saddle-nose deformity, Subglottic stenosis, Serous otitis media, Scleritis/episcleritis/proptosis, Bilateral cavitary lung nodules, Diffuse alveolar haemorrhage /*

pulmonary capillaritis, Pauci-immune crescentic glomerulonephritis (RBC casts), Palpable purpura, Mononeuritis multiplex.

- ▶ **ANCA immunofluorescence panel** — two neutrophils: left labelled *c*-ANCA — *diffuse granular cytoplasmic staining* = anti-PR3; right labelled *p*-ANCA — *perinuclear staining* = anti-MPO. Inset: *necrotising granulomatous vasculitis* — *geographic necrosis with palisading histiocytes and giant cells.*

Clinical / Diagnostic significance

- ▶ GPA is a leading cause of the **pulmonary–renal syndrome** (alongside microscopic polyangiitis, anti-GBM disease, SLE) — recognise haemoptysis + active urinary sediment as an emergency.
- ▶ **Renal involvement dominates prognosis**; early induction prevents irreversible crescentic GN and dialysis dependence.
- ▶ Treatment transformed survival: cyclophosphamide-based regimens give **>90% marked improvement**, **~75% complete remission**, **>80% 5-year survival**; but **50–70% relapse**, leaving residual damage (renal insufficiency, hearing loss, subglottic stenosis, saddle-nose, chronic sinus disease).
- ▶ A positive PR3-ANCA in a patient with sinusitis + lung nodules + microscopic haematuria is highly suggestive, but **tissue biopsy remains confirmatory**, especially in ANCA-negative or atypical cases.
- ▶ Successful **renal transplantation** is possible after remission in those who reached ESRD.

High-yield exam pointers

- ▶ **Classic triad**: upper airway + lower respiratory tract + glomerulonephritis.
- ▶ PR3-ANCA / *c*-ANCA in >90% of active GPA; antigen = **proteinase-3 (29 kDa)**; up to 20% ANCA-negative.
- ▶ **Pauci-immune crescentic GN** = renal hallmark; **necrotising granulomatous vasculitis** = histologic hallmark.
- ▶ **Saddle-nose deformity, subglottic stenosis (~16%), bilateral cavitary lung nodules** are signature lesions.
- ▶ **Lung biopsy = highest diagnostic yield**; ANCA titre does not track activity.
- ▶ **Induction**: rituximab *or* cyclophosphamide + glucocorticoids ± **avacopan (C5a-receptor inhibitor)**; **PLEX not routine** (PEXIVAS).
- ▶ **Maintenance**: rituximab / azathioprine / methotrexate ≥2 years; **TMP-SMX for PCP prophylaxis**.
- ▶ *Newly acquired hypertension favours PAN, not GPA*; GPA carries increased VTE risk.
- ▶ **Mimics to exclude**: cocaine/levamisole midline destruction, nasal NK/T-cell lymphoma.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “The Vasculitis Syndromes” (GPA definition, epidemiology, pathology/pathogenesis, ANCA biology, NIH clinical-manifestation frequencies, diagnosis, and detailed induction/maintenance regimens including avacopan and PEXIVAS).
- ▶ **CMDT 2026** — “Rheumatologic, Immunologic, & Allergic Disorders” (current ACR/Vasculitis Foundation and EULAR 2022 management approach, PR3/MPO-ANCA testing, PCP prophylaxis, saddle-nose and subglottic findings).
- ▶ *Coverage note:* the spec lists no dedicated rheumatology subspecialty textbook for this topic, so depth is drawn from Harrison 22e supplemented by CMDT 2026; both are cited above. The **2022 ACR/EULAR classification criteria** are named in CMDT but item-level point weights are not reproduced in the corpus, so they are referenced by name only and not fabricated.

**IgG4-Related Disease**

Asked in: Paper III Nov 2020 — RGUHS MD General Medicine

Definition / Introduction — IgG4-related disease (IgG4-RD) is a chronic, immune-mediated **fibroinflammatory** condition characterised by a tendency to form **tumefactive (mass-like) lesions** that mimic malignancy, lymphoma, or infection. It can affect virtually any organ, shows the **same distinctive histopathology at every site**, and has a particular tropism for blood vessels of any calibre—so it is now regarded as a **variable-vessel vasculitis**. It unifies many conditions formerly considered organ-specific entities (e.g. lymphoplasmacytic sclerosing pancreatitis → type 1 autoimmune pancreatitis; Mikulicz's disease; Riedel's thyroiditis). Diagnosis rests on **careful correlation of clinical, serologic, radiologic and pathologic findings**—pathology alone is never sufficient.

Epidemiology

- ▶ Typically a **middle-aged to elderly man** — a sharp contrast to most classic autoimmune diseases, which favour young women.
- ▶ **Male predominance ~2:1** (CMDT: ~75% of patients are men, usually >50 years); male predominance is even more striking for internal-organ disease (pancreas, kidney, retroperitoneum), whereas head-and-neck disease (orbits, lacrimal, salivary glands) is closer to 1:1.
- ▶ Male patients are ~5 years older at diagnosis and have **higher serologic activity** (higher IgG4, hypocomplementaemia).

- Presentation is usually **subacute**; fever and high CRP are usually absent. Substantial weight loss can occur (exocrine pancreatic failure → maldigestion; endocrine failure → diabetes mellitus).

Pathology and pathophysiology

The histopathology is **consistent across all organs** and forms the diagnostic backbone:

Hallmark	Description
Dense lymphoplasmacytic infiltrate	B and T lymphocytes; B cells in germinal centres , with CD19/CD138/IgG4+ plasma cells radiating outward; CD4+ T cells most abundant and diffuse
Storiform fibrosis	“Woven mat / basket-weave” pattern (Latin <i>storea</i> = woven mat)
Obliterative phlebitis	Inflammatory obliteration of veins — vascular tropism is a hallmark; obliterative <i>arteritis</i> also seen, especially in lung
Mild–moderate tissue eosinophilia	Variable; some biopsies eosinophil-rich

- **Against the diagnosis** (atypical features): intense **neutrophilic** infiltration, leukocytoclasia, **granulomatous inflammation**, **multinucleated giant cells**, and **fibrinoid necrosis**.
- **Immunohistochemistry** is essential: IgG4+ plasma cells predominate; quantify by **IgG4+ cells/high-power field** *and* the **IgG4+/IgG+ plasma-cell ratio**. In late fibrotic (acellular) phases, the ratio and the fibrosis pattern matter more than absolute cell counts.
- **Pathophysiology** — despite the name, the IgG4 molecule is *not* the primary driver:
 - IgG4 undergoes **Fab-arm exchange** (half-molecules swap), binds antigen weakly, and has **low affinity for Fcγ receptors and C1q** → it is essentially **non-inflammatory** (poor complement fixation, ADCC, phagocyte activation). IgG4 may even be a **counter-regulatory** response.
 - A unique **CD4+ cytotoxic T lymphocyte (CD4+ CTL)**, oligoclonally expanded at tissue sites, is the proposed **major disease driver** — it secretes IFN-γ, TGF-β, IL-1 (driving storiform fibrosis) and **perforin, granzyme A/B, granulysin** (cytotoxicity).
 - **Oligoclonal plasmablast expansions** circulate in blood; continuous **B-cell/plasmablast antigen presentation** sustains the CD4+ CTLs — explaining why **B-cell depletion** is therapeutic.

Organ manifestations (key clinical syndromes)

Organ / region	Characteristic presentation
Pancreas	Type 1 autoimmune pancreatitis — obstructive painless jaundice, mass mimicking adenocarcinoma; “ sausage-shaped pancreas ” (diffuse enlargement, loss of lobularity), rim of hypoattenuation, irregular

Organ / region	Characteristic presentation
	main-duct narrowing; 20–50% with new glucose intolerance
Biliary tree / liver	IgG4-related sclerosing cholangitis — mimics primary sclerosing cholangitis & cholangiocarcinoma ; obstructive jaundice; can progress to hepatic failure within months
Salivary glands	Bilateral submandibular/parotid enlargement (Mikulicz's disease); chronic sclerosing sialadenitis
Orbit / periorbital	Painless lid/periorcular swelling, orbital pseudotumor , dacryoadenitis, orbital myositis (enlarged extraocular muscles); proptosis
Retroperitoneum	Retroperitoneal fibrosis — periaortic inflammation extending to iliac vessels; ureteric entrapment → hydronephrosis , post-obstructive uropathy, renal atrophy
Kidney	Tubulointerstitial nephritis (multiple/bilateral tumoral lesions; strong link with hypocomplementaemia); membranous glomerulonephropathy in a minority
Aorta / vessels	Lymphoplasmacytic aortitis , periaortitis, inflammatory aneurysm, dissection ; coronary arteritis (wall thickening, periarterial encasement, stenosis, aneurysm)
Lung	Inflammatory pseudotumor, paravertebral mass, central-airway disease, interstitial pneumonia, pleural thickening/effusion
Thyroid	Riedel's thyroiditis ; fibrosing variant of Hashimoto's
Meninges / pituitary	Hypertrophic pachymeningitis (dural thickening/enhancement, cranial neuropathies); hypophysitis → anterior hypopituitarism and/or central diabetes insipidus, thickened stalk
Lymph nodes	Generalised or localised lymphadenopathy (1–2 cm, non-tender); may be indolent for years

- Two unifying clinical themes: **allergic phenomena** (atopy, asthma, eczema, nasal polyps, sinusitis, peripheral eosinophilia) and **tumefactive pseudotumors** that mimic cancer.
- Multiorgan disease may be present at diagnosis or evolve over months–years; subclinical involvement of other organs is common.

Serology and diagnosis

- ▶ **Serum IgG4 is elevated in the majority** but ~30% have normal levels despite classic histology (these tend to have fewer organs involved; e.g. retroperitoneal fibrosis often has normal IgG4 because disease is already fibrotic). Elevation can reach **30–40× the upper limit of normal** in multi-organ disease.
- ▶ Serum IgG4 alone is **not** a reliable diagnostic or activity marker: levels fall with therapy but often do not normalise; remissions occur with persistently high IgG4, and relapses occur with normal IgG4. **Steadily rising IgG4 after a response** flags impending flare.
- ▶ **Prozone effect** — very high IgG4 can give a **falsely low** nephelometry result; correct by **serial dilution** of serum. Missing this is dangerous (these patients are at highest risk of multi-organ injury).
- ▶ **Histopathology cut-offs (standard reference values)**: consensus generally requires >40% IgG4+/IgG+ ratio plus organ-dependent IgG4+ cell counts (e.g. >10/HPF) together with storiform fibrosis and obliterative phlebitis.
- ▶ **Classification / diagnostic frameworks**:
 - **2019 ACR/EULAR classification criteria** — a 3-step approach: (1) an **entry criterion** (characteristic involvement of a typical organ), (2) **exclusion criteria** (clinical, serologic, radiologic, pathologic red flags for mimics), and (3) **eight weighted inclusion domains** (histology, immunostaining, serum IgG4, bilateral lacrimal/parotid/sublingual/submandibular glands, chest, pancreas/biliary tree, kidney, retroperitoneum); a total **≥20 points** classifies the patient as IgG4-RD.
 - **Japanese comprehensive diagnostic criteria** — organ enlargement/mass + serum IgG4 **≥135 mg/dL** + histology (>40% IgG4+/IgG+ ratio, >10 IgG4+/HPF); *definite* = all three, *probable* = organ + histology, *possible* = organ + serology.
 - **Type 1 AIP** is diagnosed using the **HISORt criteria** — Histology, Imaging, Serology, Other-organ involvement, Response to corticosteroid therapy.
- ▶ **Differential diagnosis**: sarcoidosis, Sjögren's (lacrimal enlargement), pancreatic cancer/cholangiocarcinoma, **lymphoma**, granulomatosis with polyangiitis (proptosis, destructive sinus lesions), chronic infections (HIV, HCV), primary sclerosing cholangitis. **Most patients undergo biopsy** mainly to exclude malignancy.

Treatment

- ▶ **Not every manifestation needs immediate therapy** — indolent disease (e.g. asymptomatic lymphadenopathy) may be **watched**, but monitoring is essential because organ-threatening disease can evolve, especially with rising IgG4. **Vital-organ involvement must be treated aggressively** (risk of end-stage liver disease, pancreatic failure, renal atrophy, aortic dissection/aneurysm, destructive sinonasal lesions).

- ▶ **Glucocorticoids = first line.** Harrison: **prednisone 40 mg/day**, tapered to discontinuation or to **5 mg/day maintenance over 2–3 months**. CMDT: **prednisone 0.6 mg/kg/day** tapered over weeks–months. Response is usually swift and striking, but **steroid-free remissions are uncommon** and steroid toxicity is high in this older, often diabetic population.
- ▶ **B-cell depletion — rituximab** is the key second-line agent (and increasingly used early with steroids) for relapsing or glucocorticoid-resistant disease: **two doses of 1 g IV ~15 days apart**, producing a swift fall in serum IgG4 (by limiting repletion of short-lived IgG4-producing plasma cells) and modulating CD4+ CTL function.
- ▶ **Conventional steroid-sparing agents — azathioprine, mycophenolate mofetil** (limited evidence) as alternatives.
- ▶ **Emerging / targeted therapy — inebilizumab** (anti-CD19, positive phase-3 MITIGATE trial; CMDT cites Stone et al, *NEJM* 2025) and **obexelimab**; anti-CD19 B-cell strategies may become first-line for high steroid-toxicity risk or organ-threatening disease.
- ▶ **Prognosis —** depends on the **degree of established fibrosis** (fibrotic organs respond poorly). Bisphosphonates and infection prophylaxis as standard with immunosuppression.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Histopathology of IgG4-RD (low-/high-power composite):** label — *dense lymphoplasmacytic infiltrate, germinal centre/lymphoid follicle, storiform (“basket-weave”) fibrosis, IgG4+ plasma cells (IHC), obliterative phlebitis (vein with obliterated lumen), eosinophils.*
- ▶ **Pathophysiology schematic:** *B cell/plasmablast (antigen presentation) → CD4+ cytotoxic T cell → arrows to IFN- γ , TGF- β , IL-1 (→ storiform fibrosis) and perforin/granzyme/granulysin (→ tissue injury); side box IgG4 plasma cell → IgG4 (Fab-arm exchange, non-inflammatory); therapy arrow rituximab/inebilizumab → B-cell depletion.*

Clinical / Diagnostic significance

- ▶ **Great mimic of malignancy —** pancreatic mass, cholangiocarcinoma, orbital/lung pseudotumor; recognising IgG4-RD prevents unnecessary major surgery (e.g. Whipple, thyroidectomy).
- ▶ **A trial of corticosteroid response** can be diagnostically useful in AIP (the “R” of HISORT), but a non-resolving “mass” still mandates biopsy to exclude cancer.
- ▶ **Renal involvement + hypocomplementaemia** and the **prozone effect** are practical traps every physician must know.
- ▶ Screen newly diagnosed patients for **occult multi-organ disease** (history, exam, cross-sectional imaging, IgG4) and for **secondary diabetes/exocrine insufficiency**.

High-yield exam pointers

- ▶ IgG4-RD = **fibroinflammatory, tumefactive, multi-organ “variable-vessel vasculitis.”**

- ▶ Pathology triad: storiform fibrosis + obliterative phlebitis + IgG4+ lymphoplasmacytic infiltrate (with eosinophils); ratio IgG4+/IgG+ >40%.
- ▶ Demographics: older man, ~2:1 male, subacute, afebrile.
- ▶ Classic syndromes: type 1 AIP (“sausage pancreas”), Mikulicz’s disease, Riedel’s thyroiditis, retroperitoneal fibrosis, hypertrophic pachymeningitis, orbital pseudotumor.
- ▶ ~30% have normal serum IgG4; beware the prozone effect (falsely low) — dilute the sample.
- ▶ IgG4 is non-inflammatory (Fab-arm exchange); the CD4+ cytotoxic T cell is the proposed driver.
- ▶ Classification: 2019 ACR/EULAR criteria (≥ 20 points); AIP $\rightarrow$ HISORt.
- ▶ Treatment: glucocorticoids first-line; rituximab for relapse/resistance; inebilizumab/obexelimab emerging; pathology alone never diagnostic — correlate clinically.

SOURCE & COVERAGE

- ▶ Harrison’s Principles of Internal Medicine, 22e — “IgG4-Related Disease” (clinical features, organ table, serology incl. prozone effect, pathology/pathophysiology, glucocorticoid + rituximab regimens, emerging anti-CD19 therapy).
- ▶ CMDT 2026 — “IgG4-Related Disease” (epidemiology, diagnosis, prednisone 0.6 mg/kg/day, rituximab/inebilizumab, azathioprine/mycophenolate) and “Liver, Biliary Tract & Pancreas Disorders” (type 1 autoimmune pancreatitis, imaging, HISORt criteria, prednisone 40 mg/day taper).
- ▶ Coverage note: The Harrison/CMDT corpus describes the pathology, serology and management in depth but does **not enumerate** the exact point weights of the 2019 ACR/EULAR criteria or the numeric histology/serology cut-offs (IgG4+/IgG+ >40%, >10 IgG4+/HPF, serum IgG4 ≥ 135 mg/dL); these are stated from the universally accepted ACR/EULAR and Japanese consensus criteria and are standard internal-medicine reference values.

Management of Hyperuricemia

Asked in: Paper III Nov 2022 — RGUHS MD General Medicine

Definition / Introduction — Hyperuricemia is a sustained elevation of serum urate above the saturation point of monosodium urate (MSU), i.e. $> \sim 6.85$ mg/dL, beyond which crystallization, growth and tissue deposition occur. Humans are uniquely susceptible because evolutionary loss of **uricase** (which converts urate to the highly soluble *allantoin*) raises baseline urate; at physiologic pH uric acid exists largely as urate (weak acid, pK_a 5.8). Hyperuricemia is the central prerequisite for gout and is tightly linked to the insulin-resistance/cardiometabolic-renal cluster, yet only a minority of hyperuricemic individuals ever

develop gout. Management therefore is *not* simply “lower the number” but a graded strategy: correct reversible causes, decide *who* needs lifelong urate-lowering therapy (ULT), drive serum urate to a sub-saturation target, and cover the patient against paradoxical flares.

Pathophysiologic basis that dictates treatment

- ▶ Serum urate reflects the **balance of dietary intake, endogenous synthesis and excretion**. Hyperuricemia arises predominantly from **impaired renal urate excretion** (~90%) and, less commonly, **overproduction** (~10%); many patients have both.
- ▶ **Overproduction** drivers: high cell turnover (hematologic malignancy, psoriasis, chemotherapy, tissue hypoxia) and inherited enzyme defects — **PRPP synthetase superactivity** and **HPRT deficiency** (*Lesch-Nyhan syndrome* and variants, X-linked).
- ▶ Two-thirds of urate is eliminated renally (proximal-tubule transporters **URAT1, OAT10, GLUT9, ABCG2**) and one-third via the gut (intestinal uricolysis) — these transporters are the targets of *uricosuric* drugs and explain anti-uricosuric effects of pyrazinolate/nicotinate.
- ▶ These mechanisms define the two drug strategies: **reduce production** (xanthine oxidase inhibitors), **increase excretion / degrade urate** (uricosurics, recombinant uricase).

Non-pharmacologic measures and reversible causes (first step)

- ▶ Pursue *before/alongside* drugs; in most patients hyperuricemia cannot be corrected by these alone, but they reduce drug dose and address comorbidity.
- ▶ **Weight control** (obesity/insulin-resistance syndrome), **healthy diet** with reduced purine load, **limitation of alcohol**, and **decreased fructose-rich foods and beverages**.
- ▶ **Stop/avoid urate-raising drugs where feasible** — **thiazide and loop diuretics**, low-dose aspirin.
- ▶ Treat the dense comorbidity burden (hypertension, type 2 diabetes, CKD, ischemic heart disease); some agents lower urate as a bonus — **losartan, amlodipine, fenofibrate, and SGLT2 inhibitors** — the last offering combined urate reduction plus cardio-renal benefit.

When to start urate-lowering therapy (ULT)

- ▶ **Goal:** correct the chronic hyperuricemia/expanded urate pool (the central cause of gout) — a commitment that is **usually lifelong**.
- ▶ Consider ULT when hyperuricemia is *not* correctable by risk-factor modification, judged by:
 - **≥2 gout flares per year**, or flares of marked severity/duration, and patient willingness for long-term therapy.
- ▶ **Absolute (always-treat) indications:** any patient with **subcutaneous tophi**, **chronic gouty arthritis**, or **known uric acid nephrolithiasis** — start ULT regardless of flare frequency.

Urate-lowering and acute-flare drugs

Drug	Class / mechanism	Dosing & target	Key cautions
Allopurinol	Xanthine oxidase inhibitor; <i>first-line</i> ULT	Single morning dose; start ≤ 100 mg/d, titrate to max 800 mg/d ; in CKD with eGFR <30 mL/min start 50 mg/d and titrate slowly	Mild cutaneous reaction $\sim 2\%$; rare SCARs (SJS, TEN) — risk $\uparrow$ with CKD, higher start dose, *HLA-B5801** carriage
Febuxostat	Xanthine oxidase inhibitor	Alternative XO inhibitor; hepatic metabolism (glucuronidation + oxidation) — no dose adjustment in moderate-severe CKD	Useful in HLA-B*5801 carriers / allopurinol intolerance
Probenecid	Uricosuric; <i>second-line</i>	Start 250 mg BD , increase up to 3 g/d to target; alone or with an XO inhibitor	Needs good renal function — ineffective if serum creatinine >2 mg/dL (177 μmol/L)
Benzbromarone	Uricosuric	More effective uricosuric in CKD	<i>Not available in the United States</i>
Pegloticase	Pegylated recombinant uricase (IV)	For patients who fail/cannot tolerate full doses of other agents	Combine with methotrexate to cut immunogenicity (anti-drug antibodies $\rightarrow$ loss of efficacy, infusion reactions)
Colchicine	Anti-inflammatory (flare Rx / prophylaxis)	Flare: 1.2 mg at first sign, then 0.6 mg in 1 h , then daily dosing; prophylaxis 0.6 mg OD-BD	Eliminated via P-glycoprotein (MDR1) & CYP3A4 — reduce dose in renal disease or with clarithromycin/tacrolimus
NSAIDs	Anti-inflammatory (flare Rx)	Indomethacin 25–50 mg TID; naproxen 500 mg BD; ibuprofen 800 mg TID; celecoxib 800 then 400 mg at 12 h, then 400 mg BD	Avoid with significant comorbidity (renal, GI, cardiac)
Glucocorticoids	Anti-inflammatory (flare Rx)	Prednisone 30–50 mg/d tapered; or IM; or intra-articular for 1–few joints	Useful when NSAIDs/colchicine contraindicated
Anakinra / canakinumab	IL-1 β blockade	Reserved for refractory flares	When standard agents fail/contraindicated

- ▶ **Target serum urate:** drive to a sub-saturation point — typically $<5\text{--}6\text{ mg/dL}$ ($300\text{--}360\text{ }\mu\text{mol/L}$) — to prevent recurrent flares and dissolve tophi. A lower target ($<5\text{ mg/dL}$) accelerates tophus dissolution.
- ▶ ***HLA-B5801 screening:** **allele carriage is high among** Southeast Asian (except Japanese descent), Pacific Islander/Native Hawaiian, and black* *patients*; *screen before allopurinol in these groups and, if positive, use an alternative agent** (e.g. febuxostat).

Initiating ULT and flare prophylaxis (the practical pitfall)

- ▶ **Do not start ULT during an active flare** — abruptly lowering urate can worsen the ongoing attack.
- ▶ ULT may be started **in the resolution phase or after a flare**, always **under anti-inflammatory prophylaxis** — e.g. colchicine 0.6 mg once–twice daily or naproxen 250 mg twice daily.
- ▶ **Start low, titrate slowly:** low starting dose with gradual up-titration reduces both SCAR risk and the **paradoxical mobilization flares** caused by MSU crystals shedding from dissolving synovial tophi during rapid urate reduction.
- ▶ **Continue prophylaxis** until the patient is **normouricemic and flare-free for 3–6 months**, or until tophi resolve.

Special situations (standard medicine — see Coverage note)

- ▶ **Asymptomatic hyperuricemia:** routine ULT is generally *not* indicated for an incidentally high urate without gout, tophi, or urate stones; manage lifestyle and reversible causes, and treat comorbidities.
- ▶ **Tumor lysis syndrome (overproduction state):** prevent/treat with vigorous **IV hydration**, **allopurinol** prophylaxis, and **rasburicase** (recombinant urate oxidase) for high-risk/established cases; rasburicase is **contraindicated in G6PD deficiency** (hemolysis/methemoglobinemia).
- ▶ **Secondary/overproduction hyperuricemia** (myeloproliferative disease, inherited enzyme defects): control the underlying disorder; XO inhibition is preferred over uricosurics to avoid stone formation.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Pathogenesis-and-therapeutic-targets flow diagram** (after Fig. 384-1): boxes top-to-bottom — *Risk factors* (obesity/insulin resistance, diet/alcohol, genes, diuretics/low-dose aspirin) → **Chronic hyperuricemia / increased urate pool** → $\text{SU} > 6.85\text{ mg/dL}$ → **MSU crystallization, crystal growth, tissue deposition** → **Recurrent gout flares (acute crystal-induced inflammation)** → **Chronic gouty arthritis / tophi**. Add two side-arrows labelled “**Urate-lowering therapy (target SU $<5\text{--}6\text{ mg/dL}$): allopurinol, febuxostat, probenecid, uricase**” pointing at the hyperuricemia box, and “**Anti-inflammatory therapy: NSAIDs**,”

colchicine, glucocorticoids” pointing at the flare box, plus a “Dissolution → normal urate level” return arrow.

- ▶ **Treatment algorithm box:** label nodes — *Confirm hyperuricemia/gout* → *Lifestyle + stop diuretics* → *Indication for ULT?* (≥ 2 flares/yr, tophi, chronic arthritis, urate stones) → *Check HLA-B5801 in high-risk ethnicity* → *Allopurinol (or febuxostat) start-low titrate-to-target* → *Add colchicine/NSAID prophylaxis 3–6 months**.

Clinical / Diagnostic significance

- ▶ **Confirm before committing to lifelong therapy:** definitive diagnosis of gout rests on **needle-shaped, strongly negatively birefringent MSU crystals** in synovial fluid/tophus under polarized light; always culture fluid as septic arthritis can coexist.
- ▶ Serum urate may be **normal or low during an acute flare** (uricosuric effect of IL-6, ~2 mg/dL fall) — do not exclude gout on a single normal value; recheck after the flare and use it as the **therapeutic target**.
- ▶ **Baseline workup before/with ULT:** serum creatinine/eGFR, LFTs, hemoglobin, WBC count, HbA1c and lipids — to detect comorbidity, choose drug/dose, and monitor toxicity.
- ▶ **Imaging adjuncts:** musculoskeletal **ultrasound double-contour sign** and **dual-energy CT** detect urate deposition early; radiographic punched-out erosions with overhanging edges mark advanced tophaceous disease.
- ▶ ULT response is monitored by serial serum urate to the **<5–6 mg/dL** target; persistent failure to reach target should prompt adherence checks, dose escalation, or a switch/add of class.

High-yield exam pointers

- ▶ **Allopurinol is first-line ULT;** start ≤ 100 mg/d (50 mg/d if eGFR < 30), titrate up to **800 mg/d**, target serum urate **<5–6 mg/dL**.
- ▶ ***Screen HLA-B5801 before allopurinol in Southeast Asian/Pacific Islander/Native Hawaiian/black patients; if positive use febuxostat**.**
- ▶ **Febuxostat needs no dose adjustment** in moderate–severe CKD (hepatic metabolism).
- ▶ **Probenecid** (uricosuric, 2nd-line) is **ineffective if creatinine > 2 mg/dL**; **benzbromarone** works better in CKD but is unavailable in the US.
- ▶ **Pegloticase** (pegylated uricase) for refractory/tophaceous gout — give with **methotrexate** to limit immunogenicity.
- ▶ **Never start ULT during an acute flare;** begin in resolution phase under **colchicine/NSAID prophylaxis**, continued **3–6 months** until normouricemic and flare-free or tophi resolve.
- ▶ **Start low–go slow** to avoid SCARs (SJS/TEN) and paradoxical mobilization flares.
- ▶ **Always-treat indications:** tophi, chronic gouty arthritis, uric acid nephrolithiasis.

- ▶ Rasburicase for tumor-lysis hyperuricemia — **contraindicated in G6PD deficiency**.

SOURCE & COVERAGE

Harrison's Principles of Internal Medicine, 22e — Ch 384 "Gout and Other Crystal-Associated Arthropathies" (urate physiology, indications/targets for ULT, allopurinol/febuxostat/probenecid/benzbromarone/pegloticase dosing and cautions, flare prophylaxis, HLA-B*5801 screening, acute-flare agents).

Coverage note: The provided chapter addresses hyperuricemia management within the *gout* framework. It does **not** explicitly cover (a) the threshold/decision for treating purely **asymptomatic hyperuricemia**, or (b) **tumor lysis syndrome** prophylaxis (IV hydration, rasburicase, G6PD contraindication). These points are included only as **universally accepted standard internal medicine**, not drawn from Ch 384, and are flagged here accordingly.

Microscopic Polyangiitis

Asked in: Paper III 09/2025 · Paper III Nov 2019 (2×) — RGUHS MD General Medicine

Definition / Introduction — Microscopic polyangiitis (MPA) is a **pauci-immune, non-granulomatous, necrotizing vasculitis** of small vessels (capillaries, venules, arterioles) — with frequent involvement of small- and medium-sized arteries — that characteristically produces **necrotizing glomerulonephritis** and **pulmonary capillaritis**. The term *microscopic polyarteritis* was coined by Davson (1948) to denote the glomerulonephritis seen in some patients with polyarteritis nodosa; the 1992 Chapel Hill Consensus Conference formalised “microscopic polyangiitis” as a distinct entity defined by small-vessel necrotizing vasculitis with **few or no immune deposits**. It is one of the three ANCA-associated vasculitides (AAV), alongside granulomatosis with polyangiitis (GPA) and eosinophilic granulomatosis with polyangiitis (EGPA), and is the commonest cause of the **pulmonary–renal syndrome**.

Epidemiology & Nomenclature

- ▶ Incidence ~3–5 per 100,000; mean age of onset ~57 years; males slightly more often affected than females.
- ▶ Classified under the Chapel Hill category of *ANCA-associated small-vessel vasculitis* — grouped with GPA and EGPA because all share ANCA positivity and pauci-immune small-vessel vasculitis, but each retains a **distinct clinical phenotype** and should be regarded as a separate disease.
- ▶ The hallmark **distinguishing MPA from GPA is the absence of granulomatous inflammation**; absence of asthma/eosinophilia distinguishes it from EGPA, and the involvement of

venules/capillaries (and glomerulonephritis) distinguishes it from classic polyarteritis nodosa (PAN).

Etiopathogenesis (ANCA biology)

- ▶ **Pauci-immune lesion:** immunohistochemistry shows a *paucity of immunoglobulin deposition* in the vessel wall, implying immune-complex formation does **not** drive pathogenesis (contrast with cryoglobulinemic/IgA vasculitis).
- ▶ **ANCA** are autoantibodies against neutrophil/monocyte cytoplasmic granule proteins. Two patterns by indirect immunofluorescence:
 - **p-ANCA (perinuclear)** — target **myeloperoxidase (MPO)**; this is the **predominant association in MPA**.
 - **c-ANCA (cytoplasmic)** — target **proteinase-3 (PR3)**, a 29-kDa serine proteinase; predominant in GPA.
- ▶ **Pathogenic sequence:** TNF- α / IL-1 (or alternative-complement activation) **primes** neutrophils → MPO/PR3 **translocate to the cell surface** → circulating ANCA bind and activate the neutrophil → **degranulation, reactive-oxygen-species release, and adhesion to/killing of endothelial cells** → release of IL-1, IL-8 and further leukocyte recruitment → **necrotizing small-vessel injury**. Adoptive-transfer experiments in mice support a direct pathogenic role of anti-MPO.
- ▶ **Complement** (alternative pathway, generating **C5a**) is now recognised as central — the basis for the C5a-receptor antagonist **avacopan**.
- ▶ **Drug-induced MPA / MPO-ANCA vasculitis:** implicated agents include **propylthiouracil, hydralazine, allopurinol, penicillamine, minocycline, and sulfasalazine** — typically high-titre p-ANCA; withdrawal of the drug is the first therapeutic step.

Clinical and Laboratory Manifestations

- ▶ **Constitutional onset:** may be gradual (fever, weight loss, myalgia/arthritis) or **acute**.

Organ system	Manifestation in MPA
Renal	Necrotizing pauci-immune (crescentic) glomerulonephritis in $\geq 79\%$; frequently rapidly progressive (RPGN) → renal failure; haematuria, RBC casts, sub-nephrotic proteinuria
Pulmonary	Alveolar haemorrhage from pulmonary capillaritis in $\sim 12\%$ (haemoptysis may be first symptom); interstitial fibrosis mimicking UIP carries a poor prognosis
Neurological	Mononeuritis multiplex (vasculitic neuropathy)
Cutaneous	Palpable purpura , splinter haemorrhages, ulcers, vesiculobullous lesions

Organ system	Manifestation in MPA
GI	Mesenteric/visceral vasculitis (abdominal pain, bleeding)
NOT typical	Upper-airway destructive disease and pulmonary nodules are absent — their presence suggests GPA instead

- ▶ **Laboratory:** features of inflammation — raised ESR/CRP, anaemia, leukocytosis, thrombocytosis; ANCA positive in ~75%, predominantly anti-MPO (p-ANCA), though PR3-ANCA may occur. The renal lesion is a **segmental necrotizing glomerulonephritis**, often with intraglomerular thrombi/localised intravascular coagulation.

Diagnosis

- ▶ Based on **histologic evidence of vasculitis or pauci-immune glomerulonephritis** in a patient with a **compatible multisystem clinical picture**.
- ▶ **Tissue biopsy** (kidney, skin, nerve/muscle, or lung) remains essential — especially when the clinical picture is atypical — even though MPA is strongly ANCA-associated. Renal biopsy shows **focal segmental necrotizing GN with crescents and absent/scanty immune deposits on immunofluorescence** (pauci-immune).
- ▶ Exclude **mimics** (infective endocarditis, anti-GBM disease, SLE, cryoglobulinemia, cholesterol emboli, thrombotic microangiopathy) before committing to immunosuppression.

Differential Diagnosis (key separators)

Feature	MPA	GPA	EGPA	PAN
Vessel size	Small ($\pm$ medium)	Small–medium	Small–medium	Medium (muscular arteries)
Granulomas	Absent	Present (necrotizing)	Present (eosinophil-rich)	Absent
Dominant ANCA	MPO / p-ANCA (~75%)	PR3 / c-ANCA (>90%)	MPO in ~40–48%	ANCA-negative
Upper airway / nodules	Absent	Prominent (sinusitis, nasal, lung nodules/cavities)	Allergic rhinitis/sinus polyps; asthma	Absent
Glomerulonephritis	Common (RPGN)	Common	Less common	Absent (arteritis, not GN)
Lung haemorrhage	Common (capillaritis)	Common	Uncommon	Pulmonary arteries spared

Feature	MPA	GPA	EGPA	PAN
Distinctive clue	Pulmonary–renal syndrome	Saddle-nose, granulomas	Asthma + eosinophilia >1000/ μ L	HBV association, microaneurysms

Treatment

Trials enrol GPA and MPA together; MPA is managed identically to GPA (Harrison).

- ▶ **Severe (organ-/life-threatening) disease — Remission INDUCTION:**
 - Glucocorticoids + either cyclophosphamide OR rituximab.
 - Cyclophosphamide 2 mg/kg/day oral (reduce dose in renal impairment); or IV pulse 15 mg/kg $\times$ 3 doses every 2 weeks then every 3 weeks (similar remission, higher relapse than daily oral).
 - Rituximab (anti-CD20) 375 mg/m² weekly $\times$ 4 weeks — *non-inferior to cyclophosphamide* (RAVE/RITUXVAS), and superior in relapsing disease; preferred when fertility preservation matters or for relapse.
 - Glucocorticoid regimen: historically prednisone 1 mg/kg/day then taper; a **reduced-dose regimen** (PEXIVAS) is **non-inferior with fewer serious infections**. Life-threatening disease $\rightarrow$ IV methylprednisolone 1000 mg/day $\times$ 3 days.
 - Avacopan (oral C5a-receptor antagonist) — a glucocorticoid-sparing add-on; in the ADVOCATE trial achieved higher sustained remission at 52 weeks with markedly lower steroid exposure.
 - Plasma exchange (PLEX): **no benefit** on the composite of ESRD/death in the large PEXIVAS trial; reserve for **coexisting anti-GBM antibody**, and consider in selected fulminant cases (severe RPGN, creatinine >5.7 mg/dL — improved renal recovery at the cost of infection). Separate PLEX and rituximab by $\geq$ 48 h.
- ▶ **Remission MAINTENANCE** (after cyclophosphamide induction, switch at 3–6 months):
 - Rituximab (e.g. 500 mg $\times$ 2 then 500 mg every 6 months) — **lowest relapse rate**; or azathioprine 2 mg/kg/day; or methotrexate 15 $\rightarrow$ 20–25 mg/week; or mycophenolate mofetil 1 g BID (higher relapse). Continue $\geq$ 2 years; individualise duration (relapse risk rises after stopping).
- ▶ **Non-severe disease:** methotrexate or mycophenolate ($\pm$ rituximab) with lower-dose glucocorticoids.
- ▶ **Prognosis:** 5-year survival $\sim$ 74% with treatment; death from alveolar haemorrhage, renal, cardiac or GI disease. **Relapse in $\geq$ 34%** (25–50% across AAV). **Early diagnosis is the key prognostic determinant** — late diagnosis means more renal fibrosis and worse outcomes.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Pauci-immune crescentic glomerulus:** label *Bowman's capsule, cellular crescent compressing the tuft, segmental fibrinoid necrosis of capillary loops, ruptured GBM, and "negative" immunofluorescence (absent immune deposits).*
- ▶ **ANCA pathogenesis flow diagram:** label *TNF- α /IL-1 priming $\rightarrow$ MPO/PR3 surface translocation $\rightarrow$ ANCA binding $\rightarrow$ neutrophil activation (ROS, degranulation, C5a) $\rightarrow$ endothelial injury $\rightarrow$ necrotizing small-vessel vasculitis, with the avacopan block at the C5a receptor and rituximab block at CD20 B-cell.*

Clinical / Diagnostic significance

- ▶ Suspect MPA in any **pulmonary–renal syndrome** (haemoptysis/alveolar haemorrhage + RPGN with active urinary sediment); it is **several-fold commoner than anti-GBM disease** as a cause.
- ▶ A **p-ANCA/anti-MPO positive RPGN with pauci-immune crescentic GN on biopsy and no granulomata/no upper-airway destruction** strongly favours MPA over GPA.
- ▶ **Send anti-GBM with ANCA** in every pulmonary–renal presentation — “double-positive” patients (anti-MPO + anti-GBM) require **plasma exchange**.
- ▶ **Mononeuritis multiplex** with constitutional symptoms and renal involvement is a high-yield clue; nerve/muscle biopsy can confirm vasculitis.
- ▶ Always **exclude drug-induced MPO-ANCA vasculitis** (PTU, hydralazine, minocycline, allopurinol) — withdrawing the drug may suffice in limited disease.
- ▶ Monitor for **treatment-related infection** (the major cause of early mortality), hepatitis-B reactivation with rituximab, and cyclophosphamide-related bladder toxicity/infertility/malignancy.

High-yield exam pointers

- ▶ MPA = **pauci-immune, non-granulomatous, necrotizing small-vessel vasculitis**; *no granulomas* (vs GPA), *no asthma/eosinophilia* (vs EGPA), *glomerulonephritis present and pulmonary arteries involved* (vs PAN).
- ▶ **Davson 1948** coined “microscopic polyarteritis”; **Chapel Hill 1992** defined MPA.
- ▶ **ANCA positive in ~75%**, predominantly **anti-MPO / p-ANCA**.
- ▶ **Glomerulonephritis $\geq 79\%$, alveolar haemorrhage $\sim 12\%$; commonest cause of pulmonary–renal syndrome.**
- ▶ **Renal biopsy = focal segmental necrotizing crescentic GN, pauci-immune on IF.**
- ▶ **Induction = glucocorticoid + (cyclophosphamide or rituximab $375 \text{ mg/m}^2 \times 4$) $\pm$ avacopan; methylprednisolone pulse for life-threatening disease.**
- ▶ **PLEX no longer routine (PEXIVAS)** — reserve for **anti-GBM positivity / selected fulminant cases.**

- ▶ Maintenance with rituximab (lowest relapse) / azathioprine / methotrexate for ≥ 2 years.
- ▶ 5-yr survival $\sim 74\%$; relapse $\geq 34\%$; outcome hinges on early diagnosis.

SOURCE & COVERAGE

- ▶ Harrison's Principles of Internal Medicine, 22e — "The Vasculitis Syndromes" (Microscopic Polyangiitis; ANCA biology; treatment of ANCA-associated vasculitis) and "Glomerular Diseases" (ANCA small-vessel vasculitis / pauci-immune crescentic glomerulonephritis).
- ▶ CMDT 2026 — "Rheumatologic, Immunologic, & Allergic Disorders" (Microscopic Polyangiitis — essentials, drug-induced MPO-ANCA, treatment) and "Kidney Disease" (rapidly progressive GN).

Coverage note: The corpus does not contain the 2022 ACR/EULAR MPA classification-criteria point scores, so these were deliberately not stated; the answer uses the Chapel Hill 1992 nomenclature, which is fully sourced. All numbers, drug doses, eponyms and percentages above are taken verbatim from the cited chapters.

Mixed connective tissue disease

Asked in: Paper III May 2022 — RGUHS MD General Medicine

Definition / Introduction — Mixed connective tissue disease (MCTD) is an *overlap syndrome* in which features of systemic sclerosis (SSc, usually limited cutaneous), systemic lupus erythematosus (SLE), polymyositis/dermatomyositis and rheumatoid arthritis coexist in the same patient, characteristically accompanied by high titres of autoantibody to U1-ribonucleoprotein (anti-U1-RNP). The defining initial presentation is Raynaud's phenomenon with "puffy" (swollen) fingers and myalgia. More broadly, an *overlap syndrome* is defined as typical SSc features coexisting with clinical and laboratory evidence of another autoimmune disease — most commonly polymyositis, Sjögren's syndrome, polyarthritis, autoimmune liver disease, or SLE. MCTD was first delineated by Sharp and colleagues (1972).

Pathogenesis and immunology

- ▶ Autoantibody-driven autoimmune connective-tissue disease; the serological hallmark is anti-U1-RNP, which produces a high-titre speckled antinuclear antibody (ANA) pattern on HEp-2 immunofluorescence.
- ▶ Anti-U1-RNP is directed against the U1 small nuclear ribonucleoprotein, chiefly the 70-kDa polypeptide (U1-70K) and the A and C proteins — a *standard-textbook* specificity not detailed in the provided chapter.

- ▶ The B-cell hyperactivity, TH2-polarised T-cell response, and endothelial/microvascular injury that underlie SSc are shared mechanisms relevant to MCTD: chronic **B-cell activation** (elevated BAFF/APRIL), profibrotic cytokines (TGF- β , IL-6, IL-13), and a vasculopathy driving **Raynaud's phenomenon and pulmonary arterial hypertension (PAH)**.
- ▶ Strong association with **HLA class II (notably HLA-DR4)** genotypes (*standard immunology, flagged below*), in contrast to the anti-Sm/anti-dsDNA-linked HLA associations of SLE.

Clinical features (multisystem)

- ▶ **Hallmark triad** to recall: **Raynaud's phenomenon + swollen/puffy hands ("sausage" fingers) + high-titre anti-U1-RNP**.
- ▶ Over time, **sclerodactyly, soft-tissue calcinosis (calcinosis cutis) and cutaneous telangiectasia** appear (scleroderma-spectrum features).
- ▶ **SLE-like features**: malar (butterfly) erythema, photosensitivity, serositis, cytopenias, alopecia.
- ▶ **Myositis**: proximal muscle weakness with raised muscle enzymes (polymyositis overlap).
- ▶ **Inflammatory arthritis/arthritis**: may be erosive; some patients are **seropositive (RF/anti-CCP)** with a rheumatoid-arthritis overlap.

Organ system	Characteristic MCTD manifestations
Vascular	Raynaud's phenomenon (early, near-universal); abnormal nailfold capillaroscopy; digital ischaemia
Skin/hands	Puffy fingers, sclerodactyly, calcinosis cutis, telangiectasia, malar rash, photosensitivity
Musculoskeletal	Inflammatory polyarthritis ($\pm$ erosive), myositis with proximal weakness
Pulmonary	PAH (leading cause of death), interstitial lung disease (ILD), pleuritis
Gastrointestinal	Oesophageal dysmotility, GERD, reduced lower-oesophageal-sphincter tone (<i>standard SSc-spectrum feature</i>)
Cardiac	Pericarditis/pericardial effusion, conduction defects, myocardial involvement
Renal	Membranous/mesangial nephropathy; severe diffuse glomerulonephritis and scleroderma renal crisis are relatively uncommon
Neurological	Trigeminal (sensory) neuropathy; aseptic meningitis (often NSAID-related) — <i>standard, flagged</i>

Autoantibodies and laboratory features

- ▶ **Anti-U1-RNP in high titre is required** for the diagnosis; by definition the speckled ANA is strongly positive.
- ▶ **Absence of anti-Sm and anti-dsDNA** in high titre helps distinguish MCTD from classic SLE (*standard serology, flagged*); anti-Sm, when strongly positive, points toward SLE rather than MCTD.
- ▶ **Other overlap-associated antibodies** recognised in the SSc chapter (useful for the differential of overlap syndromes):

Autoantibody	Pattern	Principal association
U1-RNP	Speckled	MCTD — PAH, inflammatory arthritis, myositis overlap
PM/Scl	Nucleolar	Calcinosis cutis, ILD, myositis overlap (SSc-polymyositis)
Ku	Speckled	SLE / myositis overlap
Ro52 / TRIM21	—	Overlap, older-age onset, ILD
Topoisomerase I (Scl-70)	Speckled	Diffuse SSc, ILD (not MCTD)
Centromere (ACA)	Discrete speckled	Limited SSc, isolated PAH (not MCTD)

- ▶ Supportive labs: raised acute-phase reactants, anaemia, hypergammaglobulinaemia, raised creatine kinase (if myositis), low complement (variable), abnormal nailfold videocapillaroscopy.
- ▶ **Screening for organ involvement:** pulmonary function tests with DLCO, high-resolution CT chest (ILD), transthoracic echocardiography ± right-heart catheterisation for PAH, ECG, and CK/EMG for myositis.

Diagnostic criteria and classification of overlap syndromes

- ▶ MCTD is listed among the **overlap syndromes** in the scleroderma-spectrum classification (alongside SSc/polymyositis overlap).
- ▶ Several validated **classification criteria sets** exist (*standard rheumatology — not detailed in the provided Harrison chapter*): **Sharp, Alarcón-Segovia, Kasukawa, and Kahn** criteria. All require **high-titre anti-U1-RNP** plus a defined combination of clinical features.

Criteria set	Core requirement
Alarcón-Segovia (most widely used)	Serologic: anti-U1-RNP $\geq 1:1600$ (haemagglutination) plus ≥ 3 of 5 clinical — hand oedema, synovitis, myositis, Raynaud's, acrosclerosis (synovitis or myositis required)
Kasukawa	Raynaud's or swollen fingers/hands + positive anti-RNP + at least one feature from each of the SLE-, SSc-, and PM-like categories

Criteria set	Core requirement
Sharp	Major + minor clinical criteria with high-titre anti-RNP and low anti-Sm
Kahn	Anti-U1-RNP + Raynaud's + ≥ 2 of synovitis, myositis, swollen fingers

Management

- **Manifestation-directed and largely glucocorticoid-responsive disease**; therapy is tailored to the dominant organ involvement (*treatment specifics below are universally-accepted standard medicine; the provided chapter details only musculoskeletal therapy*).
- **Arthralgia/arthritis & musculoskeletal disease**: short courses of NSAIDs, methotrexate, hydroxychloroquine, and cautious low-dose glucocorticoids; physical/occupational therapy to prevent contractures (grounded in the SSc chapter).
- **Raynaud's phenomenon**: cold avoidance, dihydropyridine calcium-channel blockers; PDE5 inhibitors/prostanoids for digital ulcers.
- **Myositis & severe inflammatory disease**: moderate-to-high-dose glucocorticoids with steroid-sparing agents (methotrexate, azathioprine, mycophenolate mofetil).
- **ILD**: mycophenolate mofetil or cyclophosphamide, with rituximab in refractory disease.
- **PAH** (the prognosis-determining complication): endothelin-receptor antagonists, PDE5 inhibitors, and prostacyclin analogues — early screening and treatment are essential.
- **GERD/oesophageal disease**: proton-pump inhibitors, prokinetics, lifestyle measures.

Prognosis and course

- Generally more favourable than diffuse SSc or severe SLE, with many manifestations responding to glucocorticoids.
- **Pulmonary arterial hypertension is the leading cause of mortality** in MCTD; progressive ILD and cardiac disease also drive poor outcomes.
- The disease may **evolve over time** — some patients differentiate into a more clearly defined SSc or SLE phenotype, fuelling the ongoing debate over whether MCTD is a truly distinct entity or a transitional/overlap state.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- **Venn diagram of overlap syndromes**: three overlapping circles labelled “SLE”, “Systemic sclerosis”, “Polymyositis” (with a smaller “RA” overlap), and the central intersection labelled “MCTD — anti-U1-RNP”. Annotate central shared features: *Raynaud's, puffy hands, arthritis, myositis*.

- ▶ **Pathophysiology flow diagram:** *Genetic susceptibility (HLA-DR4) → Anti-U1-RNP autoimmunity / B-cell activation → Endothelial injury & vasculopathy → branches to “Raynaud’s / digital ischaemia” and “Pulmonary arterial hypertension (leading cause of death)”*; parallel branch *TH2 cytokines (TGF- β , IL-6, IL-13) → “Fibrosis: sclerodactyly, ILD”*.

Clinical / Diagnostic significance

- ▶ **Anti-U1-RNP in high titre is the single most important diagnostic test**; a high-titre speckled ANA in a patient with Raynaud’s and puffy hands should prompt its measurement.
- ▶ Distinguishing MCTD from SLE matters prognostically: MCTD typically **sparcs the patient from severe diffuse lupus nephritis and severe CNS lupus**, but carries a **high risk of PAH** demanding lifelong echocardiographic surveillance.
- ▶ Recognising the **overlap antibody panel** (PM/Scl, Ku, Ro52) helps classify atypical connective-tissue disease and predicts ILD/myositis risk.
- ▶ Early detection and aggressive treatment of **PAH and ILD** are the key determinants of survival.

High-yield exam pointers

- ▶ MCTD = SSc + SLE + **polymyositis** + **RA features** + **high-titre anti-U1-RNP**; first described by Sharp (1972).
- ▶ **Speckled ANA, high-titre anti-U1-RNP**; classically **anti-Sm/anti-dsDNA negative** (helps separate from SLE).
- ▶ Earliest/most consistent clue: **Raynaud’s phenomenon + swollen “puffy” hands + myalgia**.
- ▶ Later scleroderma features: **sclerodactyly, calcinosis cutis, telangiectasia**.
- ▶ **PAH = leading cause of death**; screen with echocardiography $\pm$ right-heart catheterisation.
- ▶ **Glucocorticoid-responsive disease** — better prognosis than diffuse SSc; severe lupus nephritis and renal crisis are uncommon.
- ▶ Most widely used classification criteria: **Alarcón-Segovia**; others — Kasukawa, Sharp, Kahn.
- ▶ May **evolve into SSc or SLE**; debated as a distinct entity vs an overlap state.

SOURCE & COVERAGE

Harrison’s Principles of Internal Medicine, 22e — Ch 372 “Systemic Sclerosis (Scleroderma) and Related Disorders” (MCTD/overlap-syndrome section, Tables 372-2 and 372-4). **Coverage note:** The provided chapter covers MCTD only briefly within the scleroderma spectrum — it grounds the definition, overlap concept, anti-U1-RNP/speckled-ANA serology and its associations (PAH, inflammatory arthritis, myositis), the early Raynaud’s/puffy-hands/myalgia presentation, later sclerodactyly/calcinosis/telangiectasia, SLE-like skin features, the overlap-antibody panel

(PM/Scl, Ku, Ro52), and musculoskeletal therapy. Items added as *universally-accepted standard internal medicine* and flagged in-text — Sharp 1972 origin, anti-U1-70K/A/C antigen specificity, HLA-DR4 association, the named classification criteria (Sharp, Alarcón-Segovia, Kasukawa, Kahn) and their thresholds, oesophageal/neurological detail, and the manifestation-directed pharmacotherapy (Raynaud's, myositis, ILD, PAH) — fall outside the verbatim text of the provided chapter.

Neuropathic Joint Diseases

Asked in: Paper III 09/2025 — RGUHS MD General Medicine

Definition / Introduction — **Neuropathic joint disease* (Charcot joint, *neuro-osteoarthropathy*) is a progressive, destructive arthritis that develops in a joint deprived of normal pain sensation, proprioception, or both. With loss of these protective mechanisms the joint is subjected to repeated, unperceived trauma, leading to severe cartilage and bone damage with a characteristic mismatch between gross radiographic destruction and the relative absence of pain. First described by Jean-Martin Charcot in the knees of patients with *tabes dorsalis**, it is now seen most frequently in the foot and ankle of patients with diabetes mellitus.

Etiology and characteristic joint distribution

The distribution of joint involvement is determined by the underlying neurological disorder, because the affected joints correspond to the territory of sensory loss.

Underlying disorder	Typical joint(s) affected
Diabetes mellitus (most frequent cause)	Tarsal and tarsometatarsal joints; then metatarsophalangeal and talotibial
Tabes dorsalis (tertiary syphilis)	Knees, hips, ankles
Syringomyelia	Glenohumeral (shoulder), elbow, wrist (upper limb)
Leprosy, yaws	Feet, hands
Meningomyelocele	Ankle, foot
Congenital indifference / insensitivity to pain	Ankle, foot
Peroneal muscular atrophy (<i>Charcot-Marie-Tooth disease</i>)	Foot, ankle
Amyloidosis	Variable peripheral joints

- ▶ Harrison's *Table 386-2* lists diabetes mellitus, amyloidosis, tabes dorsalis, leprosy, meningocele, congenital indifference to pain, syringomyelia and peroneal muscular atrophy as the recognised associations.
- ▶ An arthritis resembling neuropathic disease has been reported after **frequent intra-articular glucocorticoid injections**, attributed to the analgesic effect promoting overuse of an already-damaged joint (steroid cartilage damage is more typical of animal models than humans).

Pathophysiology — two complementary mechanisms

- ▶ **Neurotraumatic theory ("German" theory)**: loss of deep pain, proprioception and protective neuromuscular reflexes allows cumulative *microtrauma* — ligament tears and bone fractures — to accumulate unchecked, producing progressive joint disorganisation.
- ▶ **Neurovascular theory ("French" theory)**: an abnormal **autonomic nervous system** drives dysregulated (increased) blood flow to the joint, causing active bone **resorption** and osteopenia; loss of bone, particularly in the diabetic foot, may be the *initial* finding.
- ▶ In diabetes, **peripheral neuropathy, autonomic neuropathy and trauma** act together; denervation of intrinsic foot muscles causes clawing of the toes and anterior displacement of the submetatarsal fat pads, altering biomechanics and raising plantar pressures.
- ▶ It is not understood why only a minority of patients with neuropathy go on to develop clinically evident neuropathic arthropathy.

Pathology: changes resemble a *severe osteoarthritic joint* — fragmentation and eventual loss of articular cartilage, **eburnation** of underlying bone, marginal osteophytes, and, with advanced disease, surface erosions, fractures, devitalised bone, intra-articular loose bodies and microscopic cartilage/bone fragments.

Clinical features

- ▶ Usually **begins in a single joint** and later involves others, depending on the neurological substrate.
- ▶ The joint becomes **progressively enlarged** from bony overgrowth and synovial effusion; it is classically *swollen, boggy and relatively painless*.
- ▶ May evolve with surprising **rapidity** — a totally disorganised joint with multiple bony fragments can appear within weeks to months.
- ▶ **Hallmark:** *far less pain than expected* from the degree of destruction; occasional sudden pain occurs from intra-articular fractures of osteophytes. Free-floating cartilage/bone fragments cause mechanical (locking) symptoms.

Diabetic (Charcot) foot — exam favourite:

- ▶ Estimated incidence in diabetes ~0.5%, typically in patients **≥50 years** who have had diabetes for several years.

- ▶ Onset often attributed to antecedent trauma (e.g. *twisting* the foot); may follow a foot fracture or dislocation.
- ▶ Foot and ankle become swollen; downward collapse of the tarsal bones produces convexity of the sole — the “**rocker-bottom**” foot.
- ▶ Large osteophytes protrude dorsally; **calluses** form over the metatarsal heads and may break down into infected **ulcers and osteomyelitis**.
- ▶ The destructive change at the tarsometatarsal joints is termed a **Lisfranc fracture-dislocation**; radiographs show resorption and tapering of the distal metatarsals.

Radiographic features, staging and differential diagnosis

- ▶ **Early imaging** mimics osteoarthritis: joint-space narrowing, subchondral sclerosis, osteophytes, periarticular fractures, joint subluxation and effusions.
- ▶ **Late:** marked destructive *and* hypertrophic changes — striking osteolysis, fragmentation, dislocation and bony sclerosis (“disorganisation”).
- ▶ A useful descriptive mnemonic for the classic atrophic-hypertrophic picture is the “**6 D’s**”: *Distension* (effusion), increased *Density* (sclerosis), *Debris* (loose bodies), *Disorganisation*, *Dislocation/subluxation*, and *Destruction*.
- ▶ **Eichenholtz staging** of the Charcot foot (orthopaedic standard): *Stage 0* — acute inflammatory/prodromal (hot, swollen, red foot, near-normal X-ray); *Stage 1* — development/fragmentation; *Stage 2* — coalescence (debris absorption, reduced warmth); *Stage 3* — consolidation/reconstruction (bony remodelling, stable but deformed foot).

Feature	Neuropathic joint	Osteomyelitis
Joint margins on X-ray	Distinct/well-defined	Blurred/ill-defined
Indium-111-labelled WBC scan	No increased uptake	Increased uptake
Technetium bone scan	Increased uptake	Increased uptake (<i>non-discriminatory</i>)
Synovial neutrophils	Few (non-inflammatory)	Increased

- ▶ **Diagnosis** rests on the clinical picture plus characteristic radiographs in a patient with a known **sensory neuropathy**.
- ▶ **Differential diagnosis:** osteomyelitis, avascular necrosis, advanced osteoarthritis, stress fractures and **calcium pyrophosphate deposition disease (CPPD)** — more than one may coexist.
- ▶ **Synovial fluid** is *non-inflammatory*, often xanthochromic or frankly bloody, and contains fragments of synovium, cartilage and bone; CPPD crystals favour a crystal arthropathy, whereas a high synovial neutrophil count raises concern for superadded osteomyelitis. Tissue culture is often needed to exclude infection.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Labelled lateral radiograph of a diabetic Charcot foot:** label *collapse/loss of the medial longitudinal arch, bony fragmentation and dislocation in the midfoot, tarsometatarsal (Lisfranc) destruction, dorsal osteophytes*, and the resulting “*rocker-bottom*” sole convexity.
- ▶ **Pathophysiology flow diagram:** *Sensory + autonomic neuropathy* → two limbs — (1) *Neurotraumatic*: loss of pain/proprioception → repeated microtrauma → ligament tears/fractures; (2) *Neurovascular*: autonomic dysregulation → increased blood flow → bone resorption/osteopenia — both converging on → *progressive joint destruction / disorganisation (Charcot joint)*.

Clinical / Diagnostic significance

- ▶ **Screening prevents disease:** patients who cannot feel the **5.07 Semmes-Weinstein monofilament** have lost protective sensation and are at risk of unperceived neuropathic injury; regular foot examination, protective inserts and orthotics are pivotal.
- ▶ **Acute Charcot foot is a clinical emergency in disguise** — a hot, swollen, red foot in a neuropathic diabetic is frequently misdiagnosed as cellulitis, gout or DVT; missing it allows progression to fixed rocker-bottom deformity and ulceration.
- ▶ Distinguishing neuropathic joint from **osteomyelitis** is the central diagnostic challenge in the diabetic foot and directs whether antibiotics/surgery are needed (use joint-margin definition, indium-111 WBC scan, MRI and tissue culture).
- ▶ Established joint damage does **not** reverse with control of the underlying disease, so *early* recognition is everything.

High-yield exam pointers

- ▶ *Charcot joint* = destructive arthropathy from loss of **pain + proprioception**; named after **Jean-Martin Charcot** (first described in *tabes dorsalis*).
- ▶ **Diabetes mellitus** is the commonest cause today (incidence ~0.5%); *tabes dorsalis* → **knee/hip**, *syringomyelia* → **shoulder/upper limb**, **diabetes** → **tarsometatarsal foot**.
- ▶ Two mechanisms: **neurotraumatic** (microtrauma) + **neurovascular** (autonomic-driven bone resorption).
- ▶ Classic paradox: **gross destruction with disproportionately little pain**; joint is enlarged, boggy, unstable.
- ▶ Diabetic foot signs: **rocker-bottom deformity, Lisfranc fracture-dislocation**, calluses → infected ulcers/osteomyelitis.
- ▶ Radiology “**6 D’s**”; **Eichenholtz** stages 0–3 for the Charcot foot.
- ▶ Neuropathic vs osteomyelitis: **distinct joint margins** and **negative indium-111 WBC scan** favour neuropathic; technetium scan does *not* discriminate.

- ▶ Synovial fluid **non-inflammatory**, often **bloody/xanthochromic**.
- ▶ Treatment: **non-weight-bearing for ≥8 weeks**, bracing/splinting (with vigilant skin surveillance), and **arthrodesis** for unstable joints (nonunion common); **no proven pharmacotherapy**.

Management

- ▶ **Primary aim — stabilise and offload the joint.** Treating the underlying disorder, even successfully, usually does not reverse established joint disease.
- ▶ **Acute Charcot foot:** early recognition with **strict non-weight-bearing/immobilisation (total-contact cast)** for **at least 8 weeks** may prevent severe deformity.
- ▶ **Bracing and splinting** assist weight-bearing and limit further trauma, but require close surveillance because the insensate patient cannot perceive pressure from a poorly fitted device.
- ▶ **Surgery: arthrodesis (fusion)** of an unstable joint — with or without orthobiologics — can improve function and reduce pain when conservative measures fail; **nonunion is frequent**, especially with inadequate immobilisation.
- ▶ **Aggressive foot care, ulcer prevention and glycaemic control;** CMDT notes that **pharmacotherapy has not demonstrated efficacy** for the arthropathy itself.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Arthritis Associated with Systemic Disease, and Other Arthritides” (Neuropathic Joint Disease section: etiology, *Table 386-2*, pathophysiology, clinical features, diagnosis vs osteomyelitis, treatment; *Fig. 386-1* diabetic Charcot foot).
- ▶ **CMDT 2026** — “Rheumatologic, Immunologic & Allergic Disorders” (Neurogenic Arthropathy / Charcot Joint; synovial-fluid differential) and “Diabetes Mellitus & Hypoglycemia” (Charcot foot arthropathy, rocker-bottom deformity, 5.07 Semmes-Weinstein monofilament).

Coverage note: The corpus (Harrison + CMDT) covers this topic well for an internal-medicine answer. Two items added for exam completeness are *not* verbatim in the cited corpus but are universally accepted standard teaching: the **Eichenholtz staging** of the Charcot foot and the radiographic “**6 D's**” mnemonic; the *neurotraumatic* (“German”) / *neurovascular* (“French”) theory labels are the conventional names for the two mechanisms that Harrison describes in full.

Palindromic Rheumatism

Asked in: Paper III Nov 2020 — RGUHS MD General Medicine

Definition / Introduction — Palindromic rheumatism (PR) is a relapsing-remitting inflammatory arthropathy characterised by **recurrent, abrupt, self-limiting attacks of acute arthritis and peri-**

arthritis that resolve completely within hours to a few days, leaving **no residual joint deformity and no radiographic erosions**. The term (Greek *palindromos*, “running back again”) was coined by *Hench and Rosenberg in 1944* to describe the “coming-and-going” pattern. It is best regarded not as a static disease but as an **abortive / pre-clinical phase of inflammatory arthritis**, since a substantial proportion of patients evolve into rheumatoid arthritis (RA) — making it an important exam differential for the patient with intermittent, undifferentiated arthritis.

Clinical features of the attack

- ▶ **Onset:** sudden, often peaking within a few hours; patient frequently well one moment and incapacitated the next. Attacks may begin at any time, including at night.
- ▶ **Joint pattern:** typically **monoarticular or oligoarticular (1–3 joints)** per attack; over time many joints are affected in succession. Commonly involved — **metacarpophalangeal (MCP), proximal interphalangeal (PIP), wrists, knees, shoulders**; can also involve ankles, elbows, hips.
- ▶ **Peri-articular involvement:** a hallmark is **para-articular soft-tissue and tendon-sheath inflammation** (peri-arthritis) producing diffuse swelling beyond the joint line; transient subcutaneous nodules may appear during attacks.
- ▶ **Local signs:** affected joint becomes warm, red, tender and swollen — clinically mimicking gout or septic arthritis (pseudocellulitis-like appearance).
- ▶ **Duration:** attacks are **brief — hours to 2–3 days** (occasionally up to a week), then resolve **spontaneously and completely**.
- ▶ **Inter-critical period:** between attacks the patient is **entirely asymptomatic with a normal joint examination** — analogous to the intercritical phase of gout.
- ▶ **Frequency:** highly variable — from several attacks per week to only a few per year; the disease may run for years.
- ▶ **No systemic damage:** unlike RA, there is **no progressive deformity, no joint-space narrowing and no bony erosion**, which is the single most useful distinguishing feature.

Laboratory and imaging features

- ▶ **Acute-phase reactants (ESR, CRP)** are typically elevated **during an attack** and normalise in the inter-critical period.
- ▶ **Rheumatoid factor (RF):** positive in roughly half of patients; **anti-citrullinated peptide antibodies (ACPA / anti-CCP)** are positive in a significant minority. In RA, anti-CCP carries a diagnostic specificity approaching **95%**, so its presence in a patient with palindromic attacks strongly predicts evolution to RA.
- ▶ **Antinuclear antibody (ANA):** may be positive in the subset destined to develop a connective-tissue disease such as SLE.

- ▶ **Synovial fluid:** inflammatory (raised WBC, neutrophil-predominant) but **sterile and crystal-negative** — aspiration with **polarised-light microscopy** is essential to exclude crystal arthropathy (negatively birefringent needle-shaped monosodium urate of gout; weakly positively birefringent rhomboid calcium pyrophosphate of CPPD).
- ▶ **Radiographs:** characteristically **normal** even after years — absence of erosions distinguishes PR from established RA. (Subclinical synovitis may be seen on ultrasound/MRI in those progressing to RA.)

Natural history and risk of progression

Palindromic rheumatism is prognostically heterogeneous; broadly three outcomes are recognised:

Outcome	Approx. proportion	Comment
Evolution to rheumatoid arthritis	roughly one-third to one-half	Most important outcome; attacks become more frequent then merge into persistent symmetrical synovitis
Evolution to another connective-tissue disease	smaller subset	SLE, Sjögren's, Behçet's, systemic sclerosis-overlap reported
Persistent palindromic course or complete remission	remainder	Some have lifelong intermittent attacks; a minority remit fully

Predictors of progression to RA:

- ▶ **Seropositivity** — positive RF and especially positive **anti-CCP/ACPA** (high-titre carries greatest risk).
- ▶ **Female sex.**
- ▶ **Small-joint (hand/wrist) involvement.**
- ▶ **More frequent attacks** and longer disease duration.
- ▶ **Family history** of RA.

Diagnosis and differential diagnosis

- ▶ Diagnosis is **clinical and one of exclusion** — no internationally validated criteria exist. Commonly cited **proposed (Guerné–Weisman / Hannonen) criteria** require: recurrent sudden brief attacks of arthritis/peri-arthritis over **≥6 months**, **direct observation of at least one attack by a physician**, involvement of **≥3 different joint areas** across attacks, and **exclusion of other arthropathies**.
- ▶ A detailed **attack diary** documenting site, duration and complete resolution is invaluable.

Differential	Discriminating feature
Gout / CPPD (pseudogout)	Crystals on polarised microscopy; podagra, tophi; chondrocalcinosis on X-ray

Differential	Discriminating feature
Early rheumatoid arthritis	Symptoms persistent >6 weeks, symmetrical, erosions develop, high-titre anti-CCP
Reactive / spondyloarthritis	Antecedent infection, enthesitis, sacroiliitis, psoriasis, HLA-B27
SLE / other CTD	Multisystem features, ANA/anti-dsDNA, cytopenias
Familial Mediterranean fever & periodic fever syndromes	Recurrent fever + serositis, ethnic background, <i>MEFV</i> mutation
Whipple's disease / Behçet's	GI/oral-genital features; <i>Tropheryma whipplei</i> ; pathergy
Septic arthritis	Single hot joint, fever, positive Gram stain/culture

Management

- ▶ **Acute attack:** NSAIDs are first-line; **colchicine** and short courses of **oral or intra-articular glucocorticoids** are alternatives for severe attacks. Because attacks are brief, the aim is symptom control and shortening the episode.
- ▶ **Disease-modifying / prophylactic therapy** (for frequent attacks or seropositive patients at risk of RA):
 - **Hydroxychloroquine** is the most widely used agent — reduces attack frequency and is reported to **delay or prevent progression to RA**.
 - **Sulfasalazine** and **methotrexate** are options in refractory or clearly RA-evolving disease.
 - **Colchicine** prophylaxis benefits some patients (especially where crystal disease cannot be fully excluded).
- ▶ **Monitoring:** periodic clinical review with RF/anti-CCP and acute-phase reactants to detect early conversion to persistent RA, at which point full RA-directed DMARD therapy (e.g., methotrexate ± biologic) is instituted.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Timeline of disease activity (preferred):** an X-axis labelled “Time” with intermittent vertical spikes labelled “Acute attack (hours–days)” separated by flat baselines labelled “Complete inter-critical remission — normal joints, normal X-ray”; add an arrow at the right labelled “Progression to RA (persistent synovitis, erosions)”. Contrast with a second curve labelled “Established RA — sustained activity.”
- ▶ **Hand outline:** shade the MCP, PIP, and wrist joints labelled “common sites”, with a dashed halo around a joint labelled “para-articular / peri-arthritis swelling” to depict the characteristic soft-tissue involvement.

Clinical / Diagnostic significance

- ▶ PR is a “**window of opportunity**” — recognising seropositive PR identifies patients in a **pre-RA** state in whom early hydroxychloroquine/DMARD may modify natural history.
- ▶ **Joint aspiration with polarised microscopy** is mandatory at first presentation to exclude gout, pseudogout and sepsis, all of which can present identically.
- ▶ Documenting **complete radiographic and clinical resolution between attacks** is the key step that separates PR from early erosive RA and crystal arthropathy.
- ▶ Anti-CCP/RF status drives both prognosis and the decision to start prophylactic therapy.

High-yield exam pointers

- ▶ **Eponym:** *Hench and Rosenberg, 1944; palindromos* = “to run back again.”
- ▶ **Hallmark triad:** recurrent **brief** attacks + **complete** inter-critical remission + **no** erosions/deformity.
- ▶ **1–3 joints** per attack, peaks in hours, lasts **hours to 2–3 days**; MCP/PIP/wrist/knee favoured; **peri-articular** swelling typical.
- ▶ **Seropositivity (RF, anti-CCP) predicts progression to RA**; anti-CCP specificity ~95%.
- ▶ **One-third to one-half** evolve into RA; smaller subset to SLE/other CTD; rest remit or stay palindromic.
- ▶ **Hydroxychloroquine** reduces attack frequency and may prevent RA conversion; NSAIDs/colchicine/steroids abort acute attacks.
- ▶ **Always aspirate** to exclude gout, pseudogout and septic arthritis (a diagnosis of exclusion).
- ▶ Radiograph is **characteristically normal** — a discriminator from established RA.

SOURCE & COVERAGE

- ▶ **Harrison’s Principles of Internal Medicine, 22e** — “Disorders of the Joints and Adjacent Tissues / Gout and Other Crystal-Associated Arthropathies” (palindromic rheumatism listed among mimics of acute crystal arthritis; synovial-fluid analysis, MSU/CPPD birefringence, crystal-exclusion principles) and “**Rheumatoid Arthritis**” (RF/anti-CCP performance and ~95% ACPA specificity, 2010 ACR–EULAR classification framework, differential diagnosis of early inflammatory arthritis, predictors of persistent/erosive disease).
- ▶ **CMDT 2026** — “Rheumatologic, Immunologic & Allergic Disorders” (management principles of inflammatory arthritis; hydroxychloroquine/DMARD use).

Coverage note: The Harrison/CMDT corpus does **not** carry a dedicated section on palindromic rheumatism — it appears only as a named differential of crystal arthritis in the gout chapter, with the RA chapter supplying the antibody, prognostic and differential-diagnosis framework. The disease-specific detail (attack characteristics, Hench–Rosenberg eponym, ~one-third-to-one-half

RA conversion, Guerne–Weisman proposed criteria, hydroxychloroquine prophylaxis) is therefore drawn from **universally accepted standard rheumatology** and aligned with the corpus where it overlaps; specific conversion percentages are approximate and vary between series.

Polyarthrititis

Asked in: Paper III Jun 2024 — RGUHS MD General Medicine

Definition / Introduction — *Polyarthrititis* denotes inflammatory involvement of **four or more joints** (≥ 5 by some classifications), distinguishing it from *monoarthrititis* (one joint) and *oligo-/pauciarticular* disease (two or three joints). It is a syndrome, not a diagnosis, with a broad differential spanning immune-mediated, infective, crystal-induced, reactive and degenerative disorders. The diagnostic art lies in answering four cardinal questions — *Is it articular? Is it inflammatory? Is it acute or chronic? How many and which joints?* — and then refining by pattern (symmetry, distribution, temporal evolution) and extra-articular clues, so that “red flag” conditions are not missed while needless testing is avoided.

The diagnostic framework — four cardinal questions

- ▶ **Articular vs non-articular.** Articular disorders show *deep/diffuse pain, swelling (synovial proliferation, effusion or bony enlargement), limited active AND passive movement, crepitus, instability or deformity*. Non-articular/peri-articular lesions (bursitis, tendinitis, fibromyalgia) cause focal/point tenderness, pain on active but not passive motion, and lack true synovial swelling — a frequent masquerader of “polyarthrititis.”
- ▶ **Inflammatory vs non-inflammatory.** Inflammation is suggested by the cardinal signs (erythema, warmth, pain, swelling), **prolonged morning stiffness (often hours, ≥ 30 –45 min) that improves with activity**, systemic features (fever, rash, weight loss), and laboratory evidence — raised ESR/CRP, thrombocytosis, anaemia of chronic disease, hypoalbuminaemia. Non-inflammatory (e.g., osteoarthritis) shows brief *gel-phenomenon* stiffness (≤ 45 min, often < 15 min) worsened by activity, and normal inflammatory markers.
- ▶ **Acute (≤ 6 weeks) vs chronic (> 6 weeks).** Acute polyarthrititis tends to be infective, crystal-induced, reactive or viral; chronic polyarthrititis tends to be immune-mediated (RA, SLE) or degenerative.
- ▶ **Number and distribution of joints** — polyarticular (≥ 4), with attention to *which* joints (small vs large; upper vs lower; axial involvement), *symmetry*, and *temporal pattern*.

Causes of polyarthrititis (grouped)

Category	Representative diseases
Chronic inflammatory, symmetric small-joint	Rheumatoid arthritis (RA); SLE; mixed connective tissue disease; polyarticular juvenile idiopathic arthritis
Seronegative spondyloarthritis (often asymmetric, lower-limb, axial)	Psoriatic arthritis; reactive arthritis; enteropathic (IBD-associated) arthritis; ankylosing spondylitis
Crystal-induced	Chronic tophaceous gout (may evolve into a polyarticular RA-mimic); CPPD (pseudogout)
Infective / post-infective	Polyarticular septic arthritis; gonococcal arthritis; <i>acute viral</i> — Chikungunya, parvovirus B19, hepatitis B, rubella; <i>chronic</i> hepatitis C polyarthritides; acute rheumatic fever
Connective-tissue / vasculitic	Systemic sclerosis, inflammatory myositis (polymyositis/dermatomyositis), Still's disease, sarcoid arthropathy, granulomatosis with polyangiitis (GPA)
Non-inflammatory / degenerative	Generalised (nodal) osteoarthritis
Paraneoplastic	Hypertrophic pulmonary osteoarthropathy (lung/GI carcinoma) — clubbing, periosteal new bone, RF-negative

Pattern recognition — the key to narrowing the differential

- **Temporal evolution:** *chronic/persistent* (OA, RA); *additive* — new joints add while old persist (RA, psoriatic arthritis); *intermittent* — symptom-free intervals (crystal arthritis, Lyme); *migratory* — inflammation moves from joint to joint (acute rheumatic fever, gonococcal and viral arthritis).
- **Symmetry & distribution:** RA is symmetric and additive, affecting **PIP, MCP, intercarpal and carpometacarpal** (wrist) joints with palpable synovial hypertrophy and *swan-neck/boutonnière* deformities, and characteristically **sparcs the DIP joints**. **Spondyloarthritis, reactive arthritis and gout** are typically *asymmetric and oligoarticular*, favouring the **lower limbs**; spine/sacroiliac involvement points away from RA. **Psoriatic arthritis** may involve DIP joints with **dactylitis** (“sausage digit”), nail pitting/onycholysis and *pencil-in-cup* radiographic change.
- **Extra-articular clues:** fever (Still's disease, infection, vasculitis), rash (SLE, psoriatic), nail changes (psoriatic/reactive), oral/genital ulcers and uveitis (Behçet's, spondyloarthritis), sicca (Sjögren's), Raynaud's (scleroderma/MCTD), proximal weakness (myositis). GPA arthritis prefers **larger joints (hips, ankles, wrists)** and **sparcs the small hand joints**, helping separate it from RA.

Pattern	Think of
Symmetric small-joint polyarthritis, DIP-sparing	Rheumatoid arthritis
Asymmetric, lower-limb, axial/sacroiliac	Spondyloarthritis, reactive arthritis
Acute symmetric self-limiting + fever, recent infection	Viral (Chikungunya, parvovirus B19)
Migratory + carditis/erythema marginatum	Acute rheumatic fever
DIP + nail disease + dactylitis	Psoriatic arthritis
Polyarthralgia >50 yr, proximal stiffness, RF-negative	Polymyalgia rheumatica

Clinical evaluation & investigations

- ▶ **History:** age/sex/ethnicity (gout & spondyloarthritis — men; RA, SLE, fibromyalgia — women), onset/chronology, evolution pattern, precipitants (trauma, drugs — Table 382-2, antecedent infection, comorbidities), and a full rheumatic review of systems.
- ▶ **Examination:** count tender/swollen joints (a *28-joint count* — PIPs, MCPs, wrists, elbows, shoulders, knees — is standard), distinguish true synovitis (boggy, grape-like) from bony hypertrophy (firm) and effusion (fluctuant; “bulge sign”/patellar ballottement at the knee), assess range of motion and deformity, and seek extra-articular signs.
- ▶ **Laboratory (targeted, confirmatory — not a screening battery):** FBC; ESR/CRP; uric acid (men 4.0–8.6 mg/dL; women 3.0–5.9; up to 50% normal during an acute attack); RF (positive in ~80% of RA but also in chronic infection, SLE, Sjögren’s) and anti-CCP/ACPA (more specific — high-titre or RF/anti-CCP *double positivity* predicts erosive disease); ANA with reflex profiling when SLE/CTD suspected; ASO/anti-DNase B (rheumatic fever); viral serology and hepatitis screen. Remember low pre-test probability gives poor predictive value (4–5% of healthy people are RF/ANA positive).
- ▶ **Synovial fluid analysis** — *always* indicated when sepsis, crystals or haemarthrosis is suspected, and for a flare in a single joint of a chronic polyarthritis (see table).
- ▶ **Imaging:** plain radiographs for chronicity/erosions/chondrocalcinosis; **ultrasound with power Doppler** detects early synovitis/erosions; **MRI** for early erosive change, osteonecrosis and axial disease; **DECT** localises urate deposition.

Synovial fluid	Appearance	WBC/ μ L	PMN	Examples
Normal	Clear, viscous	<200	<25%	—
Non-inflammatory	Clear, viscous, amber (“string sign”)	<2000	mononuclear	OA, trauma

Synovial fluid	Appearance	WBC/ μ L	PMN	Examples
Inflammatory	Turbid, yellow, low viscosity	2000–50,000	PMN predominant	RA, gout, psoriatic, SLE
Septic	Opaque, purulent	>50,000 (often >100,000)	>75%	Septic arthritis
Haemorrhagic	Bloody	—	—	Trauma, coagulopathy, neuropathic

Crystals: monosodium urate — long, **needle-shaped**, **negatively birefringent** (gout); calcium pyrophosphate — short, **rhomboid**, **positively birefringent** (pseudogout). Gram stain and culture (plus NAAT for gonococcus, AFB/fungal culture for chronic monoarthritis) whenever infection is possible — crystal and septic arthritis can co-exist.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Diagnostic algorithm for musculoskeletal/polyarthritis evaluation** (Harrison Fig. 382-1): boxes/branches labelled — *Is it articular?* → *Acute vs Chronic (>6 wk)* → *Inflammation present? (morning stiffness, soft-tissue swelling, systemic symptoms, ESR/CRP)* → *Number of joints (1–3 vs >3)* → *Symmetric?* → *PIP/MCP/MTP involved?* → *Rheumatoid arthritis / SLE / Scleroderma / Psoriatic / Reactive / Enteropathic.*
- ▶ **Hand joint-distribution map** (Fig. 382-3) labelled: *1st CMC & DIP/PIP = OA (Heberden's & Bouchard's nodes); PIP/MCP/wrist = RA (DIP-sparing, swan-neck/boutonnière); DIP + dactylitis + nail pitting = psoriatic arthritis; 2nd–3rd MCP = haemochromatosis/CPD.*

Clinical / Diagnostic significance

- ▶ **Red-flag polyarthritis**: new-onset febrile polyarthritis demands exclusion of **polyarticular septic arthritis** (mortality ~30%), disseminated gonococcal infection, endocarditis and crystal disease before labelling it autoimmune.
- ▶ **Early RA recognition matters** — disease-modifying therapy (DMARDs) should begin as soon as the diagnosis is certain to prevent erosions and deformity; NSAIDs do not alter progression.
- ▶ **Viral polyarthritis** (Chikungunya, parvovirus B19) mimics early RA but is usually febrile, self-limiting within weeks, and serology-confirmed — avoids unnecessary immunosuppression. **Hepatitis C** causes a chronic, *non-erosive*, RF-positive but anti-CCP-negative polyarthritis.
- ▶ **Don't miss mimics**: PMR (polyarthralgia >50 yr, RF-negative, proximal girdle stiffness, high ESR), GPA (large joints, small-hand-sparing), and paraneoplastic hypertrophic osteoarthropathy (clubbing, periosteal reaction, RF-negative).

High-yield exam pointers

- ▶ Polyarthritis = ≥ 4 joints (Harrison); CMDT defines polyarticular as ≥ 5 joints, oligoarticular 2–4 — quote both.
- ▶ The **four questions**: articular?, inflammatory?, acute/chronic?, how many/which joints — the spine of every answer.
- ▶ Symmetric, DIP-sparing, PIP/MCP/wrist = RA; asymmetric, lower-limb, DIP + dactylitis = psoriatic/spondyloarthritis.
- ▶ Temporal patterns: **migratory** = rheumatic fever, gonococcal, viral; **additive** = RA, psoriatic; **intermittent** = crystal, Lyme.
- ▶ Anti-CCP is more specific than RF; double positivity predicts erosive RA; up to 50% of active RA/SLE have a normal ESR/CRP.
- ▶ Synovial WBC: <2000 non-inflammatory, 2000–50,000 inflammatory, >50,000 (PMN >75%) septic. MSU = negatively birefringent needles; CPPD = positively birefringent rhomboids.
- ▶ ESR, RF and ANA are **confirmatory, not screening** tests — low yield when pre-test probability is low.
- ▶ Febrile polyarthritis = exclude sepsis first.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Approach to Articular and Musculoskeletal Disorders” (J.J. Cush) — diagnostic framework, joint-pattern and temporal classification, synovial fluid analysis (Fig. 382-6), ANA patterns (Table 382-4), drug-induced musculoskeletal conditions, imaging; and “Osteoarthritis” for the degenerative differential.
- ▶ **CMDT 2026** — “Rheumatologic, Immunologic, & Allergic Disorders” (Yazdany et al.) — diagnostic value of the joint pattern (Table 23-1), joint-fluid examination (Tables 23-2/23-3), and the differential diagnosis of polyarthritis/RA-mimics (viral, hepatitis C, gout, spondyloarthritis, PMR, GPA, paraneoplastic).

Coverage note: The corpus covers the *approach to* and *differential of* polyarthritis thoroughly within these two chapters; disease-specific classification criteria (e.g., 2010 ACR/EULAR RA criteria, Jones criteria) are detailed in their dedicated chapters and are summarised here only as far as the cited sources support.

Psoriatic arthritis

Asked in: Paper III Dec 2023 — RGUHS MD General Medicine

Definition / Introduction — Psoriatic arthritis (PsA) is a chronic, immune-mediated inflammatory arthritis in the spondyloarthritis spectrum, associated with cutaneous and/or nail psoriasis and usually

negative rheumatoid factor. It may involve peripheral joints, sacroiliac joints and spine, entheses, tendon sheaths, and whole digits, producing dactylitis. Untreated disease can cause progressive erosive damage, deformity, disability, reduced quality of life, and increased cardiometabolic morbidity.

Etiopathogenesis and epidemiology

- ▶ **Psoriasis is common:** skin psoriasis affects about 2-3% of the population; PsA develops in a substantial minority of patients with psoriasis, with Harrison giving an approximate prevalence of 30% among psoriasis patients and Bologna reporting 5-30% depending on the series.
- ▶ **Temporal relation:** in nearly 80% of PsA patients, psoriasis precedes musculoskeletal disease; in about 10%, arthritis may precede skin disease, and simultaneous onset also occurs. Hence, hidden psoriasis must be actively sought.
- ▶ **Age:** PsA most often appears in adult life, classically around 30-50 years, while psoriatic disease also has peaks in early and later adulthood.
- ▶ **Genetic and immune basis:** PsA is part of the spondyloarthritis family, with HLA-B27 especially relevant in axial PsA; Harrison reports HLA-B27 in about 20% of all PsA and about 50% of axial PsA.
- ▶ **Cytokine axis:** psoriatic disease is driven predominantly by IL-17 and IL-23 pathways, with contributions from TNF-alpha, IL-1 beta, and IL-6. This explains the efficacy of TNF, IL-17, IL-12/23, and IL-23 inhibitors.
- ▶ **Nail-joint link:** nail disease is a strong predictor of PsA because the nail unit is anatomically linked to the distal interphalangeal (DIP) joint enthesis. Nail involvement is much more frequent in PsA than psoriasis without arthritis.
- ▶ **Comorbid disease burden:** depression, obesity, metabolic syndrome, diabetes mellitus, fatty liver disease, hypertension, and cardiovascular disease are common and must be screened for.

Clinical phenotypes

Phenotype	High-yield clinical features
Asymmetric oligoarthritis	Often early PsA; fewer than 4 joints; commonly lower limb or small joints of hands/feet; may later become polyarticular and more symmetric.
Symmetric polyarthritis	Resembles rheumatoid arthritis but usually seronegative, with psoriasis/nail disease, DIP disease, dactylitis, enthesitis, or axial features.
DIP-predominant arthritis	Classic clue; DIP pain, swelling, stiffness, and deformity with nail pitting, onycholysis, subungual hyperkeratosis, or oil-drop change.
Spondylitis / sacroiliitis	Inflammatory back or neck pain, morning stiffness, improvement with activity; sacroiliitis may be

Phenotype	High-yield clinical features
	unilateral/asymmetric and syndesmophytes are often bulky, asymmetric, and nonmarginal.
Arthritis mutilans	Severe destructive form with osteolysis, telescoping digits, acro-osteolysis, and major deformity; uncommon but exam-important.

- ▶ Phenotypes overlap; do not force a patient into only one group. Modern descriptions add **enthesitis**, **dactylitis**, and **tenosynovitis** as core musculoskeletal domains.
- ▶ **Dactylitis** is diffuse inflammatory swelling of a whole finger or toe, due to involvement of joints, tendons, bone, and soft tissue; persistent dactylitis predicts structural damage.
- ▶ **Enthesitis** commonly affects the Achilles tendon insertion, plantar fascia, quadriceps insertion on the patella, patellar tendon insertion on the tibia, medial/lateral epicondyles, pelvic rim, spinous processes, and intercostal muscle insertions.

Cutaneous, nail and extra-articular disease

- ▶ **Skin psoriasis**: sharply demarcated erythematous plaques with silvery micaceous scale, commonly on scalp, elbows, knees, gluteal cleft, palms/soles, and intertriginous sites. Koebner phenomenon, infection, stress, lithium, beta blockers, antimalarials, and systemic glucocorticoid withdrawal may exacerbate psoriasis.
- ▶ **Hidden psoriasis**: inspect scalp, umbilicus, gluteal/natal cleft, genitals, inframammary areas, palms/soles, and external auditory canal in all seronegative arthritis.
- ▶ **Nail matrix disease**: pitting, leukonychia, crumbling, and red spots in the lunula.
- ▶ **Nail bed disease**: onycholysis, subungual hyperkeratosis, oil-drop/salmon patch change, and splinter hemorrhages.
- ▶ **Eye disease**: uveitis occurs in about 5% of PsA; acute anterior uveitis is typical, but posterior or bilateral disease may occur.
- ▶ **Gut and mucosal disease**: Crohn disease or ulcerative colitis may coexist; painful mouth ulcers and rarely urethritis can occur.
- ▶ **Systemic risk**: patients with psoriasis/PsA have increased cardiovascular risk, endothelial dysfunction, subclinical atherosclerosis, depression, and suicidality; obesity worsens disease activity and treatment response.

Diagnosis and classification

- ▶ The diagnosis is primarily **clinical**: inflammatory musculoskeletal disease plus psoriasis, nail disease, family history, typical pattern, dactylitis, enthesitis, or characteristic imaging.
- ▶ **CASPAR criteria**: inflammatory articular disease involving joint, spine, or enthesitis plus ≥ 3 points:

CASPAR item	Points
Current psoriasis diagnosed by rheumatologist/dermatologist	2
Personal history of psoriasis	1
Family history of psoriasis in first- or second-degree relative	1
Typical psoriatic nail dystrophy: pitting, onycholysis, hyperkeratosis	1
Negative rheumatoid factor	1
Current dactylitis or past dactylitis recorded by a rheumatologist	1
Juxta-articular new bone formation on hand/foot radiograph, excluding osteophytes	1

- ▶ CASPAR is a classification tool with high specificity and sensitivity, useful in exams and studies; bedside diagnosis still rests on pattern recognition and exclusion of mimics.
- ▶ **Laboratory tests are supportive, not diagnostic:** ESR/CRP are elevated in only about 50% despite active disease; high ESR/CRP predicts more severe disease and damage.
- ▶ RF is usually negative; low-titer RF or anti-CCP can occur in fewer than 10%, so seropositivity does not completely exclude overlap or coexisting RA.
- ▶ If PsA presents as monoarthritis, perform **synovial fluid analysis** to exclude septic arthritis, gout, and CPPD. Inflammatory fluid with WBC >2000/mcL, no crystals, and negative Gram stain/culture supports inflammatory arthritis in the right clinical setting.

Investigations and imaging

- ▶ **Baseline assessment:** tender/swollen joint count, dactylitis count, enthesitis examination, nail count, psoriasis body surface area, axial symptoms, function, pain score, ESR/CRP, CBC, renal and liver function, and cardiometabolic risk profile.
- ▶ **Disease activity tools:** DAPSA and Minimal Disease Activity are commonly used; skin burden can be estimated by palms, with one patient palm approximating 1% body surface area.
- ▶ **Plain radiographs:** obtain hands, feet, pelvis, spine, and symptomatic joints. Early disease may show soft-tissue swelling; periarticular osteopenia is usually absent.
- ▶ **Characteristic X-ray signs:** marginal erosions with **fluffy periosteal new bone**, joint-space narrowing, bony ankylosis, **pencil-in-cup deformity**, ray-distribution damage, osteolysis, and **acro-osteolysis** in arthritis mutilans.
- ▶ **Axial imaging:** pelvic radiograph may show asymmetric or unilateral sacroiliitis; spine films may show bulky, asymmetric, nonmarginal “chunky” syndesmophytes, often involving cervical and lumbar spine.

- ▶ **Ultrasound with Doppler:** useful for synovitis, tenosynovitis, erosions, and differentiating inflammatory enthesitis from mechanical pain or fibromyalgia tender points.
- ▶ **MRI:** detects synovitis, erosions, enthesitis, and active axial inflammation with bone marrow edema on STIR before radiographic change. CT is reserved when MRI is unavailable/contraindicated; bone scan is neither sensitive nor specific.

Management

- ▶ **Aim:** treat to target, with remission or low disease activity, prevention of structural damage, restored function, social participation, and improved quality of life.
- ▶ **Team and domains:** manage with rheumatology plus dermatology; add ophthalmology, gastroenterology, psychiatry, cardiology, endocrinology, dietetics, physiotherapy, and occupational therapy according to domains.
- ▶ **NSAIDs:** useful initially for short-term relief of peripheral arthritis, enthesitis, dactylitis, and axial symptoms; rarely sufficient alone and require monitoring for renal, gastrointestinal, hypertensive, and cardiovascular toxicity.
- ▶ **Local glucocorticoid injections:** useful for active arthritis, enthesitis, or dactylitis. Avoid injections around weight-bearing lower-limb entheses because of tendon rupture risk.
- ▶ **Systemic glucocorticoids:** generally avoid; if unavoidable for acute arthritis flare, use the lowest effective dose for the shortest time because tapering may precipitate pustular psoriasis.
- ▶ **Conventional synthetic DMARDs:** methotrexate, sulfasalazine, or leflunomide should be considered early for active peripheral arthritis, enthesitis, or dactylitis. Methotrexate is preferred when clinically relevant psoriasis is present; csDMARDs are not useful for predominant axial disease.
- ▶ **Targeted oral agents:** apremilast may be used for active non-axial musculoskeletal disease or skin disease; JAK inhibitors such as tofacitinib or upadacitinib are options, generally after TNF inhibitor failure and with attention to cardiovascular, malignancy, zoster, and thrombotic risk.
- ▶ **Biologic DMARDs:** TNF inhibitors include etanercept, adalimumab, infliximab, certolizumab, and golimumab; IL-12/23 inhibition includes ustekinumab; IL-17 inhibition includes secukinumab, ixekizumab, and bimekizumab; IL-23 inhibition includes guselkumab and risankizumab.
- ▶ **Domain choice:** for predominant skin disease with musculoskeletal disease, IL-12/23, IL-17, or IL-23 inhibitors are preferred over TNF inhibitors. For axial disease after NSAID failure, use a biologic or JAK inhibitor rather than csDMARD. For active IBD, prefer monoclonal anti-TNF, IL-12/23, IL-23, or JAK inhibitor therapy and avoid IL-17 inhibitors in active IBD. For uveitis, monoclonal anti-TNF therapy is preferred.
- ▶ **Precautions:** screen for latent tuberculosis, hepatitis B, and hepatitis C before biologics or JAK inhibitors. Avoid starting immunosuppression during severe infection. TNF inhibitors may

worsen congestive heart failure or demyelinating disease; IL-17 inhibitors can cause mucocutaneous Candida and worsen active IBD.

- ▶ **Skin/nail therapy:** topical glucocorticoids, vitamin D analogues, topical retinoids, PUVA/UVB, and cyclosporine can help skin and nail disease but have limited musculoskeletal efficacy. Oral glucocorticoids should not be used for psoriasis.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Hand/foot PsA diagram:** label DIP arthritis, PIP involvement, dactylitis/sausage digit, nail pitting, onycholysis, fluffy periosteal new bone, pencil-in-cup deformity, ankylosis, and acro-osteolysis.
- ▶ **Domain-based management wheel:** label peripheral arthritis, axial disease, enthesitis, dactylitis, skin psoriasis, nail disease, IBD, and uveitis; place NSAIDs, csDMARDs, biologic DMARDs, and targeted synthetic DMARDs around the wheel.

Clinical / Diagnostic significance

- ▶ In any **seronegative inflammatory arthritis**, look for psoriasis in hidden sites and examine nails; a single patch in scalp, umbilicus, or gluteal cleft can clinch the diagnosis.
- ▶ Distinguish PsA from **RA** by DIP disease, nail dystrophy, dactylitis, enthesitis, asymmetric/ray distribution, absence of nodules/RF, and axial disease.
- ▶ Distinguish PsA from **OA** by inflammatory stiffness, soft-tissue swelling, erosions with new bone, nail disease, dactylitis, and absence of pure osteophyte/Heberden-node pattern.
- ▶ Distinguish PsA monoarthritis from **gout, CPPD, and septic arthritis** by synovial fluid microscopy, Gram stain, and culture; psoriasis increases uric acid turnover, so gout can coexist.
- ▶ Distinguish axial PsA from ankylosing spondylitis by asymmetric sacroiliitis, bulky nonmarginal syndesmophytes, cervical involvement, and prominent peripheral/nail disease.
- ▶ Early diagnosis matters because PsA can produce irreversible erosions, joint lysis, ankylosis, deformity, and functional loss within months in aggressive cases.
- ▶ Cardiovascular prevention is part of PsA care: screen and treat hypertension, diabetes, dyslipidemia, obesity, smoking, fatty liver disease, depression, and suicidality.

High-yield exam pointers

- ▶ PsA = psoriasis/nail disease + seronegative inflammatory arthritis + enthesitis/dactylitis/axial disease.
- ▶ Five classical phenotypes: asymmetric oligoarthritis, symmetric polyarthritis, DIP arthritis, spondylitis, arthritis mutilans.
- ▶ Dactylitis is a severity marker; enthesitis commonly affects Achilles insertion and plantar fascia.

- ▶ Nail findings: pitting, onycholysis, subungual hyperkeratosis, oil-drop change, splinter hemorrhages.
- ▶ CASPAR: inflammatory articular disease plus ≥ 3 points; current psoriasis scores 2.
- ▶ X-ray triad for exams: erosions plus fluffy new bone, pencil-in-cup deformity, asymmetric sacroiliitis/chunky syndesmophytes.
- ▶ ESR/CRP may be normal; RF/anti-CCP are usually negative but low-titer positivity can occur.
- ▶ Treatment is domain-based and treat-to-target; csDMARDs help peripheral disease, not axial disease.
- ▶ Avoid systemic steroids when possible; tapering can precipitate pustular psoriasis.

Raynaud's Phenomenon

Asked in: Paper II Nov 2019 · Paper III May 2019 (2×) — RGUHS MD General Medicine

Definition / Introduction — *Raynaud phenomenon (RP)* is a syndrome of **episodic, reversible digital ischaemia** caused by an exaggerated vasoconstrictor response of digital arteries and cutaneous arterioles to **cold exposure or emotional stress**. It manifests as a sharply-demarcated, often *triphasic* colour change of the digits — **pallor** → **cyanosis** → **rubor**. It is broadly divided into **primary (idiopathic) RP** (no underlying disease) and **secondary RP** (associated with another disorder, most importantly systemic sclerosis). Distinguishing the two is the central clinical task, because secondary RP can progress to ulceration, gangrene and digital loss.

Pathophysiology

- ▶ The final common pathway is **inappropriate vasospasm of digital arteries, precapillary arterioles and cutaneous arteriovenous shunts**, triggered by cold or sympathetic (emotional) stimuli.
- ▶ Three interacting categories of abnormality are recognised:
 - **Neural** — exaggerated sympathetic / **α -adrenergic (α_2) vasoconstrictor** reactivity of digital vessels.
 - **Vascular / endothelial** — endothelial dysfunction with reduced vasodilators (**nitric oxide**, prostacyclin) and excess vasoconstrictors (**endothelin-1**); in secondary RP there is true structural vasculopathy with intimal proliferation.

- **Intravascular** — platelet activation, raised plasma viscosity and impaired fibrinolysis (relevant in blood dyscrasias).
- ▶ In **systemic sclerosis** the digital vessels show a **proliferative obliterative vasculopathy**, so vasospasm is superimposed on fixed structural narrowing — explaining the severity, ischaemic ulcers and autoamputation seen in secondary RP.
- ▶ The therapeutic rationale follows the mechanism: **calcium-channel blockers** / **α-blockers** counter vasoconstriction, **PDE-5 inhibitors and nitrates** augment the NO–cGMP pathway, and **endothelin-receptor antagonists** / **prostacyclins** correct the vasodilator deficit.

Clinical features — the triphasic colour response

- ▶ Classic well-demarcated colour sequence on cold/stress exposure:
 - **Pallor (white)** — *ischaemic phase*; vasospasm of digital arteries.
 - **Cyanosis (blue)** — deoxygenated blood pooling in dilated capillaries and venules; accompanied by cold, numbness or paraesthesia.
 - **Rubor (red)** — on rewarming, *reactive hyperaemia* with throbbing, painful, warm digits.
- ▶ The full triphasic response is typical but **not universal** — some patients have only pallor + cyanosis, others only cyanosis.
- ▶ **Fingers > toes** (toes affected in ~40%); attacks usually begin in one or two fingertips and extend to involve whole/all fingers; the **thumbs are characteristically spared**.
- ▶ Rare sites: **earlobes, tip of nose, tongue, nipple, penis**.
- ▶ Frequent association with **migraine** and **variant (Prinzmetal) angina** from coronary vasospasm — suggesting a shared vasospastic predisposition.
- ▶ Attacks terminate spontaneously or on rewarming; the patient is typically **asymptomatic between attacks**.

Primary versus secondary RP

Feature	Primary RP (Raynaud disease)	Secondary RP
Frequency	>50% of all RP; 2–6% of adults	Less common
Sex / age	Women ≈5×; onset 15–30 / 20–40 yr	Either sex; older onset
Pattern	Symmetric, bilateral, all fingers	May be unilateral / 1–2 digits only
Underlying disease	None (by definition, after exclusion)	Rheumatic/other disease present
Nailfold capillaries	Normal (regular hairpin loops)	Abnormal — dilated/giant loops, dropout

Feature	Primary RP (Raynaud disease)	Secondary RP
ANA / serology	Negative	Often positive
Tissue damage	No pitting, ulcer or gangrene; <1% lose part of a digit	Yes — pitting, ulcers, gangrene, autoamputation
Course	Mild; improves spontaneously in ~15%, progresses in ~30%	Depends on underlying disease

- *LeRoy–Medsger criteria* for **primary RP**: symmetric attacks, **no necrosis/ulceration**, no identifiable secondary cause, **normal nailfold capillaries**, negative ANA and normal ESR.

Causes of secondary RP (Harrison/CMDT classification)

Category	Examples
Connective-tissue / rheumatic	Systemic sclerosis (80–90%; presenting symptom in 30%), SLE (~20%), dermatomyositis/polymyositis (~30%), rheumatoid arthritis, MCTD, Sjögren syndrome
Arterial occlusive	Atherosclerosis (common in men >50 yr), thromboangiitis obliterans/Buerger (young male smokers), acute arterial occlusion/embolism, thoracic outlet syndrome
Pulmonary	Pulmonary (arterial) hypertension
Neurological	Carpal tunnel syndrome, complex regional pain syndrome, intervertebral disc disease, syringomyelia, spinal cord tumour, stroke, poliomyelitis
Blood dyscrasias	Cold agglutinins , cryoglobulinaemia , cryofibrinogenaemia , myeloproliferative disorders, lymphoplasmacytic lymphoma (Waldenström macroglobulinaemia)
Trauma / occupational	Vibration injury (chain-saw, jackhammer), hammer-hand syndrome , electric shock, frostbite, typing, piano playing
Drugs & toxins	Ergot derivatives , methysergide , β-blockers , sympathomimetics, serotonin agonists (sumatriptan), cocaine, nicotine/cafeine; chemotherapy — bleomycin , vinblastine , cisplatin , gemcitabine ; vinyl chloride, epoxy resins
Endocrine / misc.	Hypothyroidism, pheochromocytoma, migraine

Diagnostic approach

- ▶ **Clinical diagnosis** — based on the characteristic colour changes; the key step is to screen for a secondary cause.
- ▶ **Bedside examination** is often normal; radial, ulnar and pedal pulses are normal in primary RP (diminished/absent pulses point to occlusive disease/Buerger). Look for **sclerodactyly**, **digital pitting/ulcers**, **skin tightening**, **telangiectasia**, **calcinosis**, **rash**, **synovitis**.
- ▶ **Nailfold capillaroscopy** — the single most useful office test. Place a drop of **grade-B immersion oil** at the cuticle and view with a **dermatoscope or ophthalmoscope set to 40 dioptres**. *Dropout of capillaries with dilatation of remaining loops (giant capillaries)* indicates **secondary RP**, most often systemic sclerosis. The finding is **highly specific but of low sensitivity**.
- ▶ **Serology** — ANA, anti-centromere (limited SSc/CREST), anti-Scl-70 (topoisomerase I, diffuse SSc), anti-RNA polymerase III, ENA panel; complement, cryoglobulins, cold agglutinins as indicated.
- ▶ **Other** — ESR/CRP, FBC (myeloproliferative/hyperviscosity), TFTs; nerve-conduction studies for carpal tunnel; vascular imaging only if fixed occlusive disease is suspected. **Digital angiography is not indicated** for diagnosis of primary RP.

Management

- ▶ **General / non-pharmacological (first-line, often sufficient in primary RP):**
 - **Keep the whole body warm** — gloves/mittens *plus* warm clothing for trunk, head and feet to prevent cold-induced reflex vasoconstriction.
 - **Stop smoking**; protect hands from trauma; treat fissures with emollients; **avoid precipitating drugs** (β -blockers, ergot, sympathomimetic decongestants/amphetamines).
- ▶ **Pharmacological (reserve for severe symptoms or tissue injury):**
 - **Dihydropyridine calcium-channel blockers = first-line** — slow-release **nifedipine 30–120 mg/day**, **amlodipine 5–20 mg/day** (also felodipine, isradipine, nisoldipine); more effective than verapamil, nicardipine and **diltiazem** (less effective). CCBs work better in **primary** than secondary RP.
 - **α 1-adrenergic antagonists** — prazosin (also doxazosin, terazosin).
 - **PDE-5 inhibitors** — **sildenafil, tadalafil, vardenafil** — useful in **secondary RP** (e.g. systemic sclerosis), added to or substituted for CCBs.
 - **Topical nitrates** (nitroglycerin); ARBs; SSRIs (**fluoxetine**) as add-ons.
 - **Endothelin-receptor antagonist bosentan** — prevents/heals **digital ulcers** in systemic sclerosis.
 - **IV prostacyclin / analogues** — **epoprostenol, iloprost, treprostinil** — for critical digital ischaemia / threatened digital loss.

- ▶ **Procedural** — **digital (peripheral) sympathectomy** for progressive ischaemia refractory to medical therapy. **Botulinum toxin** injection has shown inconsistent/negative results in controlled trials.
- ▶ **Admit** patients with **critical digital ischaemia** (severe pain, demarcation) for intensive therapy; refer secondary RP to a rheumatologist.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Triphasic colour change of a digit** — three finger panels in sequence with labels: *Phase 1 — Pallor (white): digital artery vasospasm / ischaemia; Phase 2 — Cyanosis (blue): deoxygenated blood in dilated capillaries-venules, numbness; Phase 3 — Rubor (red): reactive hyperaemia on rewarming, throbbing pain.* Add trigger arrow “Cold / emotional stress”.
- ▶ **Nailfold capillaroscopy comparison** — two boxes: *Primary RP — regular, evenly-spaced hairpin capillary loops (normal) vs Secondary RP (scleroderma pattern) — dilated/giant loops, haemorrhages and capillary dropout (avascular areas).*

Clinical / Diagnostic significance

- ▶ RP is the **commonest and earliest manifestation of systemic sclerosis** (presenting symptom in 30%, may precede skin disease by years) and is a core feature of the **CREST syndrome** (*Calcinosis, Raynaud, oEsophageal dysmotility, Sclerodactyly, Telangiectasia*) of limited cutaneous SSc.
- ▶ The triad of **RP + abnormal nailfold capillaroscopy + a specific autoantibody** (anti-centromere or anti-Scl-70) strongly predicts evolution to a definite connective-tissue disease and warrants surveillance for **interstitial lung disease and pulmonary hypertension**.
- ▶ **Red flags for secondary RP**: onset >40 yr or in a male, **asymmetric/unilateral** attacks, digital pitting/ulcers/gangrene, abnormal nailfolds, positive ANA, systemic features.
- ▶ Recognising RP as a marker of **vasospasm** also flags associations with **migraine** and **coronary (variant) angina**.

High-yield exam pointers

- ▶ **Triphasic colour change** = white → blue → red (pallor–cyanosis–rubor); thumbs typically **spared**.
- ▶ **Primary RP**: >50% of cases, young women, **bilateral/symmetric, normal nailfolds, negative ANA, no tissue loss** (<1% lose a digit).
- ▶ **Secondary RP**: **systemic sclerosis (80–90%)** is the prototype; also SLE (~20%), DM/PM (~30%), RA, MCTD.
- ▶ **Nailfold capillaroscopy** (immersion oil + ophthalmoscope at 40 D): **dilated loops + dropout = secondary RP**; highly specific, low sensitivity.

- ▶ **First-line drug** = dihydropyridine CCB (nifedipine/amlodipine); CCBs work better in primary RP.
- ▶ **PDE-5 inhibitors, bosentan and IV prostacyclins (iloprost)** are reserved for **secondary RP with digital ulcers / critical ischaemia**.
- ▶ **LeRoy–Medsgers criteria** define primary RP (symmetric, no necrosis, normal capillaries, ANA negative, normal ESR).
- ▶ **Buerger disease and acrocyanosis** are key differentials — Buerger: male smokers, absent pulses, 1–2 digits; acrocyanosis: **persistent (not episodic)**, diffuse cyanosis, no pallor phase.

SOURCE & COVERAGE

- ▶ **Harrison’s Principles of Internal Medicine, 22e** — “*Arterial Diseases of the Extremities*” (Raynaud phenomenon: classification, primary vs secondary, clinical features, treatment) and “*Systemic Sclerosis (Scleroderma) and Related Disorders*” (secondary RP, scleroderma vasculopathy, nailfold/acro-osteolysis).
- ▶ **CMDT 2026** — “*Raynaud Phenomenon*” and “*Systemic Sclerosis*” (Rheumatologic, Immunologic & Allergic Disorders) — essentials of diagnosis, Table 23–9 causes of secondary RP, nailfold capillaroscopy technique, drug regimens and doses.
- ▶ **Coverage note:** The named **LeRoy–Medsgers criteria** for primary RP and the explicit **neural/vascular/intravascular** mechanistic triad are universally-accepted standard internal medicine but are not stated verbatim in the cited corpus; all disease associations, percentages, drugs and doses given here are taken directly from Harrison 22e and CMDT 2026.

Reactive arthritis

Asked in: Paper III 09/2025 · Paper III Jul 2021 · Paper III Nov 2019 (3×) — RGUHS MD General Medicine

Definition / Introduction

Reactive arthritis (ReA) is a sterile, immune-mediated inflammatory arthritis that develops *after* a urogenital or gastrointestinal infection with well-defined triggering microorganisms that are **not cultivable from the affected joints**. It belongs to the **peripheral spondyloarthritis (pSpA)** family, is strongly linked to **HLA-B27**, and classically presents as an asymmetric lower-limb oligoarthritis accompanied by extra-articular (ocular, mucocutaneous, genitourinary) features. The historical triad of arthritis, conjunctivitis and urethritis was formerly termed *Reiter syndrome*, an eponym now largely abandoned.

Place within spondyloarthritis & classification

- ▶ **Spondyloarthritis (SpA)** is a family of immune-mediated arthritides sharing axial/peripheral joint disease, enthesitis, dactylitis, uveitis, psoriasis, IBD, absence of rheumatoid factor/nodules, familial clustering and **HLA-B27** association (Moll & Wright, 1974).
- ▶ The **2009 ASAS** classification splits SpA into **axial SpA** (radiographic = ankylosing spondylitis, and non-radiographic) and **peripheral SpA**.
- ▶ **ReA is a peripheral SpA**, alongside **psoriatic arthritis**, **IBD-associated arthritis** and **undifferentiated pSpA**. Its hallmark features per the SpA spectrum table are: *urethritis, history of preceding Salmonella/Shigella/Yersinia/Campylobacter/Chlamydia infection, mucosal ulcers, conjunctivitis and keratoderma blennorrhagica*.
- ▶ **Nomenclature discipline (Harrison)**: the term ReA is *restricted* to acute SpA triggered by a genitourinary or GI infection and related to HLA-B27. Arthritides following acute rheumatic fever, meningococcus, *Mycoplasma genitalium*, *Ureaplasma urealyticum*, *Chlamydia pneumoniae*, beta-haemolytic streptococci, some live vaccines and COVID do **not** fit the SpA construct and are termed “**post-infectious arthritides**”, not ReA.

Aetiopathogenesis

Component	Detail
GI (dysenteric) triggers	<i>Salmonella</i> , <i>Shigella</i> , <i>Yersinia enterocolitica</i> , <i>Campylobacter</i> — develops 1–4 weeks after enteritis
Urogenital (venereal) trigger	<i>Chlamydia trachomatis</i> ($\pm$ <i>Ureaplasma urealyticum</i>)
Genetic	HLA-B27 present in 50–80% of patients (Harrison); CMDT: ~80% in White, 50–60% in Black patients
Latent interval	1 day to 4 weeks between infecting episode and arthritis
Joint fluid	Culture-negative (sterile) — distinguishes from septic arthritis

- ▶ **Mechanism**: an antecedent mucosal infection at the gut or urogenital tract, in a genetically predisposed (HLA-B27⁺) host, drives a **barrier-integrity loss** allowing translocation of bacteria/microbial peptides that incite immune activation at joints and entheses. Proposed HLA-B27 mechanisms include the “**arthritogenic peptide**” theory (HLA-B27 presents microbial peptides to CD8⁺ T cells $\rightarrow$ molecular mimicry), **HLA-B27 homodimer** interaction with KIR3DL2 driving IL-17, and unfolded-protein-response-linked IL-23 release. The downstream effector axis is **TNF- α** and the **IL-23/IL-17 pathway**.
- ▶ **HLA-B27 may promote intracellular survival/persistence** of the triggering organism (e.g., *Chlamydia*) in macrophages, providing a route to chronicity.
- ▶ **Epidemiology**: young adults, male predominance for venereal-triggered disease; overall incidence $\approx$ **3.4 cases per 100,000 person-years**; about **2.6%** of patients develop ReA after an

enteric infection (Campylobacter/Salmonella/Shigella/Yersinia). Prevalence parallels the **North–South gradient of HLA-B27** (classic Scandinavian post-dysentery outbreaks, now declining with improved hygiene).

Clinical features

- ▶ **Inflammatory musculoskeletal disease is essential for diagnosis.** Typical pattern: **asymmetric, oligoarticular** (≤ 4 joints) inflammatory arthritis of **large weight-bearing lower-limb joints** (knee, ankle).
- ▶ **Enthesitis** (Achilles tendinitis, plantar fasciitis — heel pain), **tendonitis, bursitis, dactylitis** (“sausage digit”), **inflammatory back pain** and **sacroiliitis**.

System	Manifestation
Joints	Asymmetric LL oligoarthritis; enthesitis; dactylitis; sacroiliitis/spondylitis ($\geq 20\%$, esp. after recurrences)
Ocular	Conjunctivitis (mild, early); acute anterior uveitis (later, more significant, HLA-B27 ⁺)
Genitourinary	Urethritis (sterile); circinate balanitis
Mucocutaneous	Keratoderma blennorrhagica (palms/soles, indistinguishable from pustular psoriasis); painless oral ulcers/stomatitis ; nail changes mimicking psoriasis; <i>erythema nodosum</i>
Cardiac	Carditis and aortic regurgitation (uncommon)
Systemic	Fever, weight loss common at onset

- ▶ **Classic triad** (“can’t see, can’t pee, can’t bend the knee”): **arthritis + conjunctivitis + urethritis** — the full triad is present in a minority.

Investigations / Diagnosis

- ▶ **Clinical diagnosis** — recognition of the pattern plus identification of an **antecedent infection**, and **exclusion** of other causes (notably septic/gonococcal arthritis and other post-infectious arthritides).
- ▶ **Identify the trigger: stool cultures** (Salmonella, Shigella, Campylobacter, Yersinia) — often negative by the time arthritis appears, as GI symptoms have resolved; **molecular testing / NAAT for Chlamydia trachomatis*** — all patients should be offered Chlamydia screening*.
- ▶ **HLA-B27** — supports diagnosis and predicts chronicity/uveitis; not diagnostic alone.
- ▶ **Inflammatory markers:** ESR/CRP raised (non-specific). **RF and anti-CCP negative** (seronegative).
- ▶ **Synovial fluid:** inflammatory but **sterile (culture-negative)** — crucial to exclude septic arthritis.

- ▶ **Imaging:** plain films may show enthesophytes, “fluffy” periostitis, sacroiliitis in chronic/recurrent disease; MRI for early sacroiliitis/enthesitis.
- ▶ Serology for enteric pathogens is used mainly in **epidemiological studies** (low yield in routine practice).

Differential diagnosis

Mimic	Discriminating feature
Gonococcal (disseminated GC) arthritis	Marked improvement within 24–48 h of antibiotics; positive cultures/NAAT; tenosynovitis, pustular skin lesions
Septic (non-gonococcal) arthritis	Monoarticular, synovial WBC often >50,000/μL, positive Gram stain/culture
Psoriatic arthritis	Pre-existing psoriasis; keratoderma is histologically identical to pustular psoriasis
Ankylosing spondylitis / axSpA	Predominant axial disease, no antecedent infection
Rheumatoid arthritis	Symmetric small-joint polyarthritis, RF/anti-CCP positive
Behçet disease	Painful oral/genital ulcers (ReA ulcers are painless), ocular & joint overlap
Acute rheumatic fever / crystal arthritis	Migratory; ASO/streptococcal evidence; crystals on polarised microscopy

Management / Treatment

- ▶ **No formal ReA treatment guidelines exist;** management mirrors that of **peripheral SpA**.
- ▶ **Acute arthritis (first line):** NSAIDs at the highest tolerable dose are the mainstay. **Intra-articular glucocorticoids** for mono-/oligoarthritis; **short-term low-dose systemic glucocorticoids** for polyarticular involvement.
- ▶ **Antibiotics: not used routinely.** Treating an active non-gonococcal STI reduces the chance of ReA developing. For **chronic Chlamydia-induced ReA, one RCT showed a 6-month course of rifampin (300 mg BD) plus either doxycycline (100 mg BD) or azithromycin outperformed placebo* — not replicated, so *long-term antibiotics are not** recommended generally.
- ▶ **Chronic ReA (>6 months / NSAID-refractory):** conventional DMARDs — **sulfasalazine (1 g BD, up to 3 g/day) or methotrexate (up to 25 mg/week)**; if refractory, **TNF inhibitors** (or anti-IL-17 biologics), as used across the other spondyloarthropathies.
- ▶ **Course/prognosis:** often **self-limiting**, resolving over weeks to months; recurrences are common. **HLA-B27 positivity predicts evolution to chronicity**, recurrent disease and sacroiliitis/AS, sometimes with permanent articular destruction.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ “Clinical features of reactive arthritis” – stick-figure schematic with labels: *Acute anterior uveitis / conjunctivitis* (eye), *painless oral ulcers* (mouth), *urethritis + circinate balanitis* (genitalia), *keratoderma blennorrhagica* (soles), *asymmetric oligoarthritis of knee & ankle* (lower limbs), *dactylitis* (“sausage digit”), *enthesitis – Achilles/plantar fascia* (heel), *sacroiliitis* (pelvis).
- ▶ **Pathogenesis flow diagram:** *Triggering infection (GI: Salmonella/Shigella/Yersinia/Campylobacter OR GU: Chlamydia) → Barrier-integrity loss / antigen translocation → HLA-B27⁺ host (arthritogenic peptide → CD8⁺ T cell; TNF-α & IL-23/IL-17 axis) → Sterile reactive synovitis + enthesitis (1 day–4 weeks later).*

Clinical / Diagnostic significance

- ▶ Always exclude septic and gonococcal arthritis first by synovial fluid analysis and culture — the single most important practical step in any acute mono-/oligoarthritis.
- ▶ A sterile arthritis + recent diarrhoea or urethritis in a young adult should trigger HLA-B27 testing and *Chlamydia* screening of the patient (and partner).
- ▶ Anterior uveitis in an HLA-B27⁺ patient is an ophthalmic emergency requiring urgent slit-lamp review; it may recur and threaten vision.
- ▶ ReA can be the **presenting illness of underlying HIV** and may run a more severe, treatment-resistant course in that setting — screen when clinically appropriate.

High-yield exam pointers

- ▶ **Triggers:** GI — *Salmonella, Shigella, Yersinia, Campylobacter*; GU — *Chlamydia trachomatis*. Latent interval 1 day–4 weeks.
- ▶ HLA-B27 positive in 50–80%; predicts chronicity, sacroiliitis and uveitis.
- ▶ Joint fluid is **STERILE (culture-negative)** — defining feature vs septic arthritis.
- ▶ **Classic triad** = arthritis + conjunctivitis + urethritis (“can’t see, can’t pee, can’t bend the knee”); old eponym *Reiter syndrome*.
- ▶ Skin/mucosa: **keratoderma blennorrhagica** (≈ pustular psoriasis), **circinate balanitis**, **painless oral ulcers**.
- ▶ **RF/anti-CCP negative** (seronegative spondyloarthritis); part of **peripheral SpA**.
- ▶ **Treatment:** NSAIDs first → intra-articular/short systemic steroids → **sulfasalazine/methotrexate** → TNFi; antibiotics *not* routine.
- ▶ ≥20% develop **sacroiliitis/AS** with recurrence; mostly self-limiting but may become chronic.
- ▶ **DDx pearl:** gonococcal arthritis improves dramatically within 24–48 h of antibiotics; Behçet ulcers are **painful** whereas ReA ulcers are **painless**.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Spondyloarthritis” (Reactive Arthritis section: clinical features, triggers, HLA-B27 association/pathogenesis, diagnosis and treatment; SpA spectrum/ASAS classification).
- ▶ **CMDT 2026** — “Rheumatologic, Immunologic, & Allergic Disorders” (Reactive Arthritis: Essentials of Diagnosis, clinical findings, differential diagnosis, current treatment including the rifampin-plus-doxycycline/azithromycin regimen and biologics).

Coverage note: The corpus does not use the eponym *Reiter syndrome* or the “can’t see, can’t pee, can’t bend the knee” mnemonic — these are included as universally accepted standard internal-medicine teaching for completeness; all organism lists, doses, percentages and criteria above are taken verbatim from Harrison 22e and CMDT 2026.

Seronegative spondylarthritis: Define, causes and tabulate the differences between the different types

Asked in: Paper III 15 Apr 2026 — RGUHS MD General Medicine

Definition / Introduction — *Seronegative spondylarthritis* (*spondyloarthritis*, *SpA*) is a family of immune-mediated inflammatory arthritides that share overlapping clinical, genetic and pathological features and are united by the **absence of rheumatoid factor (RF) and anti-CCP antibodies** (“seronegative”) and by a striking association with **HLA-B27**. First delineated by *Moll and Wright (1974)* as distinct from rheumatoid arthritis (RA), the group is characterised by **sacroiliitis/inflammatory spinal lesions, asymmetric large-joint lower-limb oligoarthritis, enthesitis, dactylitis (“sausage digit”)**, and extra-articular features (acute anterior uveitis, psoriasis, inflammatory bowel disease [IBD]) with a familial tendency. Cumulative prevalence is ~2–3% — commoner than RA.

Concept of “seronegative” and the SpA spectrum

- ▶ “**Seronegative**” historically distinguished these arthritides from “seropositive” RA: RF and anti-CCP are *negative*, and rheumatoid nodules are absent.
- ▶ The 2009 ASAS (Assessment of SpondyloArthritis international Society) framework divides SpA by *dominant* clinical pattern into **axial SpA (axSpA)** and **peripheral SpA (pSpA)** — “axial” involvement is implied by the name but is *not* mandatory.
- ▶ Distinguishing musculoskeletal signature: **asymmetric, mono-/oligoarticular (≤4 joints) inflammatory arthritis of large lower-limb joints (esp. knee) with enthesitis, tendonitis and dactylitis** — contrasting with the symmetric polyarticular MCP/PIP involvement of RA.

Spondyloarthritis (SpA)	Conditions included
Axial SpA (axSpA)	Radiographic axSpA = Ankylosing spondylitis (AS); Non-radiographic axSpA (nr-axSpA)
Peripheral SpA (pSpA)	Psoriatic arthritis (PsA); Reactive arthritis (ReA); IBD-associated arthritis; Undifferentiated pSpA
Sometimes included under pSpA	SAPHO syndrome; acne-associated arthritis; hidradenitis suppurativa-associated arthritis

Causes — aetiology and pathogenesis

SpA is a prototypic immune-mediated disease that uniquely **couple inflammation to structural damage** — inflammatory bone loss coexists with *pathological new bone formation* (syndesmophytes, ankylosis → “bamboo spine”).

► Genetic susceptibility (strongest):

- **HLA-B27** — an MHC class I allele, *the* major genetic risk factor; present in 85–90% of AS but only ~5–8% of healthy Caucasians. Risk of axSpA is ~5% in B27-positive subjects, rising to ~20% in B27-positive first-degree relatives of patients.
- Pathogenic allotypes (e.g. *HLA-B2704, B2705) *confer risk*, whereas HLA-B2706 and B2709* do not — implicating specific peptide presentation.
- Non-MHC genes: ERAP1 (peptide-trimming enzyme; epistasis with HLA-B27), IL-23R polymorphisms (shared across SpA), and HLA-Cw6 in PsA.

► Proposed HLA-B27 mechanisms: (1) *arthritogenic peptide* theory — B27 presents microbial peptides to CD8+ T cells with molecular mimicry; (2) **HLA-B27 homodimer** formation engaging KIR3DL2 on T/NK cells → IL-17; (3) misfolding → **unfolded protein response / autophagy** → IL-23.

► Environmental / triggering factors in genetically predisposed hosts:

- **Gut barrier loss and intestinal dysbiosis** — germ-free HLA-B27 transgenic rats fail to develop disease; subclinical gut inflammation is seen in up to 50% of new-onset SpA.
- **Antecedent infection (ReA)**: enteric *Salmonella*, *Shigella*, *Yersinia*, *Campylobacter* or urogenital *Chlamydia trachomatis*.
- **Mechanical stress** at entheses → microdamage, immune activation and aberrant repair (new bone formation).
- **Effector cytokine hubs**: TNF- α (common to all domains) and the IL-23/IL-17 axis ($\gamma\delta$ T cells, Tc17/Th17, ILC3 at entheses) drive osteoproliferation via prostaglandin E2, IL-17A/F, IL-22, BMP and Wnt pathways — the rationale for biologic therapy.

Tabulated differences between the types

Feature	Ankylosing spondylitis (r-axSpA)	Psoriatic arthritis (PsA)	Reactive arthritis (ReA)	IBD-associated arthritis
Peak onset / sex	2nd–3rd decade, <45 y; M:F 2:1	Any age; $\approx$ M = F	Young men predominate	Any age
HLA-B27	85–90%	~20% overall ($\approx$ 50% if axial/spondylitic)	50–80%	~50% <i>when sacroiliitis present</i> (B27 not a risk factor for IBD itself)
Trigger / association	None; familial, B27	Cutaneous & nail psoriasis	GI (<i>Salmonella/Shigella/Yersinia/Campylobacter</i>) or GU (<i>Chlamydia</i>) infection, 1 day–4 weeks earlier	Crohn's disease / ulcerative colitis
Sacroiliitis	Bilateral, symmetric	Often asymmetric / unilateral , may have spondylitis without sacroiliitis	Asymmetric / unilateral	Bilateral, symmetric (indistinguishable from AS)
Syndesmophytes	Thin, marginal, vertical, symmetric	Chunky, non-marginal , asymmetric	Coarse, non-marginal, asymmetric	As in AS
Peripheral arthritis	~30–40%; asymmetric oligoarthritis, lower limb; hips (root joint)	Oligoarticular $\rightarrow$ polyarticular; DIP disease; arthritis mutilans	Asymmetric oligoarthritis, lower limbs	Asymmetric oligoarthritis of large joints; may parallel or run independent of bowel activity
Enthesitis / dactylitis	Enthesitis common; dactylitis rare	Both common; dactylitis a <i>severity marker</i>	Both common	Variable
Skin / mucosa	Psoriasis in ~10%	Psoriasis (definitional); nail disease ~90%	Keratoderma blennorrhagica, circinate balanitis, oral ulcers	Mucosal/IBD activity ($\pm$ erythema nodosum)

Feature	Ankylosing spondylitis (r-axSpA)	Psoriatic arthritis (PsA)	Reactive arthritis (ReA)	IBD-associated arthritis
Eye	Acute anterior uveitis ~40% (unilateral, episodic)	Uveitis ~5% (may be posterior/bilateral)	Conjunctivitis (early) + anterior uveitis	Anterior uveitis
Hallmark / eponym	“Bamboo spine”; Romanus (shiny-corner) & Andersson lesions	“Pencil-in-cup” deformity; “fluffy” periosteal new bone	<i>Reiter triad</i> = arthritis + urethritis + conjunctivitis	Gut-joint axis; arthritis may pre-date IBD

Classification criteria worth knowing

- **Modified New York criteria for AS** — *definite AS* = ≥ 1 clinical + 1 radiographic criterion:

Clinical criteria	Radiographic criterion
Low back pain >3 months, improved by exercise, not by rest	Bilateral grade ≥ 2 sacroiliitis, OR
Limited lumbar motion (frontal & lateral planes)	Unilateral/bilateral grade 3–4 sacroiliitis
Reduced chest expansion	(Sacroiliitis graded 0–4: 0 normal $\rightarrow$ 4 total ankylosis)

- **CASPAR criteria (PsA)**: inflammatory articular disease *plus* ≥ 3 points from — current psoriasis (2) / personal/family history (1); psoriatic nail dystrophy; RF negative; dactylitis; juxta-articular new bone on radiograph (each 1). Specificity 98.7%, sensitivity 91.4%.
- **ASAS criteria for peripheral SpA**: arthritis or enthesitis or dactylitis *plus* ≥ 1 of (psoriasis, IBD, preceding infection, HLA-B27, uveitis, sacroiliitis on imaging) *or* ≥ 2 of the remaining SpA features.
- **Inflammatory back pain** (vs mechanical): insidious onset <45 y, >3 months, morning stiffness >30 min, night pain (second half), improves with exercise/not rest, good NSAID response.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- **Spectrum of SpA tree** — *Root box*: “Seronegative Spondyloarthritis (RF/anti-CCP negative, HLA-B27 linked)”. *Branch 1* — **Axial SpA**: radiographic axSpA (= Ankylosing spondylitis) and non-radiographic axSpA. *Branch 2* — **Peripheral SpA**: Psoriatic arthritis,

Reactive arthritis, IBD-associated arthritis, Undifferentiated pSpA. Side note: “sometimes included — SAPHO, acne-associated, hidradenitis suppurativa”.

- ▶ **Pelvic/spine radiograph schematic** — label: **bilateral symmetric sacroiliitis, squaring of vertebral bodies, shiny corner (Romanus) sign, marginal vertical syndesmophytes, “bamboo spine”, and (for PsA) “pencil-in-cup” deformity with fluffy periosteal new bone.**

Clinical / Diagnostic significance

- ▶ **Investigations:** RF and anti-CCP *negative*; ESR/CRP raised in only ~30–50% (neither sensitive nor specific). **HLA-B27** supports diagnosis but is not confirmatory (occurs in healthy people). **X-ray pelvis (AP/Ferguson view)** for sacroiliitis; **MRI sacroiliac joints (STIR)** detects early osteitis/bone-marrow oedema before radiographic change; low-dose CT is an emerging alternative.
- ▶ **Differential diagnosis of “sacroiliitis”:** DISH (flowing right-sided thoracic osteophytes, normal SI joints), osteitis condensans ilii (multiparous women), septic sacroiliitis (TB, brucellosis), insufficiency fracture.
- ▶ **Management (treat-to-target → low disease activity/remission):** NSAIDs at full dose first-line for axial disease + physiotherapy and smoking cessation; **csDMARDs (sulfasalazine, methotrexate)** help *peripheral* disease only (ineffective for axial). Escalate to **TNF inhibitors** (etanercept, adalimumab, infliximab, golimumab, certolizumab) or **IL-17 inhibitors** (secukinumab, ixekizumab; bimekizumab), then **JAK inhibitors** (tofacitinib, upadacitinib). Screen for **latent TB, HBV, HCV** before biologics. PsA adds IL-12/23 (ustekinumab), IL-23 (guselkumab, risankizumab), PDE-4 (apremilast), TYK2 (deucravacitinib). **Systemic steroids are ineffective/avoided in axSpA.**
- ▶ **Domain-/comorbidity-tailored choice:** TNF *monoclonal antibodies* preferred for coexistent uveitis or IBD; **IL-17 inhibitors are contraindicated in active IBD**; JAKi reserved post-TNF failure (CV/malignancy black-box warning).

High-yield exam pointers

- ▶ “Seronegative” = RF and anti-CCP **negative, no nodules**; unifying link is **HLA-B27** (strongest in AS, 85–90%).
- ▶ **Moll & Wright (1974)** separated SpA from RA and described **5 PsA patterns**: asymmetric oligoarticular, symmetric polyarticular, DIP-predominant, spondylitis, arthritis mutilans.
- ▶ **Modified New York criteria** define AS; sacroiliitis graded 0–4; **CASPAR** for PsA; **ASAS** criteria for axial & peripheral SpA.

- ▶ **ReA** = *sterile* arthritis 1–4 weeks after enteric/urogenital infection; **Reiter triad** = arthritis + urethritis + conjunctivitis (“can’t see, can’t pee, can’t climb a tree”); keratoderma blennorrhagica + circinate balanitis.
- ▶ **AS sacroiliitis** = **bilateral/symmetric** with **marginal vertical syndesmophytes**; **PsA** = **asymmetric** with **chunky non-marginal syndesmophytes** and “pencil-in-cup”.
- ▶ **Acute anterior uveitis** (unilateral, episodic) is the commonest extra-articular feature of axSpA (~40%).
- ▶ Late complications of AS: vertebral fracture (lower cervical), cauda equina syndrome, aortic regurgitation, AV block, apical pulmonary fibrosis, **IgA nephropathy / AA amyloidosis**.
- ▶ **IL-17 inhibitors are contraindicated in active IBD**; TNF monoclonals preferred when uveitis/IBD coexist.

SOURCE & COVERAGE

- ▶ **Harrison’s Principles of Internal Medicine, 22e** — “Spondyloarthritis” (Deodhar & Elewaut): definition, SpA spectrum, HLA-B27/pathogenesis, modified New York & sacroiliitis grading, CASPAR & ASAS criteria, and individual disease descriptions (AS, PsA, ReA, IBD-associated, undifferentiated pSpA).
- ▶ **CMDT 2026** — “Rheumatologic, Immunologic, & Allergic Disorders” (Axial spondyloarthritis, Psoriatic arthritis, Reactive arthritis, IBD-associated spondyloarthritis): current diagnostic essentials and treatment (NSAIDs, TNFi, IL-17i, JAKi; domain-based PsA therapy).

Sjögren’s syndrome

Asked in: Paper III Jul 2021 — RGUHS MD General Medicine

Definition / Introduction — Sjögren’s syndrome (Sjögren’s disease) is a prototype systemic autoimmune disorder characterised by **lymphocytic infiltration of the exocrine glands** (chiefly lacrimal and salivary) producing **keratoconjunctivitis sicca** (dry eyes) and **xerostomia** (dry mouth), together with profound **B-cell hyperactivity**. It exists as a *primary* disorder or *secondary* to another rheumatic disease (most often rheumatoid arthritis, SLE, limited scleroderma, primary biliary cholangitis, Hashimoto thyroiditis). It is the autoimmune disease with the **highest risk of lymphoma**, making it an ideal model of both autoimmunity and lymphoid malignancy.

Epidemiology and Pathogenesis

- ▶ **Demographics**: middle-aged women predominate — female-to-male ratio **10–20:1** (CMDT quotes ~9:1); peak onset 40–60 years but any age including childhood. Prevalence ~0.5–1%; 5–

20% of patients with other autoimmune diseases express sicca features. *Earlier-onset* disease is more aggressive (more systemic features and autoantibodies).

- ▶ **Core lesion:** activated T lymphocytes dominate early periductal infiltrates; in heavy lesions B-cell populations prevail with formation of **ectopic germinal centres**. Follicular, myeloid and plasmacytoid dendritic cells and macrophages are also present; inflammasome activation correlates with lymphoma risk.
- ▶ **Autoimmune epithelitis** (term coined by *Moutsopoulos*): ductal/acinar epithelial cells are active participants — they (1) express costimulatory molecules and surface **Ro/La autoantigens**, (2) secrete proinflammatory cytokines and lymphocyte-attracting chemokines, (3) express **Toll-like receptors** (TLR) 3, 7, 9 linking innate immunity to autoreactivity, and (4) display ICAM/CD40. Epithelial cells show *increased apoptosis*, whereas infiltrating lymphocytes resist it.
- ▶ **BAFF axis:** epithelial **B-cell-activating factor** (BAFF), induced by type I/II interferons, is elevated in serum (especially with hypergammaglobulinaemia/autoantibodies) and exerts an antiapoptotic effect on B cells — the central driver of B-cell hyperactivity.
- ▶ **Genetics:** **HLA-DQA1\0501*; **interferon/BAFF-axis genes** (IRF5, STAT4, BAFF); **B-cell genes** (EBF1, BLK**); and combined deficiencies of the classical complement pathway. Triggers include viruses, hormonal factors and stressful life events on a genetically primed background.

Clinical Manifestations

Glandular (sicca) features

- ▶ **Xerostomia:** difficulty swallowing dry food, burning mouth, increased **dental caries** (caries at the gum line strongly suggests Sjögren's), dry erythematous sticky mucosa, atrophic filiform papillae and a **deeply fissured tongue**; saliva is scanty or cloudy.
- ▶ **Keratoconjunctivitis sicca:** gritty/sandy foreign-body sensation, burning, redness, photophobia (photophobia may herald corneal ulceration); due to destruction of corneal and bulbar conjunctival epithelium.
- ▶ **Parotid/major salivary gland enlargement** (intermittent or persistent) in about two-thirds; other glands → dry nose/throat/**xerotrachea**, oesophageal dysmotility, atrophic gastritis, vaginal dryness with dyspareunia, dry skin.

Extraglandular (systemic) manifestations — in ~one-third; classified as nonspecific, periepithelial, immune-complex-mediated, and lymphoma (Harrison Table 373-1):

Manifestation	~Prevalence	Remarks
Fatigue / myalgias	25%	Overlapping fibromyalgia
Arthralgias / arthritis	60%	Nonerosive ; may give <i>Jaccoud's arthropathy</i>
Raynaud's phenomenon	37%	Precedes sicca in one-third

Manifestation	~Prevalence	Remarks
Lung involvement	14%	Small-airway disease, lymphocytic interstitial pneumonitis (bronchitis sicca)
Kidney involvement	9%	Interstitial nephritis → distal (type I) RTA, hyposthenuria; nephrocalcinosis if untreated; <i>distal RTA in ~20% (CMDT)</i>
Liver involvement	6%	Primary biliary cholangitis (autoimmune cholangitis)
Small-vessel vasculitis	9%	Palpable purpura , urticaria, ulcers (immune-complex, cryoglobulin-associated)
Peripheral neuropathy	2%	Sensory/sensorimotor; mononeuritis multiplex
Glomerulonephritis	2%	Membranoproliferative with type II/III cryoglobulinaemia
Lymphoma	6%	Glandular MALT (marginal-zone) lymphoma most common

- ▶ **Neurological:** broad spectrum — peripheral neuropathy, dysautonomia, rarely CNS disease; *myelitis with anti-aquaporin-4 antibodies (NMO-spectrum)* is described.
- ▶ **Cardiovascular:** increased risk, as in RA and SLE.

Investigations and Autoantibody Profile

- ▶ **Ocular tests:** Schirmer's I test (≤ 5 mm wetting in 5 min is abnormal); tear break-up time / tear lysozyme; slit-lamp staining with **Rose Bengal** or **lissamine green** → punctate corneal/conjunctival erosions and filaments; **ocular staining score** ≥ 5 (or *van Bijsterveld score* ≥ 4).
- ▶ **Salivary tests:** **sialometry** — unstimulated whole salivary flow ≤ 0.1 mL/min; **salivary gland ultrasound** (hyperechoic bands, hypoechoic foci) of diagnostic and prognostic value; MRI/sialography.
- ▶ **Labial minor salivary gland biopsy:** the histopathologic standard — **focal lymphocytic sialadenitis with focus score** ≥ 1 (≥ 1 focus of ≥ 50 lymphocytes per 4 mm^2).
- ▶ **Serology:** elevated ESR, polyclonal **hypergammaglobulinaemia**, ANA ($\sim 95\%$), **rheumatoid factor** ($\sim 70\%$), and antibodies to **Ro52/Ro60 (SS-A)** and **La (SS-B)**; leukopenia common. Low **C4**, **cryoglobulins**, and **monoclonal gammopathy** flag higher risk of vasculitis/lymphoma. Anti-Ro52 may associate with interstitial lung disease.

- ▶ **Niche antibodies:** anticentromere (limited-scleroderma picture), antimitochondrial (autoimmune cholangitis/PBC), anti-21-hydroxylase (blunted adrenal response), anti-CCP (erosive arthritis subset), anti-calponin-3 (peripheral neuropathy), anti-AQP4 (myelitis).

Classification Criteria and Differential Diagnosis

- ▶ **2016 ACR/EULAR classification criteria** (applied to patients with at least one symptom of ocular/oral dryness or suspicion from systemic disease, after exclusions) — weighted score, classify if total ≥ 4 :

Item	Weight
Labial salivary gland with focal lymphocytic sialadenitis, focus score ≥ 1	3
Anti-SSA/Ro positive	3
Ocular staining score ≥ 5 (or van Bijsterveld ≥ 4) in ≥ 1 eye	1
Schirmer's ≤ 5 mm/5 min in ≥ 1 eye	1
Unstimulated whole salivary flow ≤ 0.1 mL/min	1

- ▶ **Mandatory exclusions:** prior head-and-neck radiation, active **hepatitis C**, **AIDS**, **sarcoidosis**, **amyloidosis**, graft-versus-host disease, **IgG4-related disease**.
- ▶ **Differential of sicca / bilateral parotid enlargement:** drugs (anticholinergic, antihypertensive, antidepressant), viral infection (HCV, HIV, mumps, EBV, CMV), sarcoidosis, **IgG4-related disease**, diabetes, amyloidosis, lymphoma. Key discriminators: HIV sicca = young males, parotid CD8 infiltrate, anti-Ro/La negative, HIV serology positive; sarcoidosis = noncaseating granulomas; HCV = lymphocytic infiltrate but milder, anti-SS-A/B negative.

Lymphoma Risk (high-yield)

- ▶ Highest lymphoma risk of any autoimmune disease (~5–10% lifetime); usually **extranodal, low-grade marginal-zone (MALT) B-cell lymphoma**, often found incidentally on labial biopsy.
- ▶ **Predictive risk factors** (Harrison Fig 373-2): persistent **parotid enlargement**, severe tongue atrophy, **palpable purpura**, **low C4**, **monoclonal gammopathy**, **cryoglobulins**, leukopenia, RF and anti-Ro/La positivity, and on histology **germinal-centre formation** with heavy focal lymphocytic infiltrates. CMDT adds splenomegaly, vasculitis, peripheral neuropathy and anaemia.
- ▶ **Worse survival** with B-symptoms, nodal mass > 7 cm, and intermediate/high histological grade. FDG-PET/CT helps exclude lymphoma when suspected.

Treatment

- ▶ **Symptomatic/local (cornerstone):** artificial tears (hydroxypropyl methylcellulose, polyvinyl alcohol, 0.5% methylcellulose), **topical ciclosporin 0.05%** or **lifitegrast 5%** eye drops; boric-acid ointment/eye-patching for corneal ulcers. Frequent sips of water, sugar-free gum/candies; meticulous oral hygiene with **fluoride** to preserve dentition. **Avoid** drugs that worsen dryness (diuretics, antihypertensives, anticholinergics, antidepressants, decongestants).
- ▶ **Secretagogues:** muscarinic agonists **pilocarpine 5 mg** (TID–QID) and **cevimeline 30 mg** TID.
- ▶ **Musculoskeletal disease:** **hydroxychloroquine 200–400 mg/day** and/or **methotrexate 0.2–0.3 mg/kg/week** for arthralgia/mild arthritis.
- ▶ **Distal RTA:** oral **sodium bicarbonate 0.5–2 mmol/kg/day** in four divided doses.
- ▶ **Systemic/severe disease (vasculitis, purpura, persistent arthritis):** glucocorticoids and **rituximab (anti-CD20)**. Emerging B-cell-directed strategies: sequential **belimumab** → **rituximab**, **ianalumab** (anti-BAFF-receptor), CD40L/CD40-targeting agents; **nipocalimab** (FcRn blocker; FDA Breakthrough Therapy designation 2024). Lymphoma is treated per standard oncological guidelines.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Pathogenesis of autoimmune epithelitis (flow diagram):** Genetic background (HLA-DQA1\0501, *IRF5*, *STAT4*, *BLK*) + triggers (*viruses, hormones, stress*) → *activated glandular epithelial cell (surface Ro/La, TLR 3/7/9, BAFF, chemokines)* → *recruitment of T cells then B cells* → *ectopic germinal centre* → *hypergammaglobulinaemia, anti-Ro/La, cryoglobulins* → *glandular destruction (sicca) and risk of MALT lymphoma*. Labels: epithelial cell, T cell, B cell, BAFF, germinal centre, anti-Ro/anti-La, lymphoma*.
- ▶ **Sicca complex face/eye schematic:** dry fissured tongue, dental caries at gum line, parotid enlargement; eye with Schirmer's strip (≤ 5 mm/5 min) and Rose Bengal-stained punctate keratitis. Labels: *xerostomia, parotid enlargement, keratoconjunctivitis sicca, Schirmer's test, Rose Bengal staining*.

Clinical / Diagnostic significance

- ▶ Suspect Sjögren's in any patient with persistent dry eyes/mouth, **bilateral parotid swelling**, Raynaud's, palpable purpura, or features of **distal RTA**; always take a drug history and exclude HCV/HIV, sarcoidosis and IgG4-related disease.
- ▶ The triad of **anti-Ro/La + focus score ≥ 1 labial biopsy + objective sicca tests** secures classification; biopsy and ultrasound carry prognostic weight.
- ▶ New or persistent parotid enlargement, purpura, low C4 or cryoglobulins mandates **active lymphoma surveillance**.
- ▶ **Checkpoint inhibitors (anti-PD-1/PD-L1)** can trigger de-novo Sjögren's — relevant in oncology patients.

- ▶ Anti-Ro/La are transplacental → risk of **neonatal lupus and congenital heart block** in offspring.

High-yield exam pointers

- ▶ **Autoimmune epithelitis** — the unifying concept; periepithelial lymphocytic infiltration of lung/kidney/liver.
- ▶ F:M **10–20:1**; prevalence ~0.5–1%; primary vs secondary (RA > SLE > scleroderma > PBC).
- ▶ **Anti-SSA/Ro and anti-SSB/La** are the hallmark antibodies; RF positive in ~70%, ANA ~95%.
- ▶ **Schirmer's** ≤5 mm/5 min; **focus score** ≥1 on labial biopsy; unstimulated salivary flow ≤0.1 mL/min.
- ▶ **2016 ACR/EULAR** weighted criteria — anti-Ro and biopsy weighted 3 each; classify at ≥4.
- ▶ **Distal (type I) RTA** in ~20%; interstitial nephritis, hyposthenuria, nephrocalcinosis.
- ▶ **Highest lymphoma risk** of all autoimmune diseases → **extranodal marginal-zone (MALT) lymphoma**.
- ▶ First-line therapy is **substitutive/secretagogue** (artificial tears, pilocarpine/cevimeline); **rituximab/Hcq/MTX** for systemic disease.
- ▶ **Jaccoud's arthropathy** (reversible nonerosive deformity) and **NMO/anti-AQP4 myelitis** are classic associations.

SOURCE & COVERAGE

- ▶ Harrison's Principles of Internal Medicine, 22e — "Sjögren's Disease" (pathogenesis, autoimmune epithelitis, extraglandular-manifestation table, lymphoma risk factors, 2016 ACR/EULAR diagnostic algorithm, treatment).
- ▶ CMDT 2026 — "Rheumatologic, Immunologic, & Allergic Disorders: Sjögren Disease" (essentials, clinical findings, distal RTA frequency, ocular/oral therapy, lifitegrast, belimumab→rituximab, ivalumab, nipocalimab, prognosis/lymphoma predictors).
- ▶ Coverage note: The dedicated 2016 ACR/EULAR criterion **weights** (3/3/1/1/1, threshold ≥4) are universally accepted rheumatology; Harrison lists the same component items and exclusions in its diagnostic algorithm but does not tabulate the numeric weights.

Clinical Presentations and Extraglandular Manifestations of Sjögren's Syndrome

Asked in: Paper III May 2025 — RGUHS MD General Medicine

Definition / Introduction — *Sjögren's disease (syndrome)* is a prototype systemic autoimmune disorder characterised by **chronic lymphocytic (CD4⁺ T-cell) infiltration of the exocrine glands** — chiefly salivary and lacrimal — producing **xerostomia** and **keratoconjunctivitis sicca (KCS)**, on a background of intense **B-cell hyperactivity** (hypergammaglobulinaemia, anti-Ro/anti-La). It may occur **alone**

(primary) or with another rheumatic disease (secondary/associated) — most often rheumatoid arthritis, limited scleroderma, SLE, primary biliary cholangitis, or Hashimoto thyroiditis. Middle-aged women dominate (F:M $\approx$ 9–20:1; prevalence $\sim$ 0.5–1%), and the disease carries the **highest lymphoma risk of any autoimmune disease**.

Glandular (sicca) manifestations — the clinical core

Most patients present with symptoms of impaired exocrine function; the course is slow and usually benign.

- ▶ **Oral (xerostomia):** difficulty swallowing dry food, *burning mouth*, **rampant dental caries** (caries at the gum line strongly suggests the disease), poor denture tolerance, “cotton mouth”, difficulty speaking. Examination shows a dry, erythematous, sticky mucosa; in severe cases the tongue dorsum loses filiform papillae and becomes **deeply fissured**; saliva is unexpressible or cloudy.
- ▶ **Ocular (keratoconjunctivitis sicca):** sensation of *sand/gravel* under the lids, burning, itching, redness, photosensitivity, eye fatigue, stringy secretions at inner canthi, intolerance of contact lenses; **corneal ulceration** is a painful complication of severe dryness. Due to destruction of corneal/bulbar conjunctival epithelium.
- ▶ **Salivary gland enlargement:** intermittent or persistent **parotid (or other major gland) enlargement in ~one-third (two-thirds in some series)** — relapsing; firm, non-tender. *A hard, nodular, or rapidly enlarging gland must raise suspicion of lymphoma.*
- ▶ **Other exocrine surfaces:** dry nose/throat/trachea (**xerotrachea**, dry cough), oesophageal mucosal dysmotility, atrophic gastritis, vaginal dryness with **dyspareunia**, and dry skin.

Extraglandular (systemic) manifestations

Systemic features occur in **~one-third** of patients and are classified by mechanism into **non-specific, periepithelial** (“autoimmune epithelitis”), **immune-complex-mediated**, and **lymphoma** (Moutsopoulos). Prevalences below are from Harrison Table 373-1 (primary disease).

Category	Manifestation	~Prevalence	Remarks
Non-specific	Fatigability / myalgias	25%	Fibromyalgia overlap
	Arthralgias / arthritis	60%	Usually non-erosive ; can give <i>Jaccoud’s arthropathy</i>
	Raynaud’s phenomenon	37%	In one-third, <i>precedes</i> sicca symptoms
Periepithelial	Lung involvement	14%	Small-airway disease / <i>lymphocytic interstitial pneumonitis</i> , bronchitis sicca, ILD

Category	Manifestation	~Prevalence	Remarks
	Kidney (interstitial)	9%	Interstitial nephritis → distal (type I) RTA, hyposthenuria; usually asymptomatic; untreated acidosis → nephrocalcinosis
	Liver	6%	Primary biliary cholangitis (stage I); antimitochondrial Ab
Immune-complex	Small-vessel vasculitis	9%	Palpable purpura, urticarial lesions, skin ulcers, mononeuritis multiplex; with cryoglobulinaemia
	Peripheral neuropathy	2%	Sensory or sensorimotor polyneuropathy
	Glomerulonephritis	2%	Membranoproliferative, with mixed type II/III cryoglobulinaemia
Malignant	Lymphoma	6%	Glandular MALT lymphoma most common

- ▶ **Renal tubular acidosis (distal type I)** is the classic renal lesion — CMDT cites it in ~20% of patients; treat with oral sodium bicarbonate. Glomerulonephritis (immune-complex/cryoglobulinaemic) is rarer.
- ▶ **Neurological spectrum is broad and can be devastating:** peripheral/sensory ataxic neuropathy, *autonomic dysfunction (dysautonomia)*, cranial (especially trigeminal) neuropathy, and CNS disease. Myelitis with anti-aquaporin-4 antibodies (**neuromyelitis optica spectrum disorder**) and MS-like lesions are recognised. *Anticalponin-3* antibodies are associated with peripheral neuropathy.
- ▶ **Cutaneous:** beyond vasculitic purpura, annular erythema and xerosis occur.
- ▶ **Cardiovascular:** like RA and SLE, an **increased cardiovascular risk** is reported. *Neonatal lupus / congenital heart block* is the offspring risk in anti-Ro/La-positive mothers.

Lymphoma — the defining late complication

- ▶ Sjögren's carries the **highest lymphoma risk among autoimmune diseases** (driven by sustained B-cell activation, BAFF, and germinal-centre formation).
- ▶ Most are **extranodal, low-grade, marginal-zone B-cell (MALT) lymphomas**, often arising in salivary glands and found incidentally on labial biopsy; affected nodes are usually peripheral.

- ▶ **Risk factors (Fig. 373-2):** *clinical* — persistent **parotid enlargement**, palpable purpura, severe tongue atrophy, splenomegaly, peripheral neuropathy; *haematologic/serologic* — leukopenia, **low C4**, **monoclonal gammopathy**, **mixed monoclonal cryoglobulins**, persistent RF/anti-Ro-La; *histologic* — heavy focal lymphocytic infiltrates and **germinal-centre formation** on minor salivary gland biopsy.
- ▶ Worse survival with **B symptoms**, **nodal mass >7 cm**, and **intermediate/high histologic grade**; FDG-PET/CT helps exclude transformation.

Laboratory and autoantibody profile

- ▶ **Cytopenias:** mild anaemia, leukopenia, infrequent lymphopenia, eosinophilia.
- ▶ **B-cell hyperactivity:** **polyclonal hypergammaglobulinaemia**, raised ESR, positive ANA (~95%) and **rheumatoid factor** (~70%).
- ▶ **Specific autoantibodies:** anti-Ro/SSA (Ro52, Ro60) and anti-La/SSB — correlate with earlier onset, systemic/extraglandular disease; Ro52 links to interstitial lung disease.
- ▶ **Markers of severity:** **cryoglobulins** and **low C4** (vasculitis, lymphoma risk); anticentromere Ab (limited-scleroderma-like picture); antimitochondrial Ab (autoimmune cholangitis); anti-citrullinated peptide Ab (associated arthritis); anti-21-hydroxylase Ab (blunted adrenal response).

Diagnosis, classification criteria & differential diagnosis

- ▶ **Objective tests:** Schirmer I test ≤ 5 mm/5 min, tear break-up time, **ocular staining score** (lissamine green/Rose Bengal; score ≥ 5 , or *van Bijsterveld* ≥ 4); **unstimulated whole salivary flow** ≤ 0.1 mL/min (sialometry); salivary gland **ultrasound** (hypoechoic areas — diagnostic/prognostic); and **labial minor salivary gland biopsy** showing **focal lymphocytic sialadenitis**, **focus score ≥ 1 focus/4 mm²**.
- ▶ **2016 ACR/EULAR classification criteria** (weighted; **total ≥ 4** classifies, with at least one sicca symptom and after exclusions): labial gland focal lymphocytic sialadenitis with focus score ≥ 1 = 3; anti-SSA/Ro positive = 3; ocular staining score ≥ 5 (or *van Bijsterveld* ≥ 4) = 1; Schirmer ≤ 5 mm/5 min = 1; salivary flow ≤ 0.1 mL/min = 1.
- ▶ **Exclusions:** prior head/neck irradiation, active **hepatitis C**, **AIDS**, **sarcoidosis**, amyloidosis, graft-versus-host disease, **IgG4-related disease**.
- ▶ **Differential of sicca / bilateral parotid swelling:** HCV and HIV (diffuse CD8⁺ infiltration), **sarcoidosis** (non-caseating granulomas), IgG4-related disease, mumps/EBV/CMV, amyloidosis, drugs (anticholinergics, antihypertensives, antidepressants), diabetes, and previously checkpoint-inhibitor (PD-1/PD-L1)–triggered sicca.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Classification of extraglandular manifestations (radial/spoke diagram):** centre box “Sjögren’s disease — B-cell hyperactivity”; four spokes labelled **Non-specific** (fatigue, arthralgia, Raynaud’s), **Periepithelial / autoimmune epithelitis** (lung, kidney–RTA, liver–PBC), **Immune-complex-mediated** (purpura/vasculitis, MPGN, peripheral neuropathy, cryoglobulinaemia, low C4), **Lymphoma** (MALT).
- ▶ **Labial minor salivary gland biopsy histology:** label acinus, duct, focal lymphocytic infiltrate (≥ 50 lymphocytes = one focus), germinal centre, and “focus score $\geq 1 / 4 \text{ mm}^2$ ”.

Clinical / Diagnostic significance

- ▶ Caries at the gum line + parotid swelling + dry eyes in a middle-aged woman is the bedside triad prompting work-up.
- ▶ A hard/rapidly enlarging parotid, palpable purpura, low C4, cryoglobulins, or monoclonal band mandates evaluation for MALT lymphoma.
- ▶ Anti-Ro/La positivity carries **obstetric implications** — neonatal lupus and **congenital complete heart block**; screen and monitor pregnancies.
- ▶ Unexplained distal RTA, nephrocalcinosis, hypokalaemic paralysis, or NMOSD/transverse myelitis should trigger sicca screening.
- ▶ Exclude HCV, HIV, sarcoidosis, IgG4-RD before labelling primary disease.

High-yield exam pointers

- ▶ Two cardinal symptoms = xerostomia + keratoconjunctivitis sicca (sicca complex).
- ▶ Pathology = autoimmune epithelitis; major infiltrating cell = activated CD4^+ T lymphocyte; driver = BAFF-mediated B-cell hyperactivity.
- ▶ Anti-Ro/SSA + anti-La/SSB are the hallmark antibodies; RF ~70%, ANA ~95%.
- ▶ Arthritis is non-erosive (Jaccoud’s); Raynaud’s precedes sicca in one-third.
- ▶ Distal (type I) RTA is the classic renal lesion (~20%); **interstitial nephritis** > glomerulonephritis.
- ▶ Highest lymphoma risk of any autoimmune disease — usually MALT type; red flags = persistent parotid swelling, purpura, low C4, cryoglobulins, monoclonal gammopathy.
- ▶ **Diagnosis:** Schirmer $\leq 5 \text{ mm}/5 \text{ min}$, focus score ≥ 1 on lip biopsy, salivary flow $\leq 0.1 \text{ mL/min}$ → 2016 ACR/EULAR score ≥ 4 .
- ▶ **Treatment:** secretagogues pilocarpine 5 mg / cevimeline 30 mg, artificial tears, topical ciclosporin/lifitegrast; hydroxychloroquine/methotrexate for arthritis; rituximab/glucocorticoids and sequential belimumab→rituximab for systemic/vasculitic disease; oral bicarbonate for RTA.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Sjögren's Disease” (Moutsopoulos & Mavragani): definition, pathogenesis, glandular/extraglandular manifestations and Table 373-1, lymphoma risk factors (Fig. 373-2), autoantibodies, 2016 ACR/EULAR diagnostic algorithm and differentials.
- ▶ **CMDT 2026** — “Sjögren Disease,” Rheumatologic, Immunologic, & Allergic Disorders: essentials, distal RTA frequency, neurologic spectrum (dysautonomia, NMO), Schirmer/lip-biopsy/sialometry/ultrasound, current B-cell therapy (belimumab→rituximab, ianalumab, nipocalimab).
- ▶ Coverage note: corpus is robust for this topic; the 2016 ACR/EULAR **weighted score** (3/3/1/1/1, **cut-off** ≥4) is stated as the universally accepted criteria — Harrison lists the same component items/thresholds (Fig. 373-3) but does not print the numeric weights.

Extra-articular Manifestations of Rheumatoid Arthritis and Their Management

Asked in: Paper III 15 Apr 2026 — RGUHS MD General Medicine

Definition / Introduction — Rheumatoid arthritis (RA) is a chronic, systemic, immune-mediated inflammatory disease characterised by a symmetric, erosive polyarthritis of the small joints. Although predominantly articular, RA is fundamentally a **systemic disease**, and clinically significant *extra-articular manifestations* (EAMs) develop during its course in **up to 40% of patients**, sometimes even before the onset of arthritis. EAMs cluster in patients with a history of cigarette smoking, early significant disability, and seropositivity for **rheumatoid factor (RF)** or **anti-citrullinated protein antibodies (ACPA)**; their presence signifies severe disease and shortens survival. Their management rests on **aggressive control of the underlying RA** plus organ-specific therapy.

Determinants and overview of extra-articular disease

- ▶ **Risk factors for EAMs:** long-standing disease, high disease activity, smoking, high-titre RF/ACPA seropositivity, the HLA-DRB1 *shared epitope*, and hypocomplementemia (for vasculitis).
- ▶ EAMs contribute disproportionately to **morbidity and mortality** — patients with systemic involvement have shortened survival (overall RA mortality ~2× general population; median life expectancy reduced ~7 years in men, ~3 years in women).
- ▶ The incidence/severity of some EAMs (notably **Felty's syndrome** and **vasculitis**) has **declined** in the era of early, aggressive DMARD therapy.
- ▶ Most frequent EAMs: subcutaneous nodules, secondary Sjögren's, interstitial lung disease, pulmonary nodules, and anaemia.

Systemic and organ-specific extra-articular manifestations

System	Manifestations (key points)
Constitutional	Fatigue, malaise, low-grade fever, weight loss, depression, cachexia; reflect inflammatory burden, may precede arthritis. Fever $>38.3^{\circ}\text{C}$ (101°F) should raise suspicion of vasculitis or infection .
Cutaneous / Nodules	<i>Rheumatoid nodules</i> in 20–40% — firm, non-tender, adherent to periosteum/tendon/bursa over pressure points (forearm, olecranon, sacrum, Achilles tendon); correlate with seropositivity. Also purpura, pyoderma gangrenosum , digital infarcts. <i>Accelerated nodulosis</i> in up to 10% on long-term methotrexate.
Ocular	Keratoconjunctivitis sicca (secondary Sjögren's, ~10%), episcleritis , scleritis , scleromalacia perforans (from scleral nodules), peripheral ulcerative keratitis.
Oral	Xerostomia, periodontitis.
Pulmonary	Pleuritis is the commonest pulmonary feature — exudative effusion (monocytes/neutrophils, characteristically low glucose, low pH). Interstitial lung disease (ILD) in ~10–12% — patterns are UIP (honeycombing) and NSIP (ground-glass + reticulation); restrictive PFTs with reduced DLCO ; diagnosed on HRCT . Pulmonary nodules ; <i>Caplan's syndrome</i> = rheumatoid pneumoconiosis (nodules + silica/coal exposure). Also organising pneumonia, bronchiolitis, bronchiectasis, pulmonary vasculitis.
Cardiac	Pericardium is the commonest cardiac site — clinical pericarditis $<10\%$ but detectable on echo/autopsy in ~50%; asymptomatic effusions up to 20%. Also myocarditis (necrotizing/granulomatous), cardiomyopathy, arrhythmia, mitral regurgitation; accelerated ischaemic heart disease .
Vasculitis	<i>Rheumatoid vasculitis</i> (now $<1\%$) — long-standing, RF/ACPA-positive, hypocomplementemic disease. Nail-fold/digital pulp infarcts, petechiae, purpura, livedo reticularis, gangrene, painful leg ulcers; mononeuritis multiplex / sensorimotor polyneuropathy.
Haematologic	Normochromic normocytic anaemia of chronic disease (commonest; tracks CRP/ESR); reactive thrombocytosis. Felty's syndrome = triad of

System	Manifestations (key points)
	neutropenia + splenomegaly + nodular RA (<1%, late severe disease). T-cell large granular lymphocyte (T-LGL) leukaemia mimics Felty's. Lymphoma risk increased 2–4× (commonest = diffuse large B-cell lymphoma).
Neurologic	Cervical (atlantoaxial C1–C2) subluxation → compressive myelopathy (<10%); peripheral entrapment (carpal tunnel/median nerve); vasculitic neuropathy.
Renal	Membranous nephropathy; secondary (AA) amyloidosis from chronic inflammation.
Skeletal / Endocrine	Generalised osteoporosis (~2× risk; ~1/3 of postmenopausal women with RA) and fragility/hip fractures; hypoandrogenism.

Associated systemic comorbidities (high-yield)

- ▶ **Cardiovascular disease** is the single most common cause of death in RA — coronary and carotid atherosclerosis and heart failure are increased ~2-fold, *independent* of traditional risk factors, driven by systemic inflammation. Aggressive control of hypertension, diabetes, obesity, smoking, and RA inflammation improves outcomes.
- ▶ **Osteoporosis** — promoted by the inflammatory milieu (osteoclast activation via RANKL), chronic glucocorticoids, and immobility.
- ▶ **Infection** — both disease- and immunosuppression-related; a single joint inflamed out of proportion must be aspirated to exclude **septic arthritis**.

General principles of management

- ▶ **Treat-to-target (T2T)**: early, aggressive therapy started *as soon as the diagnosis is certain*, with frequent escalation/modification of DMARDs to reach **low disease activity or remission** (monitored by DAS-28, CDAI, SDAI); ACR/EULAR provisional remission = tender joints ≤1, swollen joints ≤1, CRP ≤1 mg/dL, patient global ≤1, **or** SDAI ≤3.3.
- ▶ **Minimise long-term glucocorticoids**; individualise to maximise efficacy and minimise toxicity.
- ▶ Multidisciplinary care: smoking cessation, exercise (~150 min/week moderate-vigorous), physiotherapy, foot orthotics/wrist splints, cardiovascular risk reduction, osteoporosis screening/prophylaxis, and vaccination.

Pharmacological management (drug classes)

Class	Agents & key dosing	Major cautions
NSAIDs	Non-selective COX-1/COX-2 inhibition	Adjunctive/symptomatic only — do <i>not</i> prevent erosions; never monotherapy. Gastritis, PUD, renal injury.
Glucocorticoids	Low-dose prednisone 5–10 mg/d (bridging/flare); intra-articular triamcinolone 10–40 mg ($\leq 4 \times / \text{yr}$); high-dose for serious EAMs	Osteoporosis (give bisphosphonate prophylaxis), infection, hyperglycaemia; use shortest duration (< 3 months).
Conventional synthetic DMARDs (csDMARDs)	Methotrexate = anchor drug, 7.5–25 mg weekly PO/SC + folic acid 1 mg/d ; Sulfasalazine 500 mg BD $\rightarrow$ up to 3 g/d; Leflunomide 20 mg/d; Hydroxychloroquine 200–400 mg/d (≤ 5 mg/kg)	MTX: hepatotoxicity, myelosuppression, pneumonitis, teratogenic (avoid in pregnancy/significant renal impairment). SSZ: check G6PD, cytopenias. LEF: teratogenic, long half-life. HCQ: retinal toxicity — baseline + annual eye exam.
Biologic DMARDs (bDMARDs)	TNF inhibitors (etanercept, infliximab, adalimumab, golimumab, certolizumab); Abatacept (CTLA-4 Ig, blocks T-cell co-stimulation); Rituximab (anti-CD20 B-cell depletion); IL-6R inhibitors (tocilizumab, sarilumab); Anakinra (IL-1RA)	All $\uparrow$ infection. TNFi: screen/treat latent TB before starting; avoid in chronic HBV and NYHA class III/IV heart failure; rare demyelination/drug-induced lupus. Rituximab: HBV reactivation , rare PML ($\sim 1:25,000$). IL-6R: dyslipidaemia, neutropenia, GI perforation.
Targeted synthetic DMARDs (tsDMARDs)	JAK inhibitors — tofacitinib 5 mg BD, baricitinib 2 mg OD, upadacitinib 15 mg OD (oral)	FDA black-box warning: $\uparrow$ serious infection (herpes zoster), thrombosis/VTE , MACE , malignancy , death ; screen for TB.

- **Stepwise (treat-to-target) approach:** start **methotrexate** monotherapy; if inadequate response at 3–6 months, escalate to **oral triple therapy** (MTX + **sulfasalazine** + **hydroxychloroquine**) or add an **anti-TNF / non-TNF biologic** $\pm$ MTX. Switching to an agent with a *different mechanism* (e.g., abatacept, rituximab, IL-6R or JAK inhibitor) is appropriate after biologic failure; **biologic DMARDs are not combined** with each other.

Specific management of extra-articular disease

- **General rule:** effective control of underlying RA favourably modifies most EAMs, and early aggressive treatment may *prevent* their occurrence.

- ▶ **RA-ILD:** challenging because MTX and leflunomide are themselves pulmonary toxins — treat with **high-dose corticosteroids plus azathioprine, mycophenolate mofetil, or rituximab.**
- ▶ **Severe EAMs** (necrotizing scleritis, pericarditis, vasculitis): **high-dose glucocorticoids** ± cytotoxic/immunosuppressive therapy; vasculitic ulcers may need immunosuppression and skin grafting.
- ▶ **Felty's syndrome:** treat with DMARDs (methotrexate); distinguish from T-LGL leukaemia.
- ▶ **Cervical myelopathy from atlantoaxial subluxation:** neurosurgical stabilisation when neurologic compromise occurs.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Diagram 1 — “Extra-articular manifestations of RA” body chart (a labelled human figure):** label organ pointers — *Ocular:* keratoconjunctivitis sicca, episcleritis, scleritis; *Oral:* xerostomia, periodontitis; *Pulmonary:* pleural effusion, pulmonary nodules, interstitial lung disease, organising pneumonia; *Cardiac:* pericarditis, myocarditis, ischaemic heart disease; *Haematologic:* anaemia of chronic disease, neutropenia, splenomegaly, **Felty's syndrome**, lymphoma; *Neurologic:* cervical myelopathy; *Renal:* membranous nephropathy, secondary amyloidosis; *Skin:* rheumatoid nodules, purpura, pyoderma gangrenosum; *Skeletal:* osteoporosis.
- ▶ **Diagram 2 — Treat-to-target escalation ladder:** boxes from bottom to top — *MTX monotherapy* → *MTX + triple therapy OR add anti-TNF/non-TNF biologic ± MTX* → *switch mechanism (abatacept / rituximab / IL-6R / JAK inhibitor)*; side arrow labelled “**Target = low disease activity / remission (DAS-28, CDAI, SDAI)**”; bracket labelled “glucocorticoid bridge, NSAID adjunct”.

Clinical / Diagnostic significance

- ▶ Presence of EAMs marks **severe, seropositive disease** and mandates aggressive systemic therapy and vigilant monitoring.
- ▶ **Workup pearls:** HRCT + PFTs (DLCO) for suspected ILD; echocardiography for pericardial disease; nerve conduction studies for mononeuritis multiplex; CBC + splenic imaging and peripheral-blood flow cytometry (to exclude T-LGL) in cytopenic patients; flexion–extension cervical radiographs/MRI for atlantoaxial subluxation (important **pre-operative/pre-intubation** assessment).
- ▶ A new fever or a single disproportionately inflamed joint demands exclusion of **infection / septic arthritis** before attributing it to a flare.

High-yield exam pointers

- ▶ EAMs occur in **up to 40%** of RA; predicted by smoking + RF/ACPA seropositivity + high disease activity.

- ▶ **Pleuritis** = commonest pulmonary EAM; pleural fluid characteristically **low glucose, low pH** (exudate).
- ▶ **Felty's syndrome** = **neutropenia + splenomegaly + nodular RA**; mimicked by T-LGL leukaemia.
- ▶ **Caplan's syndrome** = RA pulmonary nodules + pneumoconiosis (silica/coal).
- ▶ **Cardiovascular disease** = **leading cause of death** in RA; secondary **AA amyloidosis** and membranous nephropathy are the renal EAMs.
- ▶ **Methotrexate** = anchor DMARD (+ folic acid); **hydroxychloroquine** needs **annual retinal screening**.
- ▶ **Screen for latent TB before any TNF inhibitor**; avoid TNFi in chronic HBV and NYHA III/IV heart failure.
- ▶ **RA-ILD** treated with steroids + azathioprine/mycophenolate/rituximab (avoid MTX/leflunomide-related lung toxicity).
- ▶ **Treat-to-target**: aim for low disease activity/remission (DAS-28/SDAI/CDAI).

Pharmacotherapy of Obesity in a Young Adult with Type 2 Diabetes and Hypertension (BMI 46 kg/m²)

Asked in: Paper I May 2025 — RGUHS MD General Medicine

Definition / Introduction — This 25-year-old man weighs 118 kg at a height of 1.60 m, giving a BMI of 46.1 kg/m² — *class III (extreme) obesity* (WHO/NIH: class I 30–34.9, class II 35–39.9, class III ≥40). He already carries two adiposity-driven complications — **type 2 diabetes mellitus (T2DM)** and **hypertension** — and has failed structured lifestyle measures. He therefore meets criteria for **adjunct anti-obesity pharmacotherapy** (BMI ≥30, or ≥27 with comorbidity) and, given BMI ≥40, is simultaneously a candidate for **metabolic/bariatric surgery**. The strategic principle is to choose agents

that deliver weight loss *and* concurrently improve glycaemia, blood pressure and cardiovascular risk, while deliberately avoiding weight-promoting drugs.

Clinical assessment and rationale for drug therapy

- **Eligibility:** Adjuvant pharmacotherapy is indicated for BMI ≥ 30 kg/m², or ≥ 27 kg/m² with obesity-related disease, when diet and physical activity have failed — this patient qualifies on both counts.
- **Goal of therapy:** Improve obesity-related complications and quality of life; a realistic initial target is **8–10% weight loss over 6 months**; even **5–10% total-body-weight (TBW) loss** produces clinically meaningful, dose-related improvements in blood glucose, blood pressure, triglycerides and HDL.
- **“Treat-to-multiple-target” logic:** Because he has T2DM + hypertension + extreme obesity, the ideal agent is a “threefer” — a glucose-lowering drug that also causes weight loss and lowers BP. The **incretin (nutrient-stimulated hormone) class — GLP-1 receptor agonists and the GLP-1/GIP dual agonist tirzepatide** — fits all three, and is favoured by the diabetes algorithm whenever the management goal is “HbA1c + weight reduction” or there is ASCVD/ASCVD risk.
- **Drug must accompany an active lifestyle programme** — pharmacotherapy works best as an adjunct, not a replacement, for diet, exercise and behaviour modification.

Preferred therapy — incretin-based (nutrient-stimulated hormone) agents

These directly serve all of this patient’s problems and are the cornerstone of his treatment.

Drug	Mechanism of action	Dose / route	Placebo-subtracted weight loss	Key adverse effects	Contraindications
Semaglutide 2.4 mg	GLP-1 receptor agonist — ↑glucose-dependent insulin secretion, ↓glucagon, slows gastric emptying, acts on arcuate nucleus/NTS to ↓appetite	SC once weekly; titrate 0.25→0.5→1→1.7→2.4 mg q4-weekly	~12.5% (STEP 1–4: 6.2–14.8% at 68 wk)	Nausea, diarrhoea, constipation, vomiting; pancreatitis, cholelithiasis	Personal/family history of medullary thyroid carcinoma (MTC), MEN-2; caution if pancreatitis

Drug	Mechanism of action	Dose / route	Placebo-subtracted weight loss	Key adverse effects	Contraindications
Tirzepatide	Dual GIP + GLP-1 receptor agonist — GIP acts synergistically with GLP-1 in the brain for greater appetite suppression	SC once weekly; titrate 2.5 mg → max 15 mg	~17.8% (SURMOUNT-1: 20.9% vs 3.1% placebo at 15 mg)	Nausea, diarrhoea, constipation, abdominal pain	As above (MTC, MEN-2); caution pancreatitis
Liraglutide 3.0 mg	GLP-1 receptor agonist (97% homology to human GLP-1)	SC once daily; 0.6 mg/wk increments to 3.0 mg	~5.4% (SCALE: 3.4–6.1%)	Nausea, diarrhoea, constipation, vomiting	As above

- **Indications:** chronic weight management (all three) *and* T2DM (semaglutide, liraglutide, tirzepatide are independently approved glucose-lowering drugs) — making them uniquely suited to this patient.
- **Expected efficacy:** dual benefit — tirzepatide/semaglutide give the largest weight loss of any licensed medical therapy, **lower HbA1c by ~1–2%**, do **not** cause hypoglycaemia (glucose-dependent action) and reduce systolic BP through weight loss.
- **Cardiovascular value:** the SELECT trial showed semaglutide 2.4 mg reduced **major adverse cardiovascular events (MACE)** by ~20% in overweight/obese patients with established CVD; LEADER-type data show GLP-1 RAs reduce CV events and diabetic kidney disease in T2DM — directly relevant to a young diabetic-hypertensive patient with decades of risk ahead.

Anti-diabetic drugs that also assist weight loss and comorbidity control

- **Metformin (first-line for T2DM):** reduces hepatic glucose production and modestly improves peripheral glucose uptake; **promotes mild weight loss**, lowers insulin levels and improves lipids; start low, titrate to **max 2000 mg/day**. Adverse effects: GI upset (diarrhoea, nausea, metallic taste), ↓vitamin B12, rare lactic acidosis. Avoid if **eGFR <30 mL/min**, acidosis, unstable CHF, hepatic disease.
- **SGLT2 inhibitors (empagliflozin, canagliflozin, dapagliflozin):** block proximal-tubule glucose reabsorption → glucosuria, insulin-independent glucose lowering, **modest weight loss**, and a **diuretic-mediated 3–6 mmHg fall in systolic BP** — directly helping his hypertension. They reduce ASCVD events/CV mortality, reduce heart-failure hospitalisation and slow diabetic

kidney disease. Adverse effects: genital/urinary mycotic infection, volume depletion, euglycaemic DKA; do not initiate at eGFR <45 and avoid in stage 4 CKD.

- ▶ **Drugs to deliberately AVOID** (cause weight gain and worsen the index problem): **insulin, sulfonylureas, and thiazolidinediones** (TZDs add 2–3 kg, fluid retention/CHF risk). Sulfonylureas and insulin also carry hypoglycaemia risk. These run counter to the weight-loss goal and should be later/last-line here.

Other (non-incretin) anti-obesity medications

- ▶ **Phentermine / topiramate ER (PHEN/TPM)**: catecholamine releaser + anticonvulsant (GABA modulation, carbonic-anhydrase inhibition, glutamate antagonism); oral once daily, max 15/92 mg; placebo-subtracted weight loss ~8% (EQUIP/CONQUER 6.6–9.3%). AE: paraesthesia, dry mouth, dysgeusia, insomnia, cognitive impairment; **teratogenic (oral clefts)** — needs contraception/pregnancy testing. *Caution in this patient: uncontrolled hypertension is a contraindication* to phentermine-containing agents (they raise BP/HR).
- ▶ **Naltrexone SR / bupropion SR**: opioid antagonist + dopamine/noradrenaline reuptake inhibitor — disinhibits hypothalamic POMC/α-MSH to reduce intake; oral 2 tabs BID; weight loss ~5% (COR trials 4.2–5.1%). AE: nausea, constipation, headache, **small rise in BP/pulse**; contraindicated in uncontrolled hypertension, seizure disorder, chronic opioid use, MAOI within 14 days.
- ▶ **Orlistat**: GI/pancreatic lipase inhibitor — blocks absorption of ~30% of dietary fat at 120 mg tid; minimally absorbed, so no systemic toxicity; weight loss ~4.1%. AE: steatorrhea, oily spotting, faecal urgency, fat-soluble vitamin (A, D, E, K, β-carotene) depletion — supplement vitamins.
- ▶ **Setmelanotide**: MC4-receptor agonist for **monogenic/syndromic obesity only** (POMC, PCSK1, LEPR deficiency, Bardet–Biedl syndrome) — not for common polygenic obesity, but worth knowing in a *young-onset, extreme* obesity case where a secondary cause should be excluded.

Concurrent control of hypertension and escalation to surgery

- ▶ **Treat the comorbidities in parallel**: much of his hypertension and dysglycaemia will improve as weight falls. For pharmacological BP control in a diabetic, an **ACE inhibitor or ARB** is preferred (renoprotection/albuminuria reduction); weight-neutral add-ons (CCB, thiazide) as needed. SGLT2 inhibitors and GLP-1 RAs provide additional BP lowering.
- ▶ **Exclude secondary causes** in a young, extremely obese diabetic-hypertensive: drug-induced weight gain, hypothyroidism, Cushing's syndrome, hypothalamic disease, and (for resistant hypertension) endocrine hypertension.
- ▶ **Metabolic / bariatric surgery** is indicated and appropriate here — **BMI ≥40**, or ≥35 with a comorbidity, after failure of lifestyle ± medication. **Sleeve gastrectomy** and **Roux-en-Y gastric bypass** are commonest; restrictive-malabsorptive bypass yields ~28–33% TBW loss at 12–18 months, marked T2DM improvement (Swedish Obese Subjects: 78% lower incidence of T2DM;

~68% achieve initial diabetes remission within 5 years) and reduced all-cause/CV mortality. Requires lifelong vitamin B12, iron, folate, calcium and vitamin D supplementation after malabsorptive procedures.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **CNS appetite-regulation circuit with drug action sites:** Label — *Arcuate nucleus (ARC)* with POMC/CART (anorexigenic) and AgRP/NPY (orexigenic) neurons; α -MSH $\rightarrow$ MC4R in the *paraventricular nucleus (PVN)*; *nucleus tractus solitarius (NTS)* and *brainstem*; *mesolimbic reward (VTA $\rightarrow$ NAc, dopamine)*. Map drugs onto targets: GLP-1R $\rightarrow$ liraglutide/semaglutide/tirzepatide, GIP-R $\rightarrow$ tirzepatide, MC4R $\rightarrow$ setmelanotide, μ -opioid receptor $\rightarrow$ naltrexone, POMC/dopamine $\rightarrow$ bupropion, NE release/GABA $\rightarrow$ phentermine/topiramate, gut peptides (PYY, CCK, ghrelin, leptin, amylin) as afferent inputs.
- ▶ **Obesity-treatment pyramid / algorithm:** base = *Lifestyle (diet 500–750 kcal deficit, ≥ 150 min/wk activity, behaviour therapy)* $\rightarrow$ *Pharmacotherapy (BMI ≥ 30 or ≥ 27 + comorbidity)* $\rightarrow$ *Bariatric/metabolic surgery (BMI ≥ 40 , or ≥ 35 + comorbidity)*. Side branch: T2DM algorithm — “goal = HbA1c + weight reduction $\rightarrow$ GLP-1 RA / structured medical weight programme / metabolic surgery.”

Clinical / Diagnostic significance

- ▶ **Investigations before/with therapy:** fasting lipid profile, chemistry panel, HbA1c, blood pressure, waist circumference (South-Asian cut-off >90 cm in men), TSH and overnight dexamethasone/Cushing screen if clinically suggested, ECG; baseline renal function (guides metformin/SGLT2i dosing).
- ▶ **Monitoring on therapy:** weight/BMI trajectory and “stopping rules” (review benefit at 12–16 weeks for phentermine, PHEN/TPM and NB), HbA1c, BP, renal function; watch for GLP-1 RA GI intolerance, gallstones/pancreatitis, and euglycaemic DKA with SGLT2i; vitamin B12 on metformin.
- ▶ **Management pearl:** in this *young* patient the choice of weight-losing glucose-lowering drugs (incretins $\pm$ SGLT2i + metformin) over weight-gaining ones (insulin/sulfonylurea/TZD) sets the trajectory of his diabetes, BP and lifelong cardiovascular risk.

High-yield exam pointers

- ▶ BMI = $118 \div (1.60)^2 = 46.1$ kg/m² $\rightarrow$ class III (extreme) obesity (≥ 40); qualifies for *both* pharmacotherapy and bariatric surgery.
- ▶ Drug eligibility: BMI ≥ 30 , or ≥ 27 with comorbidity, after failed lifestyle. Realistic goal 8–10% in 6 months; 5–10% TBW loss already gives clinical benefit.

- ▶ **First choice here = GLP-1 RA (semaglutide) or dual GLP-1/GIP agonist (tirzepatide)** — they treat obesity *and* T2DM, lower BP, cut CV events (SELECT –20% MACE), and don't cause hypoglycaemia.
- ▶ Approximate placebo-subtracted weight loss: **tirzepatide ~17–21% > semaglutide ~12–15% > PHEN/TPM ~8% > liraglutide/NB ~5% > orlistat ~4%.**
- ▶ **SGLT2 inhibitors** add weight loss + **3–6 mmHg systolic BP fall** + CV/renal protection; **metformin** is first-line, weight-neutral/mild loss.
- ▶ **Avoid weight-gaining agents:** insulin, sulfonylureas, thiazolidinediones. **Phentermine/PHEN-TPM and naltrexone-bupropion are contraindicated in uncontrolled hypertension.**
- ▶ GLP-1 RAs/tirzepatide contraindicated in **medullary thyroid carcinoma / MEN-2**; orlistat causes steatorrhea + fat-soluble vitamin deficiency.
- ▶ **Bariatric surgery** (sleeve gastrectomy / Roux-en-Y): **28–33% TBW loss**, T2DM remission, reduced mortality — definitive option at BMI ≥40.

Acquired Hypopituitarism

Asked in: Paper IV Dec 2023 — RGUHS MD General Medicine

Definition / Introduction — *Hypopituitarism* is deficient secretion of one or more anterior pituitary trophic hormones, arising from disease of the pituitary, pituitary stalk, or hypothalamus. **Acquired hypopituitarism** is the far commoner adult form and reflects the compressive mass effect of tumours, or local pituitary/hypothalamic traumatic, vascular, autoimmune, inflammatory, infiltrative, or irradiation damage (as opposed to inherited/developmental causes). Loss of all anterior hormones is

termed **panhypopituitarism**. It carries a documented two- to three-fold excess of cardiovascular and cerebrovascular mortality, so prompt recognition and physiological hormone replacement are essential.

Etiology of acquired hypopituitarism

Causes are best grouped by mechanism (the “vascular–traumatic–neoplastic–inflammatory/infiltrative–infective–iatrogenic” framework):

Category	Representative causes
Neoplastic / compressive	Pituitary adenoma (esp. non-functioning macroadenoma ≥ 1 cm), craniopharyngioma, Rathke’s cleft cyst, meningioma, germinoma/glioma, hypothalamic hamartoma; metastases (breast 45%, lung); lymphoma, leukaemia
Vascular	Pituitary apoplexy; Sheehan’s syndrome (postpartum necrosis); subarachnoid haemorrhage; sickle-cell disease; snake (viper) bite venom; arteritis
Traumatic / iatrogenic	Traumatic brain injury (incl. contact sports, blast); neurosurgical resection; cranial/head-&-neck radiotherapy ; cardiopulmonary bypass
Inflammatory / autoimmune	Lymphocytic hypophysitis ; immune-checkpoint-inhibitor hypophysitis; granulomatous and IgG4-related hypophysitis
Infiltrative	Sarcoidosis, haemochromatosis , Langerhans-cell histiocytosis (histiocytosis X), amyloidosis
Infective	Tuberculosis, fungal (histoplasmosis), tertiary syphilis, opportunistic AIDS-related infection, toxoplasmosis, <i>Pneumocystis</i>
Functional / drug-induced	High-dose/exogenous glucocorticoids (HPA suppression), opioids, megestrol, GnRH agonists (e.g. leuprolide), bexarotene, mitotane; starvation, anorexia nervosa, critical illness, COVID-19

- Mass lesions cause failure by compressing the gland, stalk (“stalk-section” effect → early hyperprolactinaemia from loss of dopamine inhibition, with later loss of other hormones), or hypothalamus.
- **Cranial irradiation:** up to two-thirds develop hormone insufficiency after a median dose of ~50 Gy (5000 rad) to the skull base, evolving over 5–15 years, usually from hypothalamic rather than pituitary damage.

Pattern and sequence of hormone loss

- ▶ With progressive compression/destruction, trophic hormones are typically lost in a **predictable sequence**:

GH → FSH → LH → TSH → ACTH (mnemonic “Go Look For The Adenoma”). PRL is usually preserved or *elevated* (stalk effect); PRL deficiency (failed lactation) implies severe destruction, as in Sheehan’s.

- ▶ In children the presenting feature is **growth retardation**; in adults **hypogonadism is the earliest symptom**.

Axis lost	Clinical consequence
GH	Child: short stature, hypoglycaemia. Adult (AGHD): ↑central/visceral fat, ↓lean mass, ↓exercise capacity, dyslipidaemia, ↓bone density, poor quality of life
FSH/LH (gonadotrophin)	Women: oligo-/amenorrhoea, infertility, ↓libido, breast atrophy. Men: ↓libido, erectile dysfunction, ↓muscle/beard, soft testes; osteoporosis in both
TSH	Secondary (central) hypothyroidism: low free T4 with <i>low/inappropriately normal</i> TSH
ACTH	Secondary adrenal insufficiency: fatigue, anorexia, nausea, hypotension, hypoglycaemia, hyponatraemia — no hyperpigmentation, no hyperkalaemia (mineralocorticoid axis preserved)
PRL	Failure of postpartum lactation
AVP (posterior)	Polyuria/polydipsia (AVP deficiency / cranial diabetes insipidus) — points to stalk/hypothalamic involvement

Special acquired entities (high-yield)

- ▶ **Sheehan’s syndrome** — hypopituitarism from **postpartum pituitary necrosis** after severe peripartum haemorrhage/hypotension; the gland is enlarged and vulnerable in pregnancy. Classic clues: **failure to lactate** and **postpartum amenorrhoea**; onset is usually insidious over **10–20 years** (mean diagnostic delay ~9 years), presenting with hyponatraemia, hypoglycaemia, or anaemia. Acute Sheehan MRI: enlarged pituitary with a thin peripheral rim of gadolinium enhancement.
- ▶ **Pituitary apoplexy** — acute intrapituitary haemorrhage/infarction, usually into a pre-existing adenoma. **Endocrine emergency**: sudden severe headache, visual loss, ophthalmoplegia (cranial nerves III/IV/VI), meningism, and acute hypocortisolism → hypoglycaemia, hypotension, shock. Manage with **high-dose glucocorticoids**; **urgent transsphenoidal decompression** for progressive visual loss, cranial-nerve palsy, or deteriorating consciousness.
- ▶ **Lymphocytic hypophysitis** — autoimmune; most often in **late pregnancy/postpartum women** or with coexisting autoimmunity; mimics an adenoma on MRI (enlarged homogeneously)

enhancing gland, thickened stalk). **Secondary hypoadrenalism is the commonest deficit**; AVP deficiency in up to ~20%. Suspect before operating on a postpartum sellar mass; often responds to glucocorticoids.

- ▶ **Checkpoint-inhibitor hypophysitis** — up to ~20% with CTLA-4 inhibitors (ipilimumab), less with PD-1/PD-L1 agents (delayed onset); HLA-DQ0602 association.
- ▶ **Traumatic brain injury / SAH** — ≥1 deficiency in 25–30% of moderate–severe TBI and ~55% of aneurysmal SAH survivors; mandates long-term endocrine follow-up.

Pathological subtypes of hypophysitis (Williams)

Type	Hallmark	Notes
Lymphocytic	Lymphocyte/plasma-cell infiltrate	F>M, peripartum; anterior failure ± AVP
Granulomatous	Giant cells, granulomas	Severe headache; frequent AVP deficiency; r/o sarcoid, GPA, TB, LCH
Xanthomatous	CD68+ foamy macrophages	Often secondary to Rathke's cyst rupture
IgG4-related	IgG4+ plasma cells, storiform fibrosis	M>F; systemic IgG4 disease; good GC response
Immunotherapy-induced	Diffuse lymphocyte/macrophage infiltrate	Checkpoint inhibitors; deficits usually persist
Anti-PIT1 / anti-POMC	Antibody-mediated	Anti-PIT1 (thymoma) → GH+PRL+TSH loss; anti-POMC → isolated ACTH loss

Clinical features / presentation

- ▶ Manifestations depend on **which** hormones are lost and the **degree** of deficiency, and are typically **insidious and non-specific** — fatigue, dizziness/postural hypotension, cognitive slowing, sexual dysfunction, cold intolerance.
- ▶ **Mass-effect** features when due to tumour/hypophysitis: headache, **bitemporal hemianopia** (optic-chiasm compression), cranial-nerve palsies.
- ▶ **Panhypopituitarism** in adults often presents in women as amenorrhoea; deficiencies cluster as hypogonadism, hypothyroidism, ACTH deficiency, GH deficiency ± hyperprolactinaemia.
- ▶ An undiagnosed patient may decompensate into **pituitary/adrenal crisis** during intercurrent illness or surgery — febrile, hypotensive, hyponatraemic, comatose.

Diagnosis / laboratory investigation

Principle: demonstrate a *low target-organ hormone together with a low or inappropriately normal pituitary trophic hormone* (this distinguishes secondary/central from primary gland failure).

- ▶ **ACTH axis (do first — most life-threatening):** 8–9 am cortisol + ACTH. Cortisol $<3 \mu\text{g/dL}$ indicates adrenal insufficiency; $>15 \mu\text{g/dL}$ largely excludes it; intermediate values need a cosyntropin (ACTH 1–24) 0.25 mg stimulation test — stimulated cortisol $<20 \mu\text{g/dL}$ ($\approx 550 \text{ nmol/L}$) is abnormal. ACTH is low/normal (vs high in Addison's). Insulin-tolerance test is the gold standard but is *contraindicated* in ischaemic heart disease, epilepsy, and the elderly.
- ▶ **Thyroid axis:** low free T4 with low/normal TSH = central hypothyroidism (TSH is unreliable for monitoring).
- ▶ **Gonadal axis:** low testosterone/oestradiol with low/normal LH & FSH; check PRL (hyperprolactinaemia of any cause suppresses GnRH).
- ▶ **GH/IGF-1:** AGHD inferred from symptoms plus pituitary disease; IGF-1 $<84 \mu\text{g/L}$ or ≥ 3 other deficiencies is highly suggestive. Provocative **insulin-induced hypoglycaemia** (peak GH $<3 \mu\text{g/L}$ = deficient), or glucagon/macimorelin/arginine-GHRH tests.
- ▶ **Imaging:** dedicated **pituitary MRI** (T1, pre/post gadolinium) for mass, stalk thickening, empty sella, apoplexy. Screen for **haemochromatosis** (ferritin/transferrin saturation) when no cause is evident.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Hypothalamic–pituitary axis schematic:** hypothalamus with releasing factors (CRH, GnRH, GHRH, TRH, dopamine, somatostatin) → portal vessels down the **pituitary stalk** → anterior pituitary cells (corticotroph→ACTH, gonadotroph→LH/FSH, somatotroph→GH, thyrotroph→TSH, lactotroph→PRL) → target glands (adrenal/cortisol, gonad/sex steroids, liver/IGF-1, thyroid/T4); posterior pituitary releasing AVP & oxytocin. Add an arrow legend showing the **sequence of loss:** GH → FSH → LH → TSH → ACTH (PRL preserved).
- ▶ **Coronal MRI of sella labelling:** pituitary gland, stalk, **optic chiasm**, cavernous sinus with CN III, IV, V1, V2, VI and internal carotid artery — illustrating mass/apoplexy compression.

Clinical / Diagnostic significance

- ▶ Replace glucocorticoid **BEFORE** levothyroxine — starting thyroxine first accelerates cortisol metabolism and can precipitate an **adrenal crisis**.
- ▶ Glucocorticoid doses must be **stress-dosed** ($2\text{--}3\times$ up, or parenteral) during illness, surgery, trauma; patient should carry a steroid alert card/bracelet.
- ▶ Replacement (per axis): **Hydrocortisone 10–20 mg/day** in divided doses (or prednisone 5 mg am) — *no mineralocorticoid needed*; **levothyroxine $\sim 1.6 \mu\text{g/kg/day}$** titrated to mid-high-normal free T4 (not TSH); **testosterone** (gel/patch/enanthate 200 mg IM q2wk) or cyclical **oestrogen**–

progestogen; rhGH (somatropin) titrated to mid-normal IGF-1; desmopressin for AVP deficiency. Fertility requires gonadotrophins (hCG/hMG/FSH) or pulsatile GnRH.

- ▶ Suspect and screen for hypopituitarism after TBI, SAH, cranial irradiation, and postpartum haemorrhage.

High-yield exam pointers

- ▶ Acquired causes >> congenital in adults; remember the mechanistic groups (vascular, traumatic, neoplastic, inflammatory/infiltrative, infective, iatrogenic).
- ▶ **Sequence of hormone loss:** GH → FSH → LH → TSH → ACTH; PRL preserved/raised (“Go Look For The Adenoma”).
- ▶ **Sheehan’s** = postpartum necrosis → failure to lactate + amenorrhoea; insidious over years.
- ▶ **Pituitary apoplexy** = endocrine emergency → high-dose steroids ± urgent decompression.
- ▶ **Secondary adrenal insufficiency:** no hyperpigmentation, no hyperkalaemia (mineralocorticoid spared).
- ▶ Diagnosis = *low target hormone + low/inappropriately normal trophic hormone*; cosyntropin/insulin-tolerance tests assess reserve.
- ▶ **Treat the ACTH deficit first;** give steroid before thyroxine.
- ▶ Hypopituitarism increases cardiovascular/cerebrovascular mortality 2–3 fold.

SOURCE & COVERAGE

- ▶ **Harrison’s Principles of Internal Medicine, 22e** — “Hypopituitarism” (etiology, sequence of hormone loss, apoplexy, irradiation, hypophysitis, provocative testing, replacement table).
- ▶ **Williams Textbook of Endocrinology, 15e** — “Pituitary Adenomas and Masses” and “Pituitary Physiology and Diagnostic Evaluation” (hypophysitis pathological subtypes/Fig 7.16, checkpoint-inhibitor rates, surgical hypopituitarism).
- ▶ **CMDT 2026** — “Disorders of the Pituitary, Thyroid, & Adrenal Glands” (Sheehan’s syndrome, TBI/SAH statistics, biochemical cut-offs, current replacement regimens).

Acromegaly

Asked in: Paper IV Nov 2021 — RGUHS MD General Medicine

Definition / Introduction — Acromegaly is the clinical syndrome resulting from chronic **growth hormone (GH)** and **insulin-like growth factor 1 (IGF-1)** hypersecretion in adults, almost always due to a **GH-secreting somatotrope pituitary adenoma**. When GH excess begins in children/adolescents *before* epiphyseal long-bone closure, it produces **pituitary gigantism**; after closure it causes acral and

soft-tissue overgrowth. The manifestations are indolent and frequently undiagnosed for **10 years or more**, and untreated disease carries an approximately **threefold** increase in mortality.

Etiology and pathogenesis

- ▶ **Eutopic (pituitary, ~98%)** — GH hypersecretion is usually from a **somatotrope adenoma**. Mixed **mammosomatotrope** tumours and **acidophilic stem cell adenomas** co-secrete GH and prolactin (PRL); in the latter, features of hyperprolactinaemia (hypogonadism, galactorrhoea) predominate.
- ▶ **Ectopic GH / GHRH (<1% each)** — rare. The commonest cause of **GHRH-mediated** acromegaly is a **chest or abdominal carcinoid tumour**; excess GHRH causes somatotrope *hyperplasia*. Ectopic GH itself is reported from pancreatic, ovarian, lung or haematopoietic tumours.
- ▶ **Pathogenesis (sporadic disease)** — GHRH binds its **G-protein-coupled somatotrope receptor**, using **cyclic AMP** as second messenger to drive GH secretion and somatotrope proliferation. A subset harbours **somatic activating mutations of Gsa**, which attenuate intrinsic GTPase activity → constitutive cAMP elevation → **Pit-1** induction and **CREB** activation → somatotrope proliferation and GH secretion.

Cause	Approx. prevalence
Pituitary (densely/sparsely granulated GH-cell adenoma)	60%
Mixed GH-cell and PRL-cell adenoma	25%
Mammosomatotrope-cell adenoma	10%
Plurihormonal adenoma; GH-cell carcinoma/metastases	—
MEN-1, McCune-Albright, ectopic sphenoid/parapharyngeal pituitary adenoma	—
Extrapituitary tumour (pancreatic islet cell, lymphoma)	<1%
Excess GHRH — central (hypothalamic hamartoma, choristoma, ganglioneuroma); peripheral (bronchial carcinoid, islet cell tumour, small-cell lung Ca, adrenal adenoma, medullary thyroid Ca, pheochromocytoma)	<1%

Genetic syndromes associated with GH excess

- ▶ **MEN-1 (MENIN, 11q13)** — autosomal dominant parathyroid + pancreatic islet + pituitary tumours; acromegaly is *less common* than prolactinoma.
- ▶ **MEN-4 (CDKN1B, 12p13)** — hyperparathyroidism with pituitary adenomas.

- ▶ **Carney complex** (*PRKARIA*, 17q23-24) — spotty skin pigmentation, myxomas, endocrine tumours; **acromegaly in ~20%**.
- ▶ **McCune-Albright syndrome** — polyostotic fibrous dysplasia, café-au-lait patches and endocrinopathy (including acromegaly), from a **postzygotic mosaic Gsa mutation**.
- ▶ **Familial isolated pituitary adenoma** — germline AIP mutations (11q13.2), **acromegaly/gigantism in ~15%** of afflicted families.

Clinical features

- ▶ **Acral bony overgrowth** — frontal bossing, increased hand and foot size, **mandibular enlargement with prognathism**, and a **widened space between the lower incisor teeth**.
- ▶ **Soft-tissue swelling** — increased **heel-pad thickness**, increasing shoe/glove size, ring tightening, coarse facial features and a large fleshy nose.
- ▶ **Other systemic** — hyperhidrosis; a deep, hollow-sounding voice; oily skin; arthropathy and kyphosis; **carpal tunnel syndrome**; proximal muscle weakness and fatigue; **acanthosis nigricans** and skin tags.
- ▶ **Visceromegaly** — cardiomegaly, **macroglossia**, thyroid enlargement.
- ▶ **Cardiovascular (most significant impact)** — **cardiomyopathy** with arrhythmias, **left ventricular hypertrophy**, impaired diastolic function and **hypertension** ultimately occur in most untreated patients.
- ▶ **Respiratory / metabolic** — **obstructive sleep apnoea in >60%** (soft-tissue laryngeal obstruction + central dysfunction); glucose intolerance is usual and **diabetes mellitus develops in ~25%** (GH counteracts insulin).
- ▶ **Neoplastic** — increased **colon polyps** (found in up to one-third) and colonic-malignancy mortality.
- ▶ **Outcome** — overall mortality is increased ~threefold (cardiovascular, cerebrovascular and respiratory); unless GH is controlled, survival is reduced by an average of **10 years**.

Diagnosis and laboratory investigation

- ▶ **Screening** — an **age- and sex-matched serum IGF-1** level is the single best screening test, since IGF-1 integrates GH secretion over time.
- ▶ A **single random GH** is *not* useful for diagnosis or exclusion (GH is pulsatile) and does not correlate with disease severity.
- ▶ **Confirmation** — failure of GH to suppress to **<0.4 µg/L within 1–2 h** of a **75-g oral glucose load** (OGTT); with ultrasensitive assays the normal nadir is **<0.05 µg/L**. About **20%** show a *paradoxical GH rise* after glucose.

- **Adjunctive** — measure PRL (elevated in ~25%); thyroid function, gonadotropins and sex steroids may be attenuated by tumour mass effect. ACTH-reserve testing is best deferred until after surgery.
- **Imaging** — pituitary MRI localises and sizes the adenoma; assess for mass effects (optic chiasm compression, cavernous-sinus cranial nerve involvement).

Management

- **Goals** — control GH/IGF-1 hypersecretion, ablate or arrest tumour growth, ameliorate comorbidities, restore mortality to normal and **preserve pituitary function**.

Modality	Agent / detail	Efficacy & key points
Surgery (primary)	Transsphenoidal resection by an experienced surgeon	Microadenoma remission ~70%, macroadenoma <50%; GH normalises within 1 h, IGF-1 within 3–4 days. Recurrence ~10%; hypopituitarism in up to 15%.
Somatostatin receptor ligands (SRLs)	Octreotide LAR (30 mg IM monthly), lanreotide depot (60 mg SC q4–6 wk), oral octreotide (40–80 mg/day)	Act via SST2/SST5; normalise GH/IGF-1 in ~50%; shrink tumour in ~50%; rapid symptom relief in ~75% within days–weeks. Adjuvant or primary therapy.
Multireceptor SRL	Pasireotide LAR (preferential SST5)	For tumours resistant to octreotide/lanreotide; higher rate of hyperglycaemia/new-onset diabetes.
GH-receptor antagonist	Pegvisomant (10–30 mg SC daily)	Blocks peripheral GH binding → normalises IGF-1 in ~70%; GH stays elevated (no anti-tumour effect) — monitor tumour size by MRI .
Dopamine agonist	Cabergoline (high dose, ~0.5 mg/day)	Modest, short-lived benefit; useful for mild post-operative GH/IGF-1 elevation; additive with octreotide.
Radiotherapy	Conventional external beam or Gamma Knife stereotactic	Adjuvant; slow response (5–15 yr), late hypopituitarism, relatively poor IGF-1 normalisation — reserved when surgery/medical therapy fail.

- ▶ **SRL side effects** — GI upset (nausea, cramps, diarrhoea, fat malabsorption in $\sim\frac{1}{3}$), **biliary sludge/gallstones in up to 30%**, mild glucose intolerance, asymptomatic bradycardia, hypothyroxinaemia.
- ▶ **Pegvisomant side effects** — reversible **liver enzyme elevation**, lipodystrophy, injection-site pain.
- ▶ **Combination** — SRL + pegvisomant ($\pm$ pasireotide) for treatment-resistant disease. Manage cardiovascular disease, diabetes, sleep apnoea and arthropathy aggressively.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **GH-IGF-1 axis (regulation):** *Hypothalamus* $\rightarrow$ **GHRH (+)** and **Somatostatin (-)** $\rightarrow$ *Anterior pituitary somatotrope* $\rightarrow$ **GH** $\rightarrow$ *Liver* $\rightarrow$ **IGF-1** $\rightarrow$ *peripheral target tissues (bone, soft tissue, viscera)*; show **negative feedback** of IGF-1/GH on hypothalamus and pituitary, and the GH-secreting adenoma driving the excess.
- ▶ **Management algorithm (Fig. 392-8):** boxes labelled **GH-secreting pituitary tumour** $\rightarrow$ **Surgery** $\rightarrow$ “controlled / not controlled” $\rightarrow$ **SRL** $\rightarrow$ **Pegvisomant** $\rightarrow$ **SRL + Pegvisomant** $\rightarrow$ **Pasireotide** $\rightarrow$ **Radiotherapy / Re-operation**, with “**Monitor IGF-1**” at each controlled endpoint.

Clinical / Diagnostic significance

- ▶ **IGF-1** is the screening pivot and the marker followed for biochemical control; the **75-g OGTT-GH suppression test** is confirmatory.
- ▶ Suspect acromegaly in new-onset **diabetes, hypertension, OSA, carpal tunnel syndrome or arthropathy** with coarsening facies, and serially photograph the face/hands.
- ▶ Active disease warrants **echocardiography**, OSA screening and **colonoscopy** (polyp/cancer surveillance) plus cardiovascular risk-factor control.
- ▶ A young patient with gigantism/acromegaly, especially if familial, should prompt screening for AIP, MEN-1, Carney complex and McCune-Albright.

High-yield exam pointers

- ▶ Adult onset = **acromegaly**; pre-epiphyseal-closure onset = **gigantism** (same hormonal excess).
- ▶ **$\sim 98\%$** are pituitary somatotrope adenomas; commonest **ectopic GHRH** source = **carcinoid tumour**.
- ▶ Best screening test = **age/sex-matched IGF-1**; confirm with **GH non-suppression to $<0.4 \mu\text{g/L}$ after 75-g OGTT**; random GH is useless.
- ▶ **$\sim 20\%$** show a *paradoxical GH rise* on glucose; **PRL elevated in $\sim 25\%$** .
- ▶ First-line treatment = **transsphenoidal surgery** (micro $\sim 70\%$, macro $<50\%$ remission).
- ▶ **Octreotide/lanreotide** act via **SST2/SST5**; **pegvisomant** is a **GH-receptor antagonist** that lowers IGF-1 but not GH.

- ▶ Watch for OSA (>60%), cardiomyopathy/LVH, diabetes (25%), and **colon cancer**; untreated disease cuts survival by ~10 years.

SOURCE & COVERAGE

Harrison 22e — Ch 392 “Pituitary Tumor Syndromes” (acromegaly/gigantism, Tables 392-2, 392-4, 392-6; Figs 392-7, 392-8). All classifications, percentages, drug doses and biochemical cut-offs are taken from this chapter. *Coverage note:* the chapter does not provide a formal consensus disease-activity grading or detailed pre-pregnancy management for acromegaly; these are not asserted here.

Acute Adrenal Insufficiency (Adrenal Crisis)

Asked in: Paper IV Nov 2019 — RGUHS MD General Medicine

Definition / Introduction — *Acute adrenal insufficiency*, also termed *adrenal crisis* or *addisonian crisis*, is a life-threatening endocrine emergency caused by an acute, profound deficiency of glucocorticoid (cortisol) ± mineralocorticoid (aldosterone) action relative to physiological demand. It classically manifests as **hypotension/hypovolaemic shock unresponsive to fluids and vasopressors**, often with hyponatraemia, hyperkalaemia and a pseudo-acute abdomen. It is far more frequent in **primary adrenal insufficiency** (loss of *both* gluco- and mineralocorticoid secretion) and demands immediate empirical treatment without waiting for biochemical confirmation. Prospective data record **8.3 adrenal crises and 0.5 crisis-related deaths per 100 patient-years**.

Aetiology and precipitating factors

Adrenal crisis arises either as the *first presentation* of undiagnosed insufficiency or, more often, when a known patient fails to up-titrate steroids during stress. Underlying causes are grouped as primary, secondary (central) and iatrogenic.

Category	Representative causes
Primary (adrenal, ↑ACTH)	Autoimmune adrenitis (commonest in the West; isolated 30–40%, or part of APS-1/APECED — <i>AIRE</i> gene and APS-2 — <i>HLA-DR3</i> , <i>CTLA-4</i>); tuberculous adrenitis (common cause in developing countries); HIV/CMV, histoplasmosis, cryptococcosis; bilateral adrenal haemorrhage (<i>Waterhouse-Friderichsen syndrome</i> with meningococcal sepsis; anticoagulation, antiphospholipid syndrome); metastatic/infiltrative (lymphoma, amyloid, haemochromatosis); congenital adrenal hyperplasia (<i>21-hydroxylase deficiency</i>); X-linked adrenoleukodystrophy

Category	Representative causes
	(<i>ABCD1</i>); drugs (mitotane, abiraterone, ketoconazole, etomidate, checkpoint inhibitors)
Secondary / central (↓-normal ACTH)	Pituitary/hypothalamic tumour or its surgery/irradiation; pituitary apoplexy ; Sheehan's syndrome (postpartum pituitary infarction); autoimmune hypophysitis (incl. checkpoint-inhibitor induced)
Iatrogenic (commonest overall)	Abrupt withdrawal of chronic exogenous glucocorticoids suppressing the HPA axis — affects 0.5–2% of the population; any route (oral, inhaled, topical, intra-articular)

- ▶ **Precipitants of crisis** in a known patient: intercurrent infection/sepsis (commonest), surgery, trauma, vomiting/diarrhoea preventing oral intake, myocardial infarction, **increased glucocorticoid inactivation** (e.g., **new hyperthyroidism**), and enzyme-inducing drugs such as **rifampicin** (↑ cortisol clearance).

Pathophysiology

- ▶ **Cortisol (glucocorticoid) deficiency** → loss of vascular tone and catecholamine sensitivity (vasodilatory hypotension), impaired gluconeogenesis (**hypoglycaemia**, marked in children), loss of feedback inhibition of AVP release (→ mild SIADH-type **hyponatraemia**), and inability to mount a stress response.
- ▶ **Aldosterone (mineralocorticoid) deficiency** — *primary disease only* → renal Na⁺ and water loss with K⁺ and H⁺ retention → **volume depletion**, **hyponatraemia**, **hyperkalaemia**, **metabolic acidosis**, **postural hypotension** progressing to hypovolaemic shock. In **secondary** insufficiency the renin-angiotensin-aldosterone axis is intact, so hyperkalaemia and severe salt wasting are absent and crises are correspondingly less fulminant.
- ▶ **Adrenal androgen (DHEA) deficiency** occurs in both, clinically apparent mainly in women.
- ▶ A superimposed stressor sharply raises cortisol requirement that the failing/suppressed gland cannot meet — tipping chronic insufficiency into overt crisis.

Clinical features

- ▶ **Cardiovascular**: postural hypotension progressing to **hypotension/shock refractory to pressors**; tachycardia, cool peripheries.
- ▶ **Gastrointestinal** — “**pseudo-acute abdomen**”: anorexia, nausea, vomiting, diarrhoea, diffuse abdominal/flank pain and tenderness — may be mistaken for a surgical abdomen.
- ▶ **Neurological**: weakness, confusion, decreased responsiveness, **stupor and coma**; features of neuroglycopenia from hypoglycaemia.

- ▶ **Constitutional:** fever (may reflect precipitating infection or be intrinsic to glucocorticoid deficiency), profound fatigue, salt craving, weight loss.
- ▶ **Pointers to chronic primary disease:** hyperpigmentation of palmar creases, buccal mucosa, scars, pressure points and nipples (excess POMC/ACTH stimulating melanocytes), often with vitiligo; secondary insufficiency instead shows pale, *alabaster-coloured* skin.
- ▶ **Adrenal haemorrhage** presents with abdominal/flank/lower-chest pain, a rapidly falling haemoglobin, progressive hyperkalaemia and shock.

Investigations and diagnosis

Treatment must never be delayed for results — draw baseline samples, treat, confirm later.

- ▶ **Biochemistry:** hyponatraemia ($\approx 80\%$ Harrison; $\sim 90\%$ Williams), hyperkalaemia ($\approx 40\%$ Harrison; $\sim 65\%$ Williams — primary disease only), raised urea/creatinine (volume depletion), hypoglycaemia, occasionally hypercalcaemia. Haematology shows normochromic anaemia, lymphocytosis and eosinophilia (eosinophils $>300/\mu\text{L}$) — a useful clue distinguishing crisis from an acute abdomen, where neutrophilia dominates.
- ▶ **Hormonal confirmation:**
 - Paired baseline cortisol + ACTH + renin/aldosterone drawn *before* steroids. An 8 a.m. cortisol $<3 \mu\text{g/dL}$ (83 nmol/L) with ACTH $>200 \text{ pg/mL}$ is diagnostic of primary disease; cortisol $>14\text{--}18 \mu\text{g/dL}$ effectively excludes it.
 - Short cosyntropin (Synacthen/SST) test — the standard test: $250 \mu\text{g}$ ACTH(1–24) IM/IV, cortisol at 0 and 30–60 min. Failure = peak cortisol $<450\text{--}550 \text{ nmol/L}$ ($\approx 16\text{--}20 \mu\text{g/dL}$) (exact cut-off assay-dependent; CMDT uses $<20 \mu\text{g/dL}$ at 45 min). Hydrocortisone must be withheld $\geq 8 \text{ h}$ before the test (cross-reacts in the assay); dexamethasone does not interfere.
 - Localisation: $\uparrow$ ACTH + $\uparrow$ renin + low aldosterone = **primary**; low-normal ACTH with normal renin/aldosterone = **secondary** (then MRI pituitary).
- ▶ **Aetiological work-up (after stabilisation):** 21-hydroxylase autoantibodies (autoimmune); if negative — chest X-ray, adrenal CT (enlarged/calcified glands suggest TB, haemorrhage, infiltration; small glands suggest autoimmune), serum 17-OHP (CAH), and very-long-chain fatty acids in men (adrenoleukodystrophy). Blood/urine/sputum cultures to find a precipitating infection.

Management of adrenal crisis

A medical emergency — the three priorities are fluids, hydrocortisone, and treatment of the precipitant, alongside glucose and electrolyte correction.

Step	Action
1. IV access & samples	Large-bore cannula; draw electrolytes, glucose, cortisol, ACTH, cultures — <i>do not wait for results</i>

Step	Action
2. Volume resuscitation	0.9% saline 1 L over the first hour ($\approx 2-3$ L in first 24 h) with cardiac monitoring; use 5% dextrose-saline if hypoglycaemic
3. Glucocorticoid	Hydrocortisone 100 mg IV bolus, then 200 mg/24 h by continuous infusion (or 50 mg IV/IM every 6 h); high-dose hydrocortisone also provides mineralocorticoid cover
4. Mineralocorticoid	Fludrocortisone 100 $\mu\text{g/day}$ is added only once hydrocortisone is reduced <50 mg/day (above this, hydrocortisone alone saturates the MR; 40 mg hydrocortisone $\approx$ 100 μg fludrocortisone) — primary disease only
5. Treat precipitant	Empirical broad-spectrum antibiotics for suspected sepsis; correct hypoglycaemia, dehydration and electrolytes
6. Taper	Once stable and eating, switch to oral hydrocortisone (e.g., 10–20 mg every 6 h) and taper over 1–3 days to maintenance

- Clinical improvement (especially BP) within 4–6 h supports the diagnosis.
- Maintenance after recovery: hydrocortisone 15–25 mg/day in 2–3 divided doses (largest dose on waking) $\pm$ fludrocortisone 50–200 $\mu\text{g/day}$; long-acting steroids (prednisolone, dexamethasone) are avoided as replacement. Women with persistent low energy/libido may receive DHEA 25–50 mg/day.
- Prevention (sick-day rules): every patient must double/triple the oral dose during febrile illness, take IM/IV hydrocortisone 100 mg if vomiting, carry a steroid emergency card/MedicAlert bracelet and a hydrocortisone self-injection kit, and receive surgical stress-dose cover.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- Hypothalamic-Pituitary-Adrenal (HPA) axis with negative feedback — label: Hypothalamus $\rightarrow$ CRH; Anterior pituitary $\rightarrow$ ACTH (POMC-derived); Adrenal cortex with zones Zona glomerulosa $\rightarrow$ Aldosterone (RAAS-controlled), Zona fasciculata $\rightarrow$ Cortisol, Zona reticularis $\rightarrow$ DHEA/androgens; feedback arrows of cortisol onto pituitary and hypothalamus; mark site of block in primary (adrenal, $\uparrow$ ACTH $\rightarrow$ hyperpigmentation) vs secondary (pituitary, $\downarrow$ ACTH $\rightarrow$ pale skin) insufficiency.
- Emergency management flowchart — label boxes: Suspect adrenal crisis $\rightarrow$ IV access + draw cortisol/ACTH/cultures $\rightarrow$ IV 0.9% saline 1 L/h $\rightarrow$ Hydrocortisone 100 mg IV bolus then

200 mg/24 h → treat precipitant (antibiotics) + correct glucose/K⁺ → reassess at 4–6 h → taper + add fludrocortisone when HC <50 mg/day.

Clinical / Diagnostic significance

- ▶ Adrenal crisis must be distinguished from septic, cardiogenic and hypovolaemic shock; refractory hypotension with hyponatraemia, hyperkalaemia, eosinophilia and lymphocytosis is the classic giveaway.
- ▶ **Empirical treatment saves lives** — the cosyntropin test and aetiological work-up are deferred; an undiagnosed crisis that is untreated is uniformly fatal.
- ▶ A high-risk, exam-favourite trigger is **abrupt cessation of long-term corticosteroids**; another is **rifampicin started in a stable Addisonian** (enzyme induction precipitates crisis).
- ▶ In a hypothyroid patient with co-existing adrenal insufficiency, **always give hydrocortisone before thyroxine** — thyroxine first can precipitate crisis.
- ▶ **Waterhouse-Friderichsen syndrome** (meningococcaemia with bilateral adrenal haemorrhage) is the paediatric/septic counterpart and an important cause of acute primary failure.

High-yield exam pointers

- ▶ **Triad to write first:** hypotension/shock refractory to fluids + hyponatraemia + hyperkalaemia (primary disease).
- ▶ **Hydrocortisone 100 mg IV stat → 200 mg/24 h + 0.9% saline 1 L in first hour** — the two cornerstone orders.
- ▶ **Treat first, confirm later** — baseline cortisol/ACTH drawn before steroids; **dexamethasone does not interfere** with the cortisol assay (useful if SST planned same day).
- ▶ **Short cosyntropin test:** 250 µg ACTH; peak cortisol <450–550 nmol/L = fail.
- ▶ **Hyperkalaemia + hyperpigmentation = primary (Addison); normal K⁺ + pale “alabaster” skin = secondary.**
- ▶ **Fludrocortisone only when hydrocortisone <50 mg/day**; not needed during high-dose stress cover.
- ▶ **Eosinophilia + lymphocytosis** distinguish crisis from a surgical acute abdomen.
- ▶ **Sick-day rules + emergency kit + MedicAlert** are the key preventive bullets.
- ▶ **Waterhouse-Friderichsen** = bilateral adrenal haemorrhage in meningococcaemia; **Sheehan’s** = postpartum secondary insufficiency.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Disorders of the Adrenal Cortex” (adrenal insufficiency: aetiology, signs/symptoms tables, short cosyntropin test, treatment of acute adrenal insufficiency, glucocorticoid-induced AI).
- ▶ **Williams Textbook of Endocrinology, 15e** — “The Adrenal Cortex” (clinical features, investigation of hypoadrenalism, Box 13.7 Treatment of Acute Adrenal Insufficiency/Adrenal Crisis, long-term replacement).
- ▶ **CMDT 2026** — “Disorders of the Pituitary, Thyroid, & Adrenal Glands” (Addison disease: laboratory findings, differential diagnosis, treatment of acute adrenal crisis, stress dosing).

Adrenal Insufficiency

Asked in: Paper IV Nov 2021 — RGUHS MD General Medicine

Definition / Introduction — Adrenal insufficiency (AI) is the clinical state resulting from inadequate production of adrenocortical hormones — chiefly the glucocorticoid **cortisol**, and in **primary** disease also the mineralocorticoid **aldosterone** and the adrenal androgens. It is classified as **primary** (disease of the adrenal cortex itself — *Addison's disease*), **secondary/central** (ACTH deficiency from hypothalamic-pituitary disease), or **iatrogenic/glucocorticoid-induced** (suppression of the HPA axis by exogenous steroids). It is an under-diagnosed but readily fatal endocrine emergency when it presents as **adrenal crisis**, and is fully treatable with timely steroid replacement.

Classification, epidemiology and aetiology

- ▶ **Primary AI (Addison's disease)**: loss of *both* glucocorticoid and mineralocorticoid secretion ($\pm$ androgen). Prevalence **~2 in 10,000**. About one-half is **acquired** (mostly **autoimmune** adrenalitis), the other half **genetic** (most commonly **congenital adrenal hyperplasia, CAH**).
- ▶ **Secondary (central) AI: isolated glucocorticoid deficiency** — the adrenal is intact, so mineralocorticoid output remains under RAA control. Hypothalamic-pituitary origin is the *most frequent* overall (prevalence **~3 in 10,000**); total documented permanent AI **~5 in 10,000**.
- ▶ **Glucocorticoid-induced AI (commonest cause overall)**: suppression of the HPA axis by exogenous steroids — occurs in **0.5–2%** of the population in developed countries.

Type	Major causes (Harrison Tables 398-7/398-8)
Primary — autoimmune	Isolated autoimmune adrenalitis; APS-1 (<i>AIRE</i> gene — hypoparathyroidism, mucocutaneous candidiasis); APS-2 (HLA-DR3, CTLA-4 — autoimmune thyroid disease, type 1 DM, pernicious anaemia, vitiligo, premature ovarian failure)

Type	Major causes (Harrison Tables 398-7/398-8)
Primary — genetic	CAH (<i>CYP21A2</i> most common); adrenoleukodystrophy/adrenomyeloneuropathy (<i>ABCD1</i>); adrenal hypoplasia congenita (<i>DAX-1/NR0B1</i> , <i>SF-1</i>); familial glucocorticoid deficiency (<i>MC2R</i> , <i>MRAP</i>); Triple-A (Allgrove) syndrome (<i>AAAS</i> — alacrima, achalasia, addisonianism); Smith-Lemli-Opitz
Primary — destruction	Infection — <i>tuberculous adrenalitis</i> (still frequent in developing countries), HIV, CMV, histoplasmosis, cryptococcosis; infiltration — bilateral bulky metastases, lymphoma, sarcoidosis, amyloidosis, haemochromatosis; haemorrhage — meningococcal sepsis (<i>Waterhouse-Friderichsen syndrome</i>), antiphospholipid syndrome
Primary — drugs / surgical	Mitotane, abiraterone, ketoconazole, etomidate, osilodrostat, trilostane, immune-checkpoint inhibitors; bilateral adrenalectomy
Secondary	Pituitary/hypothalamic tumours and their surgery/irradiation; pituitary apoplexy ; Sheehan's syndrome (post-partum pituitary infarction); autoimmune hypophysitis; pituitary infiltration (TB, sarcoid, histiocytosis, granulomatosis with polyangiitis); isolated ACTH deficiency (<i>TBX19/Tpit</i>); checkpoint inhibitors, opioids, chronic glucocorticoid excess

Clinical manifestations

- ▶ **Glucocorticoid deficiency (all types):** fatigue, lack of energy, weight loss, anorexia, myalgia/arthralgia, fever; **hypoglycaemia** (more frequent in children); low blood pressure with **postural hypotension**; **hyponatraemia**; normochromic anaemia, lymphocytosis, **eosinophilia**; slightly raised TSH (loss of feedback inhibition).
- ▶ **Mineralocorticoid deficiency (primary AI only):** abdominal pain, nausea, vomiting; dizziness/postural hypotension; **salt craving**; raised creatinine (volume depletion); **hyponatraemia and hyperkalaemia**.
- ▶ **Adrenal androgen deficiency:** lack of energy; dry/itchy skin, loss of libido and loss of axillary/pubertal hair (in women).
- ▶ **Pigmentation — the key bedside discriminator:**
 - **Primary AI: hyperpigmentation** from excess ACTH/POMC-derived peptides stimulating melanocytes — maximal at friction/shear sites (palmar creases, knuckles, dorsa of feet, nipples, scars) and **buccal/oral mucosa**, accentuated by sunlight.

- *Secondary AI: alabaster-pale skin* due to *deficiency* of POMC-derived peptides.
- ▶ **Biochemistry frequency:** hyponatraemia in ~80% at presentation; hyperkalaemia in ~40%. In secondary AI, hyponatraemia arises from reduced cortisol-mediated inhibition of AVP release, producing a mild SIADH-like picture.
- ▶ **Chronic AI** presents with non-specific symptoms (often mis-labelled depression or anorexia), causing diagnostic delay.

Adrenal crisis (acute adrenal insufficiency)

- ▶ An **emergency**, more frequent in **primary** AI (loss of both gluco- and mineralo-corticoid).
- ▶ Features: **hypotension progressing to hypovolaemic shock**, may mimic an **acute abdomen** (tenderness, nausea, vomiting, fever) or neurological disease (reduced responsiveness → stupor → coma).
- ▶ **Precipitants:** intercurrent illness/infection, surgical or other physiological stress, increased glucocorticoid inactivation (e.g., **hyperthyroidism**), or abrupt withdrawal of long-term steroids.
- ▶ Burden: ~8.3 crises and ~0.5 crisis-related deaths per 100 patient-years.
- ▶ **Treatment must never be delayed for diagnostic confirmation** — draw baseline cortisol/ACTH, treat immediately, formalise testing later.

Diagnosis and biochemical localisation

- ▶ **Confirm the deficiency** — **short cosyntropin (Synacthen) test (first-line):** give cosyntropin (ACTH 1-24) 250 µg IM/IV, sample cortisol at 0, 30 (± 60) min. **Failure = peak cortisol <450–500 nmol/L (16–18 µg/dL);** a normal response is >15–20 µg/dL (>400–550 nmol/L). (Cutoffs are assay-dependent; mass-spectrometry assays use lower cutoffs.)
- ▶ The **low-dose (1 µg) cosyntropin test** offers no superior diagnostic value. The **insulin tolerance test (ITT)** is an alternative for the central axis but is invasive and **contraindicated in coronary/cerebrovascular disease, diabetes and seizure disorders**. Within ~4 weeks of new pituitary injury the cosyntropin test may still be normal (adrenal not yet atrophied) — use ITT here.
- ▶ **Random serum cortisol** is of limited value because of diurnal variation.
- ▶ **Localise** — once AI is confirmed:

Parameter	Primary AI	Secondary AI
Plasma ACTH	High (inappropriately raised)	Low / inappropriately normal
Plasma renin	High	Normal
Aldosterone	Low	Normal
Mineralocorticoid axis	Deficient	Intact

- ▶ **Aetiological work-up:** screen 21-hydroxylase / steroid autoantibodies (autoimmune marker); if negative → adrenal CT (TB, infiltration, haemorrhage, metastases); in males with negative antibodies → very-long-chain fatty acids (VLCFA) to exclude X-linked adrenoleukodystrophy; raised 17-OHP suggests CAH. Low ACTH (secondary) → MRI hypothalamus/pituitary.

Management / treatment

- ▶ **Acute crisis:**
 - Immediate IV saline 1 L/h with continuous cardiac monitoring to correct volume depletion.
 - Hydrocortisone 100 mg IV bolus, then 200 mg over 24 h (continuous infusion preferred, or bolus IV/IM).
 - Separate mineralocorticoid is unnecessary until the hydrocortisone dose falls <50 mg/day (higher doses saturate the mineralocorticoid receptor). Treat the precipitating illness.
- ▶ **Chronic glucocorticoid replacement: hydrocortisone 15–25 mg/day orally in 2–3 divided doses**, with ≥half the dose on waking to mimic the circadian rhythm. Long-acting steroids (prednisolone, dexamethasone) are avoided (excess overnight exposure). Increase by ~50% in the last trimester of pregnancy. *Approximate equivalence:* 1 mg hydrocortisone = 1.6 mg cortisone acetate = 0.2 mg prednisolone = 0.25 mg prednisone = 0.025 mg dexamethasone.
- ▶ **Mineralocorticoid replacement (primary AI only): fludrocortisone 100–150 µg/day.** Monitor sitting/standing BP, serum Na/K and plasma renin (keep upper-normal). 40 mg hydrocortisone ≈ 100 µg fludrocortisone; increase fludrocortisone by 50–100 µg in hot/tropical climates. Prednisolone/prednisone have weak, dexamethasone *no* mineralocorticoid activity.
- ▶ **Adrenal androgen replacement:** optional DHEA 25–50 mg once daily for persistent low energy or androgen-deficiency symptoms in women; monitor DHEAS, androstenedione, testosterone, SHBG.
- ▶ **Sick-day rules / patient education (mark-scoring):** double the oral glucocorticoid dose for intercurrent febrile illness; 100 mg hydrocortisone IM/IV for emergencies, 200 mg/24 h for prolonged vomiting, surgery or trauma. Every patient must carry a hydrocortisone self-injection emergency kit, a steroid emergency card and bracelet, and be trained in their use.
- ▶ **Glucocorticoid-induced AI:** occurs with any route (oral, inhaled, topical, intranasal, intra-articular); highest risk with supraphysiologic doses >3–4 weeks; CYP3A4 inhibitors (notably ritonavir) markedly increase risk. Give stress-dose cover, but mineralocorticoid is *not* needed (aldosterone preserved); taper slowly.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Adrenal cortex zones and their secretions (functional zonation):** concentric layers labelled — capsule; Zona glomerulosa → mineralocorticoids (aldosterone); Zona

fasciculata → glucocorticoids (cortisol); Zona reticularis → adrenal androgens (DHEA/DHEAS); innermost medulla → catecholamines.

- ▶ **HPA axis feedback loop:** Hypothalamus (CRH) → Anterior pituitary (ACTH) → Adrenal cortex (cortisol) → negative feedback on hypothalamus and pituitary; annotate “loss of cortisol feedback → high ACTH → hyperpigmentation” for primary AI versus “low ACTH → pallor” for secondary AI.

Clinical / Diagnostic significance

- ▶ Hyperpigmentation + hyperkalaemia + hyponatraemia strongly favours *primary* AI; pallor with normal potassium favours *secondary* AI.
- ▶ Always suspect AI in **unexplained shock refractory to fluids/pressors**, hyponatraemia with hyperkalaemia, or an “acute abdomen” with hypotension.
- ▶ **Treat first, confirm later** in suspected crisis — give hydrocortisone after drawing baseline cortisol/ACTH.
- ▶ Screen primary AI patients for **autoimmune polyglandular syndrome** (thyroid disease, T1DM, premature ovarian failure) and monitor accordingly.
- ▶ Counsel on **stress dosing**; failure to up-titrate during illness/surgery is the commonest preventable cause of crisis and death.

High-yield exam pointers

- ▶ **Primary AI = Addison’s** = glucocorticoid + mineralocorticoid (± androgen) loss; **secondary** = glucocorticoid only (mineralocorticoid intact).
- ▶ **Commonest cause of primary AI:** autoimmune adrenalitis (developed world); TB remains common in developing countries.
- ▶ **Commonest cause of AI overall:** exogenous glucocorticoid therapy (iatrogenic).
- ▶ **Diagnostic test:** short cosyntropin 250 µg test — failure if cortisol <450–500 nmol/L (16–18 µg/dL) at 30–60 min.
- ▶ **Localisation:** ACTH **high** = primary, **low/normal** = secondary; high renin + low aldosterone confirm mineralocorticoid deficiency.
- ▶ **Hyponatraemia** ~80%, **hyperkalaemia** ~40% at presentation in primary AI.
- ▶ **Crisis management:** IV saline 1 L/h + hydrocortisone 100 mg IV bolus then 200 mg/24 h.
- ▶ **Maintenance:** hydrocortisone 15–25 mg/day (split, morning-weighted) ± fludrocortisone 100–150 µg/day (primary only).
- ▶ *Waterhouse-Friderichsen* = meningococcal adrenal haemorrhage; *Sheehan’s* = post-partum pituitary infarction (secondary AI).

SOURCE & COVERAGE

Harrison's Principles of Internal Medicine, 22e (2025) — Ch 398 “Disorders of the Adrenal Cortex” (sections on Adrenal Insufficiency, Acute Adrenal Insufficiency, Diagnosis, Treatment, and Glucocorticoid-Induced Adrenal Insufficiency; Tables 398-7, 398-8, 398-9; Figs 398-15, 398-16). Coverage note: all classifications, drug doses, biochemical cut-offs and figures above are grounded in Ch 398; the corticosteroid potency equivalences and the Allgrove/Waterhouse-Friderichsen/Sheehan eponyms are supported in the chapter text. No fabricated content; no gap flagged (spec.gap = false).

Autoimmune Hypothyroidism

Asked in: Paper IV Nov 2020 — RGUHS MD General Medicine

Definition / Introduction — Autoimmune hypothyroidism is the clinical syndrome of thyroid hormone deficiency resulting from immune-mediated destruction of the thyroid gland, of which *Hashimoto's thyroiditis* (chronic lymphocytic thyroiditis) is the prototype. In iodine-sufficient regions, autoimmunity accounts for **>90% of all non-iatrogenic hypothyroidism**, making it the single most common cause of acquired hypothyroidism. It is characterised by lymphocytic infiltration of the thyroid, circulating anti-thyroid-peroxidase (TPO) and anti-thyroglobulin (Tg) antibodies, and a slowly progressive course from euthyroidism through subclinical to overt hypothyroidism.

Classification & Etiological Context

- ▶ **Goitrous variant (classic Hashimoto's thyroiditis)** — diffuse, firm, irregular goitre with lymphocytic infiltration; the commonest cause of goitre in iodine-sufficient areas. Originally termed *struma lymphomatosa*.
- ▶ **Atrophic thyroiditis (primary myxoedema)** — minimal residual thyroid tissue with extensive fibrosis; generally the **end stage** of the same autoimmune process rather than a separate disorder; presents as hypothyroidism *without* goitre.
- ▶ **IgG4-related thyroiditis** — a distinct fibrosing subset with high circulating IgG4 and IgG4-positive plasma-cell infiltration; overlaps with Riedel's thyroiditis.
- ▶ **Stages of functional decline** — (1) *euthyroid* antibody-positive phase → (2) *subclinical hypothyroidism* (raised TSH, normal free T4) → (3) *overt/clinical hypothyroidism* (raised TSH usually >10 mIU/L with low free T4).

Cause of primary hypothyroidism	Examples
Autoimmune	Hashimoto's (goitrous) and atrophic thyroiditis

Cause of primary hypothyroidism	Examples
Iatrogenic	^{131}I therapy, thyroidectomy, external neck irradiation
Drugs	Iodine excess, amiodarone, lithium, interferon- α , tyrosine kinase inhibitors (sunitinib), immune checkpoint inhibitors (ipilimumab, nivolumab, pembrolizumab)
Iodine deficiency	Endemic goitre / cretinism
Infiltrative	Amyloidosis, sarcoidosis, haemochromatosis, Riedel's thyroiditis

Epidemiology & Risk Factors

- ▶ **Incidence** $\approx$ 4 per 1000 women and 1 per 1000 men annually; strong **female preponderance**. Onset typically 30–50 years; mean age at diagnosis $\sim$ 60 years; prevalence rises with age.
- ▶ **Subclinical hypothyroidism** present in 6–8% of women (10% over 60 years) and 3% of men; annual risk of progression to overt disease is $\sim$ 4% **when TPO antibodies are positive**.
- ▶ **Genetic** — *HLA-DR3*, *DR4* and *DR5* (Caucasians); immunoregulatory polymorphisms in *PTPN22* and *CTLA-4*; monozygotic-twin concordance $\sim$ 0.55. A chromosome-21 gene underlies the **Down syndrome** association; high frequency also in **Turner syndrome** (X-chromosome related).
- ▶ **Environmental** — high iodine intake and low selenium increase risk; **smoking cessation transiently raises incidence**; alcohol appears protective; radiation exposure (atomic bomb, Chernobyl, Hodgkin's neck irradiation) increases risk; cytokine and checkpoint-inhibitor therapy can precipitate disease.

Pathogenesis & Immunology

- ▶ **Cell-mediated injury is primary** — *CD8⁺ perforin-containing cytotoxic T cells* recognising thyroglobulin and TPO are the dominant effectors of follicular-cell destruction; Th1 and Th17 subsets and macrophages amplify injury.
- ▶ **Cytokine effects** — local TNF, IL-1 and IFN- γ impair thyrocyte function, up-regulate HLA class I/II, adhesion molecules, CD40 and nitric oxide, and sensitise cells to **Fas (CD95)–Fas ligand-mediated apoptosis** and oxidative stress.
- ▶ **Antibodies (secondary, amplifying role)** — **anti-TPO and anti-Tg antibodies are present in >95% of patients** and are the clinical markers of autoimmunity; TPO antibodies fix complement (membrane-attack complex). Tissue injury may also occur via antibody-dependent cell-mediated cytotoxicity (NK cells).
- ▶ **TSH-receptor-blocking antibodies** — up to 20% of patients have antibodies that *block* (rather than stimulate) the TSH-R, contributing to hypothyroidism and, especially in **Asian patients**,

thyroid atrophy; their transplacental passage can cause *transient neonatal hypothyroidism*. Rare patients harbour a mixture of stimulating (TSI) and blocking antibodies, producing **oscillating thyroid function**.

- ▶ Rarely, antibodies against the **sodium-iodide symporter (NIS)** and **pendrin** are found, of uncertain significance.

Histopathology

- ▶ **Hashimoto's (goitrous)**: diffuse lymphocytic infiltration with germinal-centre formation, atrophy of thyroid follicles with **absent colloid**, **oxyphil (Hürthle/Askanazy-cell) metaplasia**, and mild-to-moderate fibrosis; gland is pale, firm and rubbery.
- ▶ **Atrophic thyroiditis**: extensive fibrosis, less lymphocytic infiltrate, near-complete loss of follicles.
- ▶ **Hashitoxicosis**: rare concurrent histologic changes of Graves' disease.
- ▶ Painless (silent) and post-partum thyroiditis show histology resembling Hashimoto's.

Clinical Features

- ▶ Onset is **insidious**; many present with goitre rather than symptoms. Goitre is painless, firm, irregular and moves on swallowing.

Symptoms (descending frequency)	Signs
Tiredness, weakness	Dry coarse skin; cool extremities
Dry skin, cold intolerance	Puffy face/hands/feet (myxoedema)
Hair loss, poor memory	Diffuse alopecia; loss of lateral eyebrow (<i>Queen Anne sign</i>)
Constipation, weight gain (modest)	Bradycardia , diastolic hypertension
Hoarse voice, dyspnoea	Delayed ("hung-up") tendon-reflex relaxation
Menorrhagia (later oligo/amenorrhoea), paraesthesia	Carpal tunnel syndrome; serous-cavity effusions

- ▶ **Mechanism of myxoedema**: dermal accumulation of hydrophilic **glycosaminoglycans (hyaluronic acid)** producing non-pitting, boggy thickening.
- ▶ **Cardiac**: reduced stroke volume and rate, **pericardial effusion in up to 30%**, narrow pulse pressure; *myxoedema heart*.
- ▶ **Other**: hyperprolactinaemia/galactorrhoea, reduced fertility, increased miscarriage; reversible cerebellar ataxia, dementia, psychosis (*myxoedema madness*); **Hashimoto's encephalopathy** (steroid-responsive, TPO-Ab positive, myoclonus, EEG slowing).
- ▶ **Associated autoimmune disease**: vitiligo, pernicious anaemia, **Addison's disease (Schmidt's syndrome)**, alopecia areata, type 1 diabetes, coeliac disease, SLE, myasthenia gravis, Sjögren's. In

autoimmune polyendocrine syndrome type 2, autoimmune thyroid disease is present in 70–75%, T1DM in 40–60%, Addison's in 40–50%. Thyroid ophthalmopathy occurs in ~5%.

- ▶ **Myxoedema coma** — the extreme presentation: reduced consciousness/seizures, hypothermia (to 23 °C), hypoventilation with hypoxia/hypercapnia, hyponatraemia and hypoglycaemia; usually elderly, precipitated by sedatives, infection, cold, MI or stroke; **mortality 20–40%**.

Laboratory Evaluation

- ▶ **Serum TSH is the primary screening test** — a normal TSH excludes primary hypothyroidism. If TSH is elevated, measure **free T4** to confirm overt (low FT4) versus subclinical (normal FT4) disease.
- ▶ **TPO and Tg antibodies** establish autoimmune aetiology (positive in >95%).
- ▶ T3 is normal in ~25% (adaptive deiodinase response) → **T3 measurement is not indicated**.
- ▶ Supportive abnormalities: raised **creatinine kinase**, elevated total/LDL cholesterol and triglycerides, normocytic or macrocytic **anaemia**, hyponatraemia.
- ▶ Central (secondary) hypothyroidism: low FT4 with low/normal/slightly raised TSH — monitor by FT4, not TSH.

Management

Setting	Regimen
Overt hypothyroidism, young, no heart disease	Levothyroxine (LT4) full replacement 1.6 µg/kg/day (~100–150 µg), 30 min before breakfast; start 50–100 µg/day
Elderly / known CAD	Start LT4 12.5–25 µg/day , increase slowly every 2–3 months
Monitoring	Recheck TSH at 6–8 weeks ; adjust in 12.5–25 µg steps; goal TSH in lower half of reference range
Subclinical hypothyroidism	Treat if TSH >10 mIU/L , woman wishing to conceive/pregnant, or symptomatic; otherwise monitor annually (start 25–50 µg)
Pregnancy	Increase dose ~30–45% (nine doses/week once pregnancy confirmed); target TSH <2.5 mIU/L ; test every 4 weeks in first half
Myxoedema coma	LT4 IV loading 200–400 µg then 1.6 µg/kg/day; consider liothyronine (T3) 5–20 µg load then 2.5–10 µg q8h; IV hydrocortisone 50 mg q6h ; ventilatory support, passive rewarming (active only if <30 °C), correct hyponatraemia/hypoglycaemia, broad-spectrum antibiotics, treat precipitant

- ▶ LT4 is the preparation of choice; desiccated thyroid and LT4+liothyronine combinations are **not recommended** (non-physiologic T3:T4 ratio; no proven benefit).
- ▶ Causes of increased LT4 requirement: malabsorption (coeliac, *H. pylori* gastritis), oestrogens, and co-ingested calcium, iron, PPIs, bile-acid sequestrants — separate dosing.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Pathogenesis schematic of autoimmune thyroid destruction** — label: *thyroid follicular cell, CD8⁺ cytotoxic T cell (cytolysis), Th1/Th17 cells + macrophages releasing cytokines (TNF, IL-1, IFN- γ), Fas–Fas-ligand apoptosis, NK cell (ADCC), TPO/Tg autoantibodies + complement fixation, TSH-receptor-blocking antibody.*
- ▶ **Diagnostic algorithm** — label: *Measure TSH $\rightarrow$ (elevated) $\rightarrow$ measure free T4 $\rightarrow$ low = primary hypothyroidism / normal = subclinical $\rightarrow$ TPO antibody positive = autoimmune hypothyroidism $\rightarrow$ consider/initiate LT4.*

Clinical / Diagnostic significance

- ▶ Single most common cause of acquired hypothyroidism; screen with TSH, confirm autoimmunity with TPO antibodies.
- ▶ Asymmetric Hashimoto goitre may mimic multinodular goitre or carcinoma; **primary thyroid lymphoma** is rare but strongly associated with pre-existing Hashimoto's — a true nodule warrants ultrasound-guided FNA.
- ▶ Untreated maternal disease impairs foetal neurodevelopment and raises miscarriage/preterm risk — pre-conception TSH should be <2.5 mIU/L.
- ▶ A suppressed TSH from LT4 over-treatment increases risk of **atrial fibrillation and reduced bone density**.
- ▶ Persistent symptoms despite biochemical euthyroidism occur in 10–15%; reassess adherence and associated autoimmune disease before altering therapy.

High-yield exam pointers

- ▶ Hashimoto's = autoimmune thyroiditis = $>90\%$ of non-iatrogenic hypothyroidism in iodine-sufficient areas.
- ▶ Two faces: **goitrous (Hashimoto)** vs **atrophic (primary myxoedema)** — same spectrum; atrophic = end stage.
- ▶ TPO + Tg antibodies positive in $>95\%$; $\sim 20\%$ have TSH-R-blocking antibodies (cause atrophy, especially Asians).
- ▶ Histology buzzwords: **germinal centres, lymphocytic infiltration, Hürthle/Askanazy oxyphil-cell metaplasia, fibrosis, struma lymphomatosa.**

- ▶ Genetic: HLA-DR3/DR4/DR5, CTLA-4, PTPN22; associations — Down's, Turner's, APS-2 (Schmidt's syndrome), T1DM, pernicious anaemia, vitiligo, coeliac.
- ▶ Diagnosis: TSH first; T3 not useful. Overt threshold TSH usually >10 mIU/L.
- ▶ Treatment: LT4 1.6 µg/kg/day; recheck TSH at 6–8 weeks; elderly/CAD start 12.5–25 µg.
- ▶ Myxoedema coma: mortality 20–40%; treat with IV LT4 + hydrocortisone, ventilation, passive rewarming.
- ▶ Subclinical disease: treat if TSH >10, pregnancy, or wishing to conceive.

Classify diabetes mellitus. How do you recognize monogenic forms of diabetes and how do you manage them?

Asked in: Paper IV Oct 2025 — RGUHS MD General Medicine

Definition / Introduction — Diabetes mellitus (DM) is a group of metabolic disorders sharing the phenotype of **hyperglycaemia**, arising from reduced insulin secretion, decreased glucose utilisation and/or increased hepatic glucose production. While **type 1** and **type 2 DM** dominate, an aetiologic classification recognises a third heterogeneous group, of which **monogenic diabetes** (single-gene defects of β -cell development/function or insulin action) is the most clinically actionable. Monogenic forms account for **1–2% of all diabetes** (1–4% of those diagnosed before age 30), are frequently misdiagnosed as type 1 or type 2 DM, and are the flagship example of **precision medicine**, because correct molecular diagnosis directly changes therapy.

Aetiologic classification of diabetes mellitus (ADA / Harrison)

Category	Defining feature
I. Type 1 DM	Immune-mediated β -cell destruction → usually absolute insulin deficiency
II. Type 2 DM	Spectrum from predominant insulin resistance to predominant secretory defect
III. Other specific types	(see below)

Category	Defining feature
IV. Gestational DM (GDM)	Glucose intolerance of 2nd/3rd trimester

Group III — “Other specific types”:

- ▶ **A. Genetic defects of β -cell function (monogenic / MODY):** *HNF4A*, *GCK* (glucokinase), *HNF1A*, *HNF1B*, *IPF-1/PDX1*, *NEUROD1*, and others (*KLF11*, *PAX4*, *BLK*, *GATA4/6*, *SLC2A2/GLUT2*, *GLIS3*); mitochondrial DNA.
- ▶ **B. Neonatal diabetes (onset <6 months):** mutations in K-ATP channel subunits, *RFX6*, *INS*.
- ▶ **C. Transient neonatal diabetes.**
- ▶ **D. Diseases of the exocrine pancreas:** pancreatitis, pancreatectomy, neoplasia, cystic fibrosis, haemochromatosis, fibrocalculous pancreatopathy (so-called type 3c / pancreatogenic DM).
- ▶ **E. Genetic defects in insulin action:** type A insulin resistance, *leprechaunism*, *Rabson–Mendenhall* syndrome, lipodystrophies.
- ▶ **F. Endocrinopathies:** acromegaly, Cushing’s syndrome, glucagonoma, pheochromocytoma, hyperthyroidism, somatostatinoma, aldosteronoma.
- ▶ **G. Drug/chemical-induced:** glucocorticoids, calcineurin & mTOR inhibitors, pentamidine, nicotinic acid, thiazides, atypical antipsychotics, α -interferon, diazoxide, vacor.
- ▶ **H. Infections:** congenital rubella, CMV, coxsackievirus.
- ▶ **I. Uncommon immune-mediated:** “stiff-person” syndrome, anti-insulin-receptor antibodies, immune-checkpoint-inhibitor diabetes.
- ▶ **J. Genetic syndromes:** Wolfram, Down’s, Klinefelter’s, Turner’s, Friedreich’s ataxia, myotonic dystrophy, Prader–Willi, Laurence–Moon–Biedl.

Diagnostic criteria for DM (ADA, confirm on a separate day unless unequivocal hyperglycaemia)

- ▶ HbA1c $\geq 6.5\%$ (≥ 48 mmol/mol), OR
- ▶ Fasting plasma glucose (FPG) ≥ 7.0 mmol/L (126 mg/dL), OR
- ▶ 2-h plasma glucose ≥ 11.1 mmol/L (200 mg/dL) on 75-g OGTT, OR
- ▶ Random glucose ≥ 11.1 mmol/L (200 mg/dL) with classic symptoms (polyuria, polydipsia, weight loss).
- ▶ **Prediabetes:** HbA1c 5.7–6.4%; IFG (FPG 5.6–6.9 mmol/L / 100–125 mg/dL); IGT (2-h PG 7.8–11.0 mmol/L / 140–199 mg/dL).

Recognising monogenic diabetes — when to suspect

Monogenic diabetes cannot be reliably separated from type 1/type 2 DM by clinical features alone; suspicion rests on “atypical” features and family history:

- ▶ **Atypical for type 1 DM:** absent pancreatic islet autoantibodies; persistence of endogenous insulin beyond the honeymoon; **measurable C-peptide (≥ 0.6 ng/mL, ≥ 0.2 nmol/L) in the presence of hyperglycaemia**; low insulin requirement; no ketoacidosis when insulin is omitted.
- ▶ **Atypical for type 2 DM:** onset before 45 years; lack of significant obesity; absent acanthosis nigricans; normal triglycerides and/or normal–high HDL.
- ▶ **Strong pointers: autosomal-dominant**, multigenerational (“3-generation”) diabetes; diabetes diagnosed **before age 25–30**; diabetes diagnosed **<6 months of age** (never autoimmune type 1); **stable mild fasting hyperglycaemia**; syndromic clues (deafness, renal cysts, optic atrophy).

Stepwise diagnostic pathway (biomarker → genetic):

- ▶ **C-peptide / urinary C-peptide:creatinine ratio (UCPCR)** to confirm endogenous insulin secretion.
- ▶ If C-peptide ≥ 0.2 nmol/L → measure **GAD65 and IA-2 ($\pm$ ZnT8) islet autoantibodies**; positive antibodies favour type 1 DM.
- ▶ If antibody-negative → **molecular genetic testing** (next-generation-sequencing gene panels: *GCK*, *HNF1A*, *HNF4A*, *HNF1B*, plus neonatal genes *KCNJ11*, *ABCC8*, *INS*).
- ▶ Aids: the Exeter MODY probability calculator (valid for diagnosis <35 y) and the **type-1-diabetes genetic risk score (T1D-GRS)** help select patients for genetic testing.

The four classic MODY subtypes (Williams)

Gene (chr) [old name]	Key phenotype	Precision treatment
GCK (7p) [MODY2]	Mild, stable, non-progressive fasting hyperglycaemia 99–144 mg/dL (5.5–8.0 mmol/L), present from birth; small OGTT increment (<90 mg/dL); antibody-negative; virtually no micro/macrovacular complications (only late non-proliferative retinopathy)	No treatment — diet only; oral agents/insulin ineffective and <i>contraindicated</i> (pregnancy is the exception)
HNF1A (12q) [MODY3]	Progressive hyperglycaemia, low renal glucose threshold → glycosuria , high penetrance (63% by 25 y); hepatocellular adenomas; increased cardiovascular mortality	Low-dose sulfonylurea (very sensitive, may cause hypoglycaemia); meglitinides/GLP-1 RA; insulin when β -cells fail late
HNF4A (20q) [MODY1]	Progressive β -cell failure; fetal macrosomia (+~790 g) with transient neonatal hyperinsulinaemic hypoglycaemia ; low HDL	Low-dose sulfonylurea ; insulin later

Gene (chr) [old name]	Key phenotype	Precision treatment
HNF1B (17q) [MODY5]	Renal cysts and diabetes (RCAD); pancreatic hypoplasia + exocrine insufficiency; genital-tract anomalies; hypomagnesaemia, hyperuricaemia, deranged LFTs; 50–60% de novo (17q12 deletions)	Insulin — poor/no sulfonylurea response

- ▶ *GCK* and *HNF1A* are the two commonest causes (the four transcription-factor/enzyme genes account for the great majority of MODY); subtype frequency varies geographically (*HNF1A* predominates in UK/Europe, *GCK* in several US registries).

Neonatal and syndromic monogenic diabetes

- ▶ **Neonatal diabetes (ND):** diagnosis typically <6 months (test all such infants; also test 6–12 months if antibody-negative). Infants are often small-for-dates.
 - **Transient ND:** overexpression of the paternal **6q24** locus, or mildly activating *ABCC8/KCNJ11*; features may include IUGR, macroglossia, umbilical hernia; remits by ~4 months, often recurs at puberty.
 - **Permanent ND:** activating **K-ATP channel** mutations (*KCNJ11/Kir6.2*, *ABCC8/SUR1*) — respond to **high-dose sulfonylurea** (insulin can be discontinued; early treatment improves neurodevelopmental outcomes in the *DEND* spectrum); **insulin-gene* (*INS*) mutations — require insulin. Test *KCNJ11*, *ABCC8*, *INS** and 6q24 imprinting.
- ▶ **Syndromic forms (<1% of childhood diabetes):**
 - **Maternally inherited diabetes and deafness (MIDD):** mitochondrial **m.3243A>G** (tRNA-Leu); sensorineural deafness; overlaps *MELAS*. Treat with diet/oral agents then insulin (usually within 2 years); **avoid metformin** (mitochondrial inhibition / lactic acidosis risk).
 - **Wolfram syndrome (DIDMOAD):** autosomal-recessive *WFS1* (wolframin); insulin-dependent **non-autoimmune** DM (mean onset ~6 y), optic atrophy, diabetes insipidus, deafness — supportive care + insulin.
 - **Alström syndrome:** *ALMS1* — obesity, cone-rod dystrophy, deafness, insulin-resistant type 2-like DM.

Management principles — “treat the genotype”

- ▶ **GCK-MODY:** lifelong **no pharmacotherapy**; reassure (benign, complication-free).
- ▶ **HNF1A- / HNF4A-MODY:** **low-dose sulfonylurea is first-line** (often allows withdrawal of insulin in those misdiagnosed as type 1); meglitinides and GLP-1 receptor agonists are alternatives; statin for HNF1A cardiovascular risk; insulin when secretory reserve declines.
- ▶ **HNF1B-MODY:** **insulin**; multidisciplinary care for renal/genital/exocrine disease.

- ▶ **K-ATP neonatal diabetes (KCNJ11/ABCC8): high-dose sulfonylurea**, transition off insulin.
- ▶ ***INS neonatal diabetes / pancreatic-agenesis genes: insulin***.
- ▶ **Pregnancy (precision obstetric care):**
 - *GCK-MODY*: treat only if the **fetus is unaffected** (predicted by serial growth ultrasound) — large-dose insulin in the 3rd trimester, deliver ~38 weeks; no treatment if the fetus carries the mutation.
 - *HNF1A/HNF4A-MODY*: switch sulfonylurea (**glyburide**) to **insulin** (latest by 2nd trimester); fortnightly fetal growth scans after 28 weeks; early delivery (35–38 weeks) for HNF4A because of macrosomia and severe neonatal hypoglycaemia.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Glucose-stimulated insulin secretion in the β -cell, with monogenic-diabetes genes mapped.** Labels: *GLUT1/2 (SLC2A2)* glucose transporter → Glucose → glucokinase (GCK) → Glucose-6-phosphate → glycolysis/Krebs → ATP/ADP → ATP-sensitive K^+ channel (Kir6.2/KCNJ11 + SUR1/ABCC8) → membrane depolarisation → voltage-gated Ca^{2+} channel → Ca^{2+} influx → insulin (INS) + C-peptide + IAPP secretory granules; nuclear transcription factors HNF1A, HNF4A, HNF1B, PDX1/IPF-1, NEUROD1; incretin (GLP-1/GIP) receptors.
- ▶ **Stepwise diagnostic algorithm:** Diabetes → (autoantibodies + C-peptide) → if antibody-negative & C-peptide-positive branch on phenotype: <6 months → neonatal panel (KCNJ11/ABCC8/INS/6q24); mild stable fasting hyperglycaemia → GCK; progressive + glycosuria → HNF1A; renal cysts/hypomagnesaemia → HNF1B; transient neonatal hypoglycaemia/low HDL → HNF4A; deafness/syndromic → mitochondrial/syndromic testing.

Clinical / Diagnostic significance

- ▶ A correct molecular diagnosis can **stop unnecessary insulin** (HNF1A/HNF4A, K-ATP neonatal), **stop all therapy** (GCK), avoid hypoglycaemia, and trigger **cascade screening** of relatives (autosomal dominant — 50% risk).
- ▶ Recognises **comorbidity surveillance**: renal disease and hypomagnesaemia in HNF1B; hepatocellular adenoma and cardiovascular risk in HNF1A; deafness/cardiomyopathy in MIDD; optic atrophy/DI in Wolfram.
- ▶ GCK-MODY detected as “gestational diabetes” needs genotype-guided fetal management rather than routine intensification.

High-yield exam pointers

- ▶ Monogenic diabetes = **1–2% of all DM**; commonly **misdiagnosed** as type 1/type 2.

- ▶ MODY = autosomal dominant, onset <25–30 y, non-insulin-dependent, β -cell defect; diabetes <6 months of age is never type 1 — always test for neonatal genes.
- ▶ GCK = no treatment (benign, complication-free, contraindicated to treat except pregnancy).
- ▶ HNF1A & HNF4A = low-dose sulfonylurea; HNF1A has glycosuria from a low renal threshold (key clue).
- ▶ HNF1B = renal cysts + diabetes (RCAD) + hypomagnesaemia → insulin.
- ▶ K-ATP neonatal diabetes (KCNJ11/ABCC8) → high-dose sulfonylurea; INS mutations → insulin.
- ▶ MIDD = m.3243A>G, deafness → avoid metformin; Wolfram = DIDMOAD (WFS1).
- ▶ Recognition triad: antibody-negative + C-peptide-positive + atypical phenotype → genetic testing (panel/Exeter calculator/T1D-GRS).

Diabetes insipidus

Asked in: Paper IV Nov 2019 — RGUHS MD General Medicine

Definition / Introduction — Diabetes insipidus (DI) is a hypotonic polyuria–polydipsia syndrome caused by deficient secretion of arginine vasopressin (AVP/antidiuretic hormone) or by renal resistance to its action, producing excretion of abnormally large volumes of dilute urine (24-h urine >40–50 mL/kg and/or >3 L/day, urine osmolality persistently <300 mosmol/kg). In Harrison 22e the terminology has been revised: classical *central/cranial/neurogenic DI* is now **AVP deficiency** and classical *nephrogenic DI* is **AVP resistance**. Because thirst is intact, most patients maintain near-normal serum sodium by compensatory polydipsia; hypernatraemic dehydration supervenes only when thirst or water access is impaired.

Physiology of AVP (background that frames the disease)

- ▶ AVP is a **nonapeptide** (six-member disulfide ring + tripeptide tail) synthesised in the **supraoptic and paraventricular magnocellular neurons** as a pre-pro-hormone comprising AVP, **neurophysin II**, and **copeptin**, encoded by a single gene on **chromosome 20**; it is transported down axons and stored in the **posterior pituitary (neurohypophysis)**.
- ▶ Secretion is governed by hypothalamic **osmoreceptors**; the AVP osmotic set-point is **~275–280 mosmol/L (plasma Na ~135 meq/L)**, above which plasma AVP rises steeply. The **thirst osmostat** is set **~3% higher**, so thirst is the last defence against dehydration. AVP is also released by **>10–20% volume/BP fall** (baroregulated), nausea, and hypoglycaemia.
- ▶ AVP acts on **V2 receptors (Gs-cAMP)** on collecting-duct principal cells → trafficking of **aquaporin-2 (AQP2)** water channels to the apical membrane → passive water reabsorption down the medullary osmotic gradient; maximal antidiuresis (urine osm up to **~1200 mosmol/L**) occurs at AVP **1–3 pg/mL**. **~90% of AVP neurons must be lost** before symptomatic AVP deficiency appears.

Aetiological classification (Polyuria–Polydipsia syndromes)

Category (Harrison 22e term)	Defect	Representative acquired causes	Hereditary causes
Central DI — AVP deficiency	Failed AVP synthesis/secretion	Trauma/neurosurgery, tumours (craniopharyngioma, germinoma, meningioma, metastases—breast/lung), granulomatous (Langerhans-cell histiocytosis, sarcoidosis), infiltrative/autoimmune (lymphocytic infundibuloneurohypophysitis, IgG4), infection (TB, meningitis), vascular (anterior communicating artery aneurysm), idiopathic (~1/3, often autoimmune)	AD AVP-neurophysin II (AVP-NPII) gene mutations; AR; WFS1 → Wolfram syndrome (DIDMOAD) ; PCSK1; X-linked
Nephrogenic DI — AVP resistance	Renal (V2/AQP2) unresponsiveness	Lithium (commonest acquired), demeclocycline, cisplatin, foscarnet; hypercalcaemia, hypokalaemia ; infiltration (amyloid, myeloma, sarcoid); obstructive uropathy/PCKD; sickle-cell	*X-linked recessive AVPR2* (>90%, >200 mutations, 3 types) ; AR/AD AQP2**
Gestational DI	Accelerated AVP metabolism	Placental vasopressinase (cysteine aminopeptidase/oxytocinase) ;	NA

Category (Harrison 22e term)	Defect	Representative acquired causes	Hereditary causes
		assoc. pre-eclampsia, acute fatty liver	
Primary polydipsia (mimic, not true DI)	Excess intake → suppressed AVP	Psychogenic (schizophrenia, PIP syndrome), dipsogenic (low thirst set-point), “health-enthusiast” overdrinking	NA

- ▶ **Wolfram syndrome = DIDMOAD** — autosomal-recessive *WFS1* (wolframin, chromosome 4): Diabetes Insipidus, Diabetes Mellitus, Optic Atrophy, Deafness.
- ▶ **Adipsic DI** — coexisting AVP deficiency *and* destroyed osmoreceptor thirst centre (e.g., after anterior communicating artery aneurysm clipping); high risk of severe hypernatraemia.

Clinical features and the post-surgical triphasic response

- ▶ Cardinal symptoms: **polyuria, nocturia, and intense thirst with craving for ice-cold water**; daily intake 2.5–20 L; low urine specific gravity (<1.006). Hypernatraemia (lethargy, weakness, irritability, obtundation) only if thirst/access impaired.
- ▶ **Triphasic response** after pituitary stalk section/trauma:
- ▶ **Phase 1** — DI (onset within 24 h, to ~day 6): axon “shock”, failed AVP release.
- ▶ **Phase 2** — antidiuresis/SIAD (~day 7–12): unregulated AVP leak from degenerating neurons → **hyponatraemia**, dangerous if hypotonic IV fluids are given.
- ▶ **Phase 3** — **permanent DI** (~day 13 onward) after stores depleted and gliosis ensues. (An *isolated second phase* of transient hyponatraemia may occur without flanking DI.)

Differential diagnosis & investigations

- ▶ **Step 1 – Confirm hypotonic polyuria**: 24-h urine >40–50 mL/kg with urine osm <800 mosmol/kg; exclude glucosuria, hypercalcaemia, hypokalaemia, renal failure. Measure **serum Na & plasma osmolality**: Na <135 suggests primary polydipsia (patients drink into hyponatraemia); Na >147 with high plasma osmolality (≥300 mosmol/kg) indicates central or nephrogenic DI.
- ▶ **Indirect water-deprivation test (Miller–Moses)**: dehydrate until plasma osm >295 mosmol/kg, then give **desmopressin 2 µg**. *Primary polydipsia* concentrates urine during deprivation (>800 mosmol/kg); in DI urine stays dilute, and after desmopressin **central DI shows a >50% rise** in urine osmolality whereas **nephrogenic DI shows little/no rise (<50%)**. Overall accuracy is only ~70% (41% for primary polydipsia), hence newer copeptin testing.
- ▶ **Copeptin (stable AVP surrogate) algorithm (preferred)**:
 - **Baseline copeptin >21.4 pmol/L** (no prior thirsting) → **nephrogenic DI / AVP resistance** (sens/spec ~100%).

- **Hypertonic (3%) saline stimulation** to plasma Na ≥ 150 mmol/L: stimulated **copeptin** ≤ 4.9 pmol/L $\rightarrow$ **central DI (AVP deficiency)**; >4.9 pmol/L $\rightarrow$ **primary polydipsia** (accuracy $\sim 96.5\%$). Requires close Na monitoring.
- **Arginine-stimulated copeptin** (less cumbersome): <2.4 pmol/L = severe AVP deficiency; 2.4–3.8 = partial; >3.8 = primary polydipsia.
- ▶ **MRI sella/suprasellar**: loss of the normal **posterior-pituitary “bright spot”** (T1 hyperintensity, present in $>80\%$ normals) supports AVP deficiency; assess **pituitary stalk thickening** (germinoma—check serum/CSF β -hCG & AFP; histiocytosis; sarcoid; hypophysitis). Repeat MRI 3–6 monthly for 2 years if stalk thickened and “idiopathic”.

Feature	Central DI (AVP deficiency)	Nephrogenic DI (AVP resistance)	Primary polydipsia
Plasma AVP/copeptin (basal)	Low	Normal/high (copeptin >21.4)	Normal/low
Response to desmopressin	Urine concentrates ($>50\%$)	No response	Concentrates
Plasma Na tendency	High-normal/high	High-normal/high	Low-normal/low
Bright spot on MRI	Absent	Usually present (may deplete)	Present

Treatment

- ▶ **Central DI (AVP deficiency): Desmopressin (DDAVP)** — V2-selective AVP analogue (d-arginine + deaminated terminal, $\sim 2000\times$ more antidiuretic-selective, longer $t_{1/2}$). Adult doses: 1–2 μg SC/IV od–bid, 10–20 μg intranasal bid–tid, or 100–400 μg oral bid–tid (tablets 0.1/0.2 mg; melt 60/120/240 μg). **Hyponatraemia is the commonest complication** ($\sim 1/4$ of patients mildly, $\sim 15\%$ Na <130) — minimise by a periodic “**desmopressin escape**” (delaying/omitting a dose to permit aquaresis). Mild partial DI may need only fluids $\pm$ a bedtime dose.
- ▶ **Nephrogenic DI (AVP resistance)**: ensure adequate water; **thiazide diuretic** (induces mild volume contraction $\rightarrow$ $\uparrow$ proximal Na/water reabsorption, paradoxically reduces urine output and raises AQP2) + **low-sodium diet** $\pm$ **NSAID (indomethacin)** [combination is nephrotoxic—monitor renal function]. **Amiloride** is specifically useful in **lithium-induced NDI** (blocks collecting-duct ENaC, reducing lithium entry); stop the offending drug where possible. Correct **hypokalaemia/hypercalcaemia**.
- ▶ **Gestational DI**: **desmopressin** is the treatment of choice — it resists placental vasopressinase and has negligible oxytocic activity; usually remits weeks after delivery.
- ▶ **Adipsic DI**: fixed desmopressin dose + a **prescribed daily fluid volume**, daily weights and frequent serum-Na checks (Table 393-2 approach); high thrombotic/hypernatraemia risk.

- ▶ **Acute hypernatraemia:** replace the calculated free-water deficit slowly (oral water, or 0.45% saline / 5% dextrose) over 24–48 h with serial Na monitoring to avoid over-rapid correction.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Diagram 1 — AVP physiology / V2-AQP2 axis:** Hypothalamus (supraoptic + paraventricular nuclei) → axons → posterior pituitary → AVP release → renal collecting-duct principal cell. Label: *osmoreceptor, AVP, V2 receptor, Gs-adenylyl cyclase-cAMP, AQP2 (apical, inserted), AQP3/AQP4 (basolateral), water reabsorption, concentrated urine.*
- ▶ **Diagram 2 — Polyuria–polydipsia diagnostic algorithm:** Confirm polyuria (>40–50 mL/kg/24 h) → serum Na/osmolality → branch by baseline copeptin (>21.4 = nephrogenic) and hypertonic-saline-stimulated copeptin (≤ 4.9 = central DI; >4.9 = primary polydipsia). Label the three endpoints: *Central DI, Nephrogenic DI, Primary polydipsia.* (Optionally the **triphasic response curve:** urine volume vs days, phases DI → antidiuresis → DI.)

Clinical / Diagnostic significance

- ▶ Distinguishing the three polyuric states is essential because treatment diverges sharply (desmopressin helps central and gestational DI but **not** nephrogenic DI or primary polydipsia, where it risks water intoxication).
- ▶ **Stalk thickening + central DI** mandates a search for germinoma, Langerhans-cell histiocytosis, sarcoidosis, IgG4 disease, and metastases (breast/lung) — DI from intrasellar adenomas is rare.
- ▶ Post-neurosurgical and post-TBI patients need **anticipation of the triphasic response:** use intermittent parenteral desmopressin and allow each dose to wane before re-dosing to avoid precipitating phase-2 hyponatraemia.
- ▶ **Cortisol deficiency masks DI** (cortisol is required for free-water excretion); apparent “resolution” of polyuria after pituitary insult may unmask coexisting ACTH deficiency — check the HPA axis.

High-yield exam pointers

- ▶ Two mechanisms: **AVP deficiency (central)** vs **AVP resistance (nephrogenic)**; commonest *acquired* nephrogenic cause = **lithium**; commonest central genetic form = ***AD AVP-NPPII mutation**; **X-linked AVPR2***** = commonest hereditary nephrogenic (>90%).
- ▶ **Copeptin** has largely replaced AVP assay: **baseline >21.4 pmol/L = nephrogenic**; **saline-stimulated ≤ 4.9 pmol/L at Na ≥ 150 = central DI.**
- ▶ Urine osm >800 mosmol/kg essentially **excludes DI** (points to primary polydipsia).
- ▶ **Wolfram = DIDMOAD** (DI + DM + Optic atrophy + Deafness), **WFS1/wolframin**, chromosome 4.
- ▶ **Desmopressin (DDAVP)** = drug of choice for central & gestational DI; **hyponatraemia** is its chief hazard.

- ▶ **Nephrogenic DI:** thiazide + low-salt diet ± NSAID; **amiloride** for lithium-induced NDI.
- ▶ **Triphasic response:** DI → antidiuresis (SIAD/hyponatraemia ~day 7–12) → permanent DI.
- ▶ **Adipsic DI** (osmoreceptor + AVP loss) carries the highest hypernatraemia/mortality risk.

SOURCE & COVERAGE

Diabetic Ketoacidosis

Asked in: Paper IV Jun 2024 — RGUHS MD General Medicine

Definition / Introduction — Diabetic ketoacidosis (DKA) is an acute, life-threatening metabolic decompensation of diabetes defined by the biochemical triad of **hyperglycaemia** (serum glucose >13.9 mmol/L [250 mg/dL]; ≥200 mg/dL or any value in a known diabetic per current criteria), **ketonaemia/ketonuria** (serum β-hydroxybutyrate >3.0 mmol/L or urine ketones ≥2+) and **high-anion-gap metabolic acidosis** (arterial/venous pH <7.3 and/or serum bicarbonate <15 mmol/L). It results from *absolute or relative insulin deficiency* combined with *counter-regulatory hormone excess*. It is classically a hallmark of type 1 DM but also occurs in type 2 DM under severe stress, in ketosis-prone diabetes, and as *euglycaemic DKA* with SGLT-2 inhibitors. DKA and the hyperglycaemic hyperosmolar state (HHS) lie on a continuum, with up to one-third of patients showing mixed features.

Etiology and precipitating factors

- ▶ **Counter-regulatory drive:** the core lesion is a fall in the *insulin-to-glucagon ratio*, with accompanying rises in **glucagon, catecholamines, cortisol and growth hormone**.
- ▶ Common precipitants (mnemonic — the “I”s):
 - **Insulin deficiency/omission** — inadequate dosing, missed injections, insulin-pump infusion-site occlusion or device malfunction; insulin rationing due to cost.
 - **Infection** — pneumonia, urinary tract infection, gastroenteritis, sepsis (most common precipitant overall).

- **Infarction/Ischaemia** — myocardial, cerebral, mesenteric, peripheral; tissue ischaemia.
 - **Inflammation** — acute pancreatitis (note hyperamylasaemia is often salivary, not pancreatic).
 - **Intoxication / Iatrogenic drugs** — alcohol, cocaine; corticosteroids, atypical antipsychotics, immune-checkpoint inhibitors, **SGLT-2 inhibitors**.
 - **Pregnancy** and new-onset diabetes (DKA may be the *presenting* feature of type 1 DM).
- Psychiatric and eating disorders, low socioeconomic status, and prior DKA episodes markedly raise recurrence risk.

Pathophysiology

- **Insulin deficiency + glucagon/counter-regulatory excess** unleashes three deranged pathways:
- **Hyperglycaemia** — accelerated hepatic *gluconeogenesis* and *glycogenolysis* plus reduced peripheral glucose uptake.
 - **Ketogenesis** — unrestrained adipocyte *lipolysis* releases free fatty acids; the liver shunts these toward **ketone bodies** (β -hydroxybutyrate and acetoacetate). β -hydroxybutyrate is generated at roughly **threefold** the rate of acetoacetate; acetone (a breakdown product) produces the *fruity breath*.
 - **Volume/electrolyte loss** — glucose $>$ renal threshold (~ 180 mg/dL) causes **osmotic diuresis**, dehydration and urinary loss of Na^+ , K^+ , phosphate and water; vomiting compounds losses.
- Ketoacids consume bicarbonate $\rightarrow$ **high-anion-gap metabolic acidosis** with compensatory **Kussmaul (tachypnoeic) respiration**.
- A vicious cycle ensues: stress hormones worsen insulin resistance, hyperglycaemia and ketosis. Inflammatory markers (cytokines, CRP) are elevated.
- **Potassium paradox**: total-body K^+ is depleted (deficit $\sim 3\text{--}5$ mmol/kg) from osmotic diuresis, acidosis and GI loss, yet *serum* K^+ is normal-to-high at presentation because acidosis and insulin lack shift K^+ extracellularly — it falls sharply once insulin and fluids are given.

Clinical features

- **Symptoms**: polyuria, polydipsia, marked fatigue, **nausea, vomiting**, and **abdominal pain** (may mimic an acute surgical abdomen); evolves over hours to ~ 24 h.
- **Signs**: dehydration, **tachycardia and hypotension**, mild hypothermia, **Kussmaul respiration** with a **fruity (acetone) odour**, abdominal tenderness, and progressive **lethargy $\rightarrow$ obtundation $\rightarrow$ coma** (frank coma in only $\sim 10\%$).
- Signs of infection may be present *without fever* — an elevated or even normal temperature should prompt a search for infection, as uninfected patients are typically hypothermic.

Investigations and diagnosis

- **Confirm the triad:** capillary/serum glucose, **blood β -hydroxybutyrate** (preferred), and venous blood gas (pH, HCO_3^-). Venous pH suffices — arterial sampling is unnecessary (venous–arterial pH differs by only 0.02–0.15).
- **Ketone testing caveat:** the **nitroprusside** reagent detects *acetoacetate/acetone* but **NOT β -hydroxybutyrate**, so it can grossly *underestimate* ketosis (especially with concurrent lactic acidosis/shock); false-positives occur with **captopril, penicillamine and valproic acid**. Hence **direct β -hydroxybutyrate assay is preferred**.
- **Corrected sodium:** add **1.6 mmol/L** to measured Na^+ for every **5.6 mmol/L (100 mg/dL)** rise in **glucose**; a *normal* measured Na^+ in DKA signals profound water deficit.
- Other findings: high BUN/creatinine (pre-renal), **leukocytosis** (up to 25,000/ μL , may be without infection), hypertriglyceridaemia, raised salivary amylase. Septic screen, ECG (peaked T waves of hyperkalaemia; ischaemia), CXR, cultures.
- **Severity grading & DKA vs HHS:**

Parameter	Mild DKA	Moderate DKA	Severe DKA	HHS
Arterial/venous pH	7.25–7.30	7.0–7.25	<7.0	>7.3
Serum bicarbonate (meq/L)	15–18	10–<15	<10	>18
β -hydroxybutyrate (mmol/L)	3–6	3–6	>6	<1.0
Plasma glucose	>250 mg/dL (often 250–600)	>250 mg/dL	>250 mg/dL	usually >600 (up to 1000+)
Anion gap	↑	↑	↑	normal–slightly ↑
Serum osmolality	variable	variable	variable	>320 (marked)
Mental status	alert	alert/drowsy	stupor/coma	confusion/coma
Ketones	present (++)	present	present	absent/minimal

- **Differential diagnosis:** starvation ketosis, **alcoholic ketoacidosis** (HCO_3^- usually >15 meq/L), lactic acidosis and other high-anion-gap acidoses; simple hyperglycaemia (no ketonaemia).

Management

General principles: restore circulating volume and perfusion, correct hyperglycaemia/osmolality and acidosis, replace electrolytes, and *identify and treat the precipitant*. Maintain a meticulous **flow sheet**; pass a **nasogastric tube** if vomiting/altered sensorium. Avoid sedatives/opioids (mask early cerebral oedema). Treat mild–moderate DKA in a step-down unit; severe DKA in ICU.

Component	Practical regimen
1. Fluids	0.9% saline (or lactated Ringer's) 2–3 L over first 1–3 h (~10–20 mL/kg/h); total deficit ≈3–5 L. Switch to 0.45% saline 250–500 mL/h once haemodynamically stable. When glucose ≈250 mg/dL (13.9 mmol/L), change to 5–10% dextrose + 0.45% saline at 150–250 mL/h. Ringer's lactate gives faster resolution with less hyperchloraemia.
2. Insulin	Regular insulin 0.1 unit/kg IV bolus, then 0.1 unit/kg/h infusion; increase 2–3 fold if no fall in 2–4 h. Aim glucose fall 50–100 mg/dL/h. Reduce to 0.02–0.1 unit/kg/h when glucose ~250 mg/dL. Uncomplicated mild–moderate DKA may use SC rapid-acting analogue. Withhold insulin if $K^+ < 3.3$ mmol/L until corrected.
3. Potassium	If $K^+ < 3.5$ → give 10–20 mmol/h until > 3.5 (and hold insulin if < 3.3). If $K^+ 3.5$ –5 → 10–20 mmol per litre of fluid, target 4–5. If $K^+ > 5$ → start insulin, hold K^+ ; recheck 2-hourly. Require adequate urine output.
4. Bicarbonate	Not routinely recommended (no outcome benefit; risks hypokalaemia, paradoxical CSF acidosis, leftward O_2 -dissociation shift). Consider only if pH < 7.0 : ~50–100 mmol $NaHCO_3$ in sterile water with KCl, repeat until pH > 7.0 –7.1.
5. Phosphate	Seldom needed; replace only if severe hypophosphataemia (< 1 mg/dL) develops, at 3–4 mmol/h (over-replacement risks hypocalcaemic tetany).
6. Resolution & transition	End-points: glucose ~150–200 mg/dL, $HCO_3^- \geq 18$, normalised pH/anion gap, patient eating. Give SC long-acting insulin with a 2–4 h overlap before stopping the infusion to prevent rebound DKA.

- ▶ Euglycaemic DKA (SGLT-2 inhibitors): start 5–10% dextrose with insulin from the outset alongside saline; titrate dextrose to prevent hypoglycaemia. Resolution is judged by bicarbonate/acidosis correction, NOT glucose, since glucose is already near-normal.

Complications

- ▶ Cerebral oedema — the most feared complication, predominantly in **children**, typically as DKA is *resolving*. Risk factors: age < 5 y, new-onset diabetes, longer symptom duration, low initial pH, high initial BUN, **bicarbonate therapy**, rapid glucose correction, excess fluid in first 4 h, and rising serum Na^+ . Headache or deteriorating sensorium during therapy is the warning sign → treat with IV mannitol 1–2 g/kg over ~15 min ± hypertonic saline.

- ▶ Hyperchloraemic (normal-anion-gap) acidosis after saline resuscitation — benign, self-corrects over 12–24 h.
- ▶ Hypokalaemia, hypoglycaemia, hypophosphataemia, hypomagnesaemia (therapy-related).
- ▶ Venous thromboembolism, upper-GI bleeding, ARDS, aspiration, and complications of the precipitant.
- ▶ **Prognosis:** mortality is low (<1% in the young/uncomplicated) but rises sharply with age (>20% in the elderly), coma, MI, bowel infarction or end-stage kidney disease; even a single episode confers a ~13-fold one-year increase in mortality.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Pathophysiology flow chart:** Box “Insulin deficiency + ↑ Counter-regulatory hormones (glucagon, catecholamines, cortisol, GH)” → three arms — (1) ↑ Gluconeogenesis + glycogenolysis + ↓ glucose uptake → Hyperglycaemia → osmotic diuresis → dehydration / electrolyte loss / ↑ osmolality; (2) ↑ Lipolysis → ↑ Free fatty acids → hepatic ketogenesis → ↑ β -hydroxybutyrate + acetoacetate → ketonaemia/ketonuria → high-anion-gap metabolic acidosis → Kussmaul breathing; (3) Vomiting → further volume/electrolyte loss. Labels: *insulin/glucagon ratio, FFA, ketone bodies, anion gap, K^+ shift (intra→extracellular)*.
- ▶ **Management timeline bar:** parallel tracks labelled Fluids (0.9% saline → 0.45% saline → add dextrose at glucose 250), Insulin (0.1 U/kg bolus → 0.1 U/kg/h → 0.02–0.1 U/kg/h), Potassium (replace when 3.3–5; hold if >5), Monitor (glucose 1–2 h; electrolytes/anion gap 2–4 h), ending at Resolution → SC insulin overlap.

Clinical / Diagnostic significance

- ▶ DKA may be the **first presentation of type 1 diabetes** — measure ketones whenever a type 1 patient’s glucose is persistently >250 mg/dL or during any intercurrent illness (“sick-day rules”: never *omit* insulin, monitor glucose/ketones 1–3 hourly, maintain hydration).
- ▶ β -hydroxybutyrate (point-of-care meter) is **superior to urine nitroprusside** for both diagnosis and tracking response, and avoids the shock-related false-negative pitfall.
- ▶ **SGLT-2 inhibitor users** need counselling on euglycaemic DKA — suspect it on acidosis with near-normal glucose; withhold the drug during acute illness, surgery, low-carbohydrate diets or fasting.
- ▶ Always hunt the precipitant (the “I”s) — failure to do so, or inadequate fluid replacement, is the commonest cause of poor recovery.
- ▶ Recurrent DKA flags non-adherence/psychosocial issues mandating structured education and mental-health support.

High-yield exam pointers

- ▶ **Diagnostic triad:** hyperglycaemia + ketonaemia (β -OHB >3) + acidosis (pH <7.3, HCO_3^- <15).
- ▶ Core mechanism: ↓ **insulin/glucagon ratio** → **gluconeogenesis + lipolysis + ketogenesis**; counter-regulatory hormones = glucagon, catecholamines, cortisol, GH.
- ▶ **β -hydroxybutyrate** $\approx 3\times$ **acetoacetate**; nitroprusside misses β -OHB; false-positives with captopril, penicillamine, valproate.
- ▶ **Corrected Na** = +1.6 mmol/L per 100 mg/dL glucose rise; K^+ deficit 3–5 mmol/kg with paradoxical normal/high serum K^+ .
- ▶ First-hour priority is **fluids before/with insulin**; insulin bolus 0.1 U/kg then 0.1 U/kg/h; **hold insulin** if $\text{K}^+ < 3.3$.
- ▶ **Add dextrose** when glucose ≈ 250 mg/dL; resolution = $\text{HCO}_3^- \geq 18$ + closed anion gap, *not* glucose alone.
- ▶ **Bicarbonate only** if pH <7.0; phosphate only if <1 mg/dL — neither improves outcome.
- ▶ **Cerebral oedema** = leading cause of death in children; treat with mannitol 1–2 g/kg.
- ▶ **Euglycaemic DKA** with SGLT-2 inhibitors: glucose may be <200 mg/dL — start dextrose + insulin together; judge by acidosis.
- ▶ Overlap SC long-acting insulin 2–4 h before stopping the IV infusion to prevent rebound.

SOURCE & COVERAGE

Dyslipidemia

Asked in: Paper IV Nov 2022 — RGUHS MD General Medicine

Definition / Introduction — **Dyslipidemia** is a disorder of lipoprotein metabolism in which there is a substantial increase or decrease in specific circulating lipids or lipoproteins (cholesterol, triglycerides, or both). Lipoproteins are complexes of an “oil-droplet” hydrophobic core (triglycerides, cholesteryl esters) surrounded by phospholipids, free cholesterol and **apolipoproteins**. Dyslipidemia may be

primary (genetic) or secondary (to other medical conditions/drugs), and is an important *causal* factor for atherosclerotic cardiovascular disease (ASCVD); severe hypertriglyceridemia additionally risks acute pancreatitis. Because treatment proven to reduce cardiovascular risk, accurate classification and aggressive management are essential.

Lipoprotein physiology (basis of classification)

- ▶ **Major classes by density/size (inverse relationship):** chylomicrons (least dense, largest) → VLDL → IDL → LDL → HDL (most dense, smallest).
- ▶ **Key apolipoproteins:** apoB-48 (chylomicrons, intestine), apoB-100 (VLDL, IDL, LDL; ligand for the LDL receptor), apoA-I (major HDL protein; promotes efflux via ABCA1, activates LCAT), apoC-II (essential cofactor for lipoprotein lipase, LPL), apoE (ligand for hepatic clearance of remnants).
- ▶ **Three pathways:** *exogenous* (dietary lipids → chylomicrons → LPL lipolysis → remnants cleared by liver via apoE); *endogenous* (hepatic VLDL → IDL → LDL, cleared by LDL receptor); *reverse cholesterol transport* (HDL returns peripheral cholesterol to liver via SR-BI / CETP).
- ▶ **Lp(a)** = LDL-like particle with apo(a) disulphide-linked to apoB-100; an independent, highly heritable causal risk factor for ASCVD and aortic stenosis.
- ▶ Discrete “nodes” that go wrong in disease: (1) LPL-mediated lipolysis, (2) receptor-mediated hepatic uptake of apoB lipoproteins, (3) hepatocyte/enterocyte cholesterol handling, (4) VLDL assembly/secretion, (5) plasma lipid transfer & phospholipid hydrolysis.

Etiological classification (Harrison 22e, phenotype/mechanism-based)

Phenotype	Representative primary disorder	Gene(s)	Lipid pattern	Inheritance
Severe hypertriglyceridemia	Familial chylomicronemia syndrome (FCS)	<i>LPL</i> , <i>APOC2</i> , <i>APOA5</i> , <i>GPIHBP1</i> , <i>LMF1</i>	↑Chylomicrons, ↑VLDL; ↓HDL	AR
Hypercholesterolemia (↑LDL)	Familial hypercholesterolemia (FH)	<i>LDLR</i>	↑LDL	AD (~1/250)
Hypercholesterolemia	Familial defective apoB-100 (FDB)	<i>APOB</i>	↑LDL	AD (~1/1500)
Hypercholesterolemia	ADH type 3	<i>PCSK9</i> (gain-of-function)	↑LDL	AD
Hypercholesterolemia	Autosomal recessive hyperchol. (ARH)	<i>LDLRAP1</i>	↑LDL	AR

Phenotype	Representative primary disorder	Gene(s)	Lipid pattern	Inheritance
Mixed (↑TG + ↑LDL)	Familial dysbetalipoproteinemia (FDBL, type III)	<i>APOE2/E2</i>	↑Remnants/IDL (chol≈TG)	AR (~1/10,000)
Mixed	Familial combined hyperlipidemia (FCHL)	Polygenic	↑VLDL ± ↑LDL (small-dense), ↑apoB, ↓HDL	~1/100–200
Low HDL	Tangier disease	<i>ABCA1</i>	HDL <5 mg/dL	AR/co-dominant

- ▶ **Secondary causes (Table 419-3):** ↑TG — high-carbohydrate diet, alcohol, obesity, insulin resistance/**type 2 diabetes**, lipodystrophy, CKD, nephrotic syndrome, hypothyroidism, Cushing's, pregnancy, drugs (estrogen, glucocorticoids, isotretinoin/retinoids, beta-blockers, bile-acid resins). ↑LDL-C — **hypothyroidism**, cholestasis, nephrotic syndrome, Cushing's, anorexia, drugs (corticosteroids, cyclosporin, sirolimus, carbamazepine).
- ▶ *Fredrickson/WHO phenotypes* (classic, parallel framework): I chylomicrons; **IIa** LDL; **IIb** LDL+VLDL; **III** IDL/β-VLDL (FDBL); **IV** VLDL; **V** chylomicrons+VLDL.

Clinical features

- ▶ Most dyslipidemia is **asymptomatic**, detected on screening; the dominant consequence is **premature ASCVD** (MI, ischemic stroke, peripheral vascular disease).
- ▶ **FH**: corneal arcus, **tendon xanthomas** (dorsum of hands, Achilles); untreated heterozygous men have ~50% chance of MI before age 60. **Homozygous FH** — LDL-C >400 mg/dL, cutaneous xanthomas, ASCVD by age 30.
- ▶ **FDBL (type III)**: *tuberoeruptive xanthomas* (elbows, knees, buttocks) and **palmar xanthomas** (*xanthomata striata palmaris*) — virtually pathognomonic; cholesterol and TG raised to similar degree, HDL usually normal; prominent peripheral vascular disease.
- ▶ **Severe HTG / chylomicronemia (FCS)**: **eruptive xanthomas** (extensor surfaces), **lipemia retinalis** (opalescent retinal vessels), hepatosplenomegaly, and recurrent **acute pancreatitis** (suspect if fasting TG >500 mg/dL).
- ▶ **Tangier disease**: enlarged grayish-orange tonsils, hepatosplenomegaly, peripheral neuropathy with HDL-C <5 mg/dL.

Diagnosis & screening

- ▶ **Screen all adults** with a fasting lipid panel (total cholesterol, TG, HDL-C); screen children at **ages 9–11** and earlier with a family history of hypercholesterolemia/premature ASCVD.

- ▶ **Friedewald formula:** $\text{LDL-C} = \text{Total cholesterol} - (\text{TG}/5) - \text{HDL-C}$ (TG/5 estimates VLDL-cholesterol). Accurate only on fasting plasma and **invalid** if TG >400 mg/dL (and not valid in FDBL).
- ▶ **Non-HDL-C** = $\text{Total cholesterol} - \text{HDL-C}$ — captures cholesterol in VLDL/IDL/LDL; a better atherogenic marker. **apoB** and **Lp(a)** provide additional risk information.
- ▶ Diagnose the dyslipidemia phenotype, then **rule out secondary causes** (Table 419-3) before invoking a primary disorder. Confirmatory tests: FH gene panel (**LDLR**, **APOB**, **PCSK9**); **apoE2/E2 genotype** or β -quantification (VLDL-C/total TG ratio >0.30, “broad β band”) for FDBL.
- ▶ **Risk stratification:** ASCVD pooled-cohort 10-year risk calculator; refine borderline cases with apoB, Lp(a), hs-CRP, and coronary artery calcium (CAC) score.

Management

- ▶ **Goals:** prevent ASCVD events, and prevent pancreatitis when TG is severely elevated.
- ▶ **Lifestyle / therapeutic lifestyle change (first step for all):** reduce **saturated and trans fats**, weight loss in the obese, aerobic exercise, restrict alcohol; treat hypothyroidism/diabetes; restrict total fat and simple carbohydrates in severe HTG.
- ▶ **Statin intensity:** **high-intensity statin** for established ASCVD or those at high risk; in primary prevention a **10-year risk** >7.5% merits statin regardless of LDL-C. In ASCVD, lower LDL-C with drug therapy **as long as it remains >70 mg/dL**, using combination therapy if needed. FH patients require treatment from childhood.
- ▶ **TG-lowering when TG >500 mg/dL** (to prevent pancreatitis): **fibrates** and **omega-3 fatty acids** (fish oils); statins added if ASCVD risk is elevated.

Class (drug)	Mechanism	LDL-C effect	Key adverse effects
Statins (atorvastatin, rosuvastatin, etc.)	↓HMG-CoA reductase → ↑hepatic LDL receptors	↓~30–55% (doubling dose → ~6% more)	Myalgia (3–5%), myopathy/rhabdomyolysis, ↑transaminases, small ↑incident T2DM
Ezetimibe	Blocks intestinal NPC1L1 → ↓absorption	↓~18% (additive to statin)	Very safe; 2nd-line add-on
PCSK9 inhibitors (evolocumab, alirocumab; inclisiran = siRNA)	↓PCSK9 → ↑LDL receptors; also ↓Lp(a)	↓~60%	Injection-site reactions; SC q2wk (antibody) / q6mo (inclisiran)
Bempedoic acid	ATP-citrate lyase inhibitor → ↑LDL receptors	↓~18% with statin (~23% mono)	↑uric acid/gout, ↑LFTs, cholelithiasis; no ↑diabetes

Class (drug)	Mechanism	LDL-C effect	Key adverse effects
Bile-acid sequestrants (cholestyramine, colestipol, colesevelam)	↓bile-acid reabsorption → ↑LDL receptors	↓LDL but ↑TG	Bloating, constipation; avoid in HTG
Fibrates (fenofibrate, gemfibrozil)	PPARα agonist → ↑LPL, ↓apoC-III, ↓VLDL	TG ↓~30%	Myopathy (esp. with statin), gallstones, ↑creatinine, warfarin potentiation
Omega-3 (EPA/DHA, icosapent ethyl)	↓VLDL synthesis	TG ↓~30% (3–4 g/day)	Dyspepsia; icosapent ethyl ↓CV events in HTG

- ▶ **Homozygous FH / refractory cases:** add **lomitapide** (MTP inhibitor), **mipomersen** (apoB antisense), **evinacumab** (ANGPTL3 antibody), **LDL apheresis**, and rarely liver transplantation.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Lipoprotein metabolic pathways:** label *Intestine* → *Chylomicron* → *LPL (with apoC-II)* → *Chylomicron remnant* → *Liver (apoE-mediated uptake)* for the exogenous arm; *Liver* → *VLDL* → *IDL* → *LDL* → *LDL receptor* for the endogenous arm; and *Peripheral cell* → *ABCA1* → *nascent HDL* → *LCAT* → *mature HDL* → *SR-BI/CETP* → *Liver* for reverse cholesterol transport. Label **LPL**, **apoB-100**, **apoE**, **LDL receptor**, **PCSK9**, **HDL**, **SR-BI**, **CETP**.
- ▶ **Xanthoma plate:** label **tendon xanthoma** (Achilles, FH), **tuberoeruptive + palmar xanthoma** (FDBL), **eruptive xanthoma + lipemia retinalis** (chylomicronemia), **corneal arcus**.

Clinical / Diagnostic significance

- ▶ LDL-C reduction provides robust, dose-dependent reduction in MI, stroke and total mortality — “lower is better” within tolerated limits.
- ▶ **Cascade screening** of first-degree relatives is highly effective in FH (50% of siblings/children affected).
- ▶ Severe HTG mandates urgent TG lowering to avert pancreatitis; **low HDL-C** (<40 mg/dL men, <50 mg/dL women) is an independent risk marker but is **no longer a therapeutic target** for pharmacologic raising.
- ▶ A discordantly elevated **apoB** (relative to LDL-C) flags small-dense LDL of FCHL/metabolic syndrome and warrants aggressive therapy.

High-yield exam pointers

- ▶ **Friedewald formula** and its limitation (invalid if TG >400 mg/dL or in FDBL); learn **non-HDL-C** = TC – HDL-C.

- ▶ **FH** = autosomal dominant, *LDLR/APOB/PCSK9*, LDL-C usually **>190 mg/dL**, tendon xanthomas, prevalence ~1/250.
- ▶ **FDBL (type III)** = **apoE2/E2**, **palmar + tuberoeruptive xanthomas** (pathognomonic), chol ≈ TG, broad-β band, VLDL-C/TG ratio **>0.30**.
- ▶ **FCS** = LPL/apoC-II axis defect, TG >500 mg/dL, eruptive xanthomas, lipemia retinalis, **pancreatitis** risk.
- ▶ **Statins** first-line; **high-intensity** for ASCVD/high risk; LDL target driven by risk, treat ASCVD while LDL **>70 mg/dL**.
- ▶ Add-on order: statin → **ezetimibe** → **PCSK9 inhibitor**; **bempedoic acid** for statin-intolerant.
- ▶ **Fibrates + fish oil** for TG >500 mg/dL to prevent pancreatitis; **bile-acid resins** raise TG (avoid in HTG).
- ▶ Statin caution: myopathy risk ↑ with **gemfibrozil**, macrolides, azole antifungals, ciclosporin; slight ↑ incident diabetes outweighed by CV benefit.
- ▶ Always **exclude secondary causes** (hypothyroidism, nephrotic syndrome, DM, cholestasis, drugs) before labelling a primary genetic disorder.

SOURCE & COVERAGE

Harrison 22e — Ch 419 “Disorders of Lipoprotein Metabolism” (D.J. Rader). *Coverage note:* All classifications, drugs, doses, eponyms and numbers above are grounded in Ch 419. Harrison 22e organises dyslipidemia by **mechanism/phenotype** (severe HTG, hypercholesterolemia, mixed hyperlipidemia, low HDL) rather than the classic **Fredrickson/WHO Types I–V**; the Fredrickson scheme is included as a universally accepted parallel framework for exam completeness (Harrison explicitly names only “type III hyperlipoproteinemia” = FDBL).

Myxedema Coma (Myxedema Crisis): Risk Factors, Triggers, Clinical Manifestations and Treatment

Asked in: Paper IV May 2025 — RGUHS MD General Medicine

Definition / Introduction — Myxedema coma is the **decompensated, life-threatening end-stage of severe, long-standing hypothyroidism**, in which failing thyroid hormone-dependent homeostasis produces depressed consciousness, hypothermia and multi-organ slowing. It is an *endocrine emergency* of the elderly, almost always **primary** in origin, and carries a high mortality (Harrison quotes **20–40%**, CMDT **30–100%**) despite intensive care. The term “coma” is in fact a *misnomer* — the conscious level ranges from simple lethargy and obtundation through somnolence to true coma — hence the newer term **myxedema crisis**. Outcome is *independent of the absolute T4 and TSH levels* and depends chiefly on early recognition and treatment.

Pathophysiology — how chronic hypothyroidism decompensates

- ▶ Long-standing thyroid hormone deficiency lowers basal metabolic rate, thermogenesis, cardiac output, ventilatory drive and hepatic drug metabolism; an acute stress then overwhelms this fragile reserve and tips the patient into crisis.
- ▶ **Alveolar hypoventilation** is the central event: depressed central ventilatory response to hypoxia and hypercapnia, plus respiratory-muscle weakness and obstructive sleep apnoea, lead to **CO₂ retention and CO₂ narcosis** with resultant hypoxia — a major driver of the depressed sensorium.
- ▶ **Hypothermia** results from reduced thermogenesis; the cold itself further slows metabolism, creating a vicious cycle (temperature may fall to 23 °C / 74 °F).
- ▶ **Dilutional hyponatraemia** (SIADH-like, from reduced free-water clearance and inappropriate vasopressin secretion) and **hypoglycaemia** add to cerebral dysfunction.
- ▶ **Impaired adrenal reserve** (relative adrenocortical insufficiency) coexists, especially as metabolic demand rises with treatment.
- ▶ Reduced hepatic/renal clearance means sedatives, opioids and anaesthetics accumulate — both a *trigger* and a *perpetuating factor*.

Risk factors and precipitating triggers

Crisis develops when a precipitant is superimposed on a high-risk host. CMDT data: 94% have primary hypothyroidism, ~50% were previously **undiagnosed**, and ~80% are women.

Host / risk factors	Precipitating triggers
Elderly (almost always), female	Drugs impairing respiration/CNS — sedatives, hypnotics, anaesthetics, antidepressants, opioids
Severe long-standing or undiagnosed hypothyroidism	Infection / sepsis — especially pneumonia
Non-adherence to / discontinuation of levothyroxine	Cold exposure (winter presentation, hypothermia)
Post-radioiodine, post-thyroidectomy, autoimmune (Hashimoto)	Cardiac events — congestive heart failure, myocardial infarction
Coexisting cardiac/cerebrovascular disease	Cerebrovascular accident (stroke) , trauma , surgery
	Gastrointestinal bleeding , metabolic stress, hypoglycaemia

- ▶ Sedatives/anaesthetics/opioids are doubly dangerous — their metabolism is *slowed* in hypothyroidism, so they further depress cognition and respiratory drive and can precipitate **respiratory arrest**.

Clinical manifestations

The picture is **decompensated hypothyroidism plus altered sensorium**; features superimpose on the chronic stigmata of myxedema (dry, cool, doughy non-pitting skin, puffy facies, periorbital oedema, macroglossia, hoarse voice, alopecia, loss of outer third of eyebrows).

System	Features
Neurological	Reduced level of consciousness (lethargy → coma); seizures/convulsions ; delayed relaxation of deep tendon reflexes (may be absent if areflexic); impaired memory/psychosis (“myxedema madness”); abnormal CNS signs
Thermoregulatory	Hypothermia — subnormal temperature, may reach 23 °C; patient may be afebrile despite serious infection
Respiratory	Hypoventilation → hypoxia + hypercapnia (CO ₂ narcosis); respiratory-muscle weakness; pleural effusion; sleep apnoea
Cardiovascular	Bradycardia , hypotension , reduced contractility/stroke volume, low voltage ECG, pericardial effusion
Renal / metabolic	Dilutional hyponatraemia , hypoglycaemia , rhabdomyolysis , acute kidney injury (AKI)
Gastrointestinal	Ileus, megacolon, constipation, faecal impaction, urinary retention

- ▶ CMDT frequencies at presentation: **hyponatraemia ~65%**, **hypothermia ~50%**, **hypotension ~40%**, **bradycardia ~20%**, **hypoglycaemia ~15%**.

Diagnosis

- ▶ **Clinical diagnosis** — do not wait for confirmatory tests; *delay in therapy worsens prognosis*. Send serum FT4 and TSH rapidly, then **treat empirically** on clinical grounds.
- ▶ Expected biochemistry: **low FT4** with **markedly elevated TSH** in primary disease (TSH may be low/normal in central hypothyroidism).
- ▶ Supportive labs: hyponatraemia, hypoglycaemia, raised CPK, hypercapnia/hypoxia on ABG, hypercholesterolaemia, anaemia, raised lactate dehydrogenase.
- ▶ **Diagnostic scoring systems** (e.g., the *Popoveniuc* scoring system) aid recognition but are an adjunct to, not a replacement for, clinical judgement.
- ▶ Exclude/treat coexisting **adrenal insufficiency** — check cortisol; hyponatraemia in any hypothyroid patient mandates evaluation for adrenal insufficiency.

Treatment

Management is **ICU-based** and combines thyroid hormone replacement with aggressive correction of physiological disturbances. Because gut/IM/SC absorption is unpredictable in the hypometabolic state, give drugs **intravenously** wherever possible.

1. Thyroid hormone replacement

- ▶ **Levothyroxine (T4)**: IV loading bolus **200–400 µg** (Harrison) / **200–500 µg** (Williams) / **500 µg** (CMDT) to replete the peripheral pool — may improve within hours; then daily **IV/oral T4 ~1.6 µg/kg/day** (reduce IV dose by ~25%), or **50–100 µg IV daily** (lower dose if suspected coronary artery disease).
- ▶ **Liothyronine (T3)**: because peripheral **T4 → T3 conversion is impaired**, adding T3 is rational. Loading **5–20 µg** then **2.5–10 µg every 8 h** (Harrison); CMDT: **10–20 µg bolus** then **10 µg every 8–12 h** for the first 48 h. Use **lower doses** in small, elderly or cardiac-risk patients — excess T3 can provoke **arrhythmias**.

2. Glucocorticoid

- ▶ **Hydrocortisone** — parenteral **50 mg every 6 h** (Harrison) / **5–10 mg/h** (Williams) — for presumed **relative adrenal insufficiency**, ideally before/with T4.

3. Supportive / corrective measures

- ▶ **Ventilatory support** — assisted ventilation with controlled O₂; **regular ABG** monitoring, usually needed for the **first 48 h** (hypercapnia is an indication to admit/ventilate).
- ▶ **Passive rewarming with blankets only**; **avoid active external warming** — peripheral vasodilatation can precipitate **cardiovascular collapse** (external warming considered only if temperature <30 °C, with space blankets to prevent further heat loss).
- ▶ **Hyponatraemia/hypoglycaemia**: use **hypertonic saline** and **IV glucose (5% dextrose)** for severe derangements; **avoid hypotonic fluids** (worsen water intoxication/dilutional hyponatraemia).
- ▶ **Treat the precipitant**: early **broad-spectrum antibiotics** pending exclusion of infection; correct cardiac events, bleeding, metabolic upset.
- ▶ **Avoid sedatives**; if unavoidable, use reduced doses and monitor levels (impaired drug metabolism).
- ▶ General comatose care: frequent turning, aspiration precautions, attention to faecal impaction and urinary retention; switch to **oral levothyroxine** once consciousness/oral intake returns.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Vicious-cycle flow diagram of myxedema coma pathogenesis**. Centre box: *Severe long-standing hypothyroidism*. Arrows to four limbs, each labelled: (1) **Hypoventilation → hypoxia + hypercapnia (CO₂ narcosis)**; (2) **Reduced thermogenesis → hypothermia**; (3) **Reduced free-water clearance → dilutional hyponatraemia**; (4) **Impaired adrenal reserve + hypoglycaemia**. All four converge on a central output box: **Depressed consciousness /**

coma → death. Add an external arrow labelled **Precipitant** (infection, cold, sedatives, MI/CHF, stroke) feeding the central box.

- ▶ **Management box** (“4 pillars”). Four labelled columns: (i) IV Levothyroxine ± Liothyronine, (ii) IV Hydrocortisone, (iii) Ventilation + passive rewarming (blankets), (iv) Correct Na⁺/glucose + treat precipitant.

Clinical / Diagnostic significance

- ▶ A **high index of suspicion** in any obtunded, hypothermic, bradycardic elderly patient — *especially in winter or after sedation* — is life-saving; treat before biochemical confirmation.
- ▶ **Always co-treat for adrenal insufficiency** with hydrocortisone *before/with* thyroid hormone — starting T4 alone can precipitate adrenal crisis.
- ▶ Patients may be **afebrile despite severe sepsis**; sepsis/pneumonia must be actively sought and empirically covered.
- ▶ **Hyponatraemia mandates** evaluation for adrenal insufficiency and avoidance of hypotonic fluids.
- ▶ Prognosis hinges on early therapy, control of the precipitant and ventilatory support — *not* on the absolute hormone levels.

High-yield exam pointers

- ▶ **Endocrine emergency**; mortality 20–40% (Harrison), up to 30–100% (CMDT) — *treat empirically, do not await TSH/FT4*.
- ▶ Triad/hallmarks: **altered sensorium + hypothermia + hypoventilation** (CO₂ narcosis), on a background of myxedema.
- ▶ **94% primary hypothyroidism**, ~50% undiagnosed, ~80% women (CMDT); almost always elderly.
- ▶ **Commonest precipitants**: infection (**pneumonia**), **cold exposure**, sedatives/opioids/anaesthetics, MI/CHF, stroke, GI bleed, drug non-adherence.
- ▶ **Loading IV levothyroxine 200–500 µg**, then daily T4; **add IV liothyronine (T3)** because T4→T3 conversion is impaired; watch for **arrhythmia**.
- ▶ **IV hydrocortisone** for relative adrenal insufficiency — give *with/before* thyroxine.
- ▶ **Passive rewarming (blankets) only** — active external warming → **cardiovascular collapse**.
- ▶ **Avoid hypotonic fluids**; correct hyponatraemia (hypertonic saline) and hypoglycaemia (dextrose); ventilate for hypercapnia.
- ▶ “Myxedema coma” is a **misnomer** — consciousness ranges from lethargy to coma (myxedema crisis).

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Hypothyroidism” (clinical features, myxedema-coma pathogenesis, levothyroxine/liothyronine and hydrocortisone dosing, warming and fluid rules, mortality figures).
- ▶ **Williams Textbook of Endocrinology, 15e** — “Hypothyroidism and Thyroiditis” (myxedema-coma definition, predisposing factors, alternate T4/T3 regimens, gastric rewarming, diagnostic scoring systems, supportive care).
- ▶ **CMDT 2026** — “Disorders of the Pituitary, Thyroid, & Adrenal Glands” (myxedema-crisis epidemiology, presenting frequencies of hyponatraemia/hypothermia/hypotension/bradycardia/hypoglycaemia, IV levothyroxine 500 µg + liothyronine regimen, mortality 30–100%, admission criteria).
- ▶ *Coverage note:* The corpus references diagnostic scoring systems (e.g., Popoveniuc) but does not reproduce the individual point values; these are therefore named but not tabulated, to avoid fabricating specifics.

Syndrome of Inappropriate Antidiuresis (SIADH/SIAD)

Asked in: Paper IV May 2025 — RGUHS MD General Medicine

Definition / Introduction — The **syndrome of inappropriate antidiuresis (SIAD/SIADH)** is a disorder of water homeostasis in which arginine vasopressin (AVP/ADH) is secreted — or its renal action is sustained — at plasma osmolalities that should normally suppress it, in the *absence* of an osmotic or appropriate haemodynamic (hypovolaemic/hypervolaemic) stimulus. The cardinal biochemical hallmark is **hypotonic, euvolaemic hyponatraemia** with inappropriately concentrated urine. It is the single most common cause of hypoosmolality in clinical practice (20–40% of all hypoosmolar patients) and is fundamentally a **diagnosis of exclusion**, defined since 1967 by the **Schwartz–Bartter criteria**.

Etiology

SIAD results either from pituitary (eutopic) hypersecretion of AVP driven by CNS/pulmonary disease and drugs, or from ectopic (paraneoplastic) AVP production. A small subset have a gain-of-function *V2-receptor* mutation (**nephrogenic SIAD**) with undetectable AVP. Causes fall into five groups:

Category	Representative causes
Malignancy (ectopic AVP)	Small-cell lung carcinoma (≈75% of malignancy-associated SIAD; ~10% present with Na <130), mesothelioma, head & neck/oropharyngeal, GI (stomach, duodenum, pancreas), GU (ureter, bladder, prostate), thymoma, lymphoma, Ewing sarcoma

Category	Representative causes
Pulmonary disease	Bacterial/viral pneumonia, tuberculosis, lung abscess, aspergillosis, empyema, advanced COPD, positive-pressure ventilation, respiratory failure
CNS disorders	Subarachnoid haemorrhage, head trauma, meningitis, encephalitis, brain abscess/tumour, subdural haematoma, stroke, hydrocephalus, Guillain-Barré, SLE, acute intermittent porphyria, MS
Drugs	SSRIs, tricyclics, carbamazepine/oxcarbazepine, chlorpropamide, vincristine, cyclophosphamide/ifosfamide, NSAIDs, antipsychotics, nicotine, clofibrate, MDMA (“Ecstasy/Molly”), AVP analogues (desmopressin, oxytocin)
Other	Hereditary nephrogenic SIAD (V2R gain-of-function), HIV/AIDS, prolonged endurance exercise, pain, nausea, stress, general anaesthesia, post-operative state, idiopathic (common in the elderly)

Pathophysiology

- ▶ Persistent AVP action on renal **V2 receptors** → **aquaporin-2** insertion in collecting-duct principal cells → water retention, free-water excretion fails, and intake of free water (at thirst thresholds shifted downward) generates hyponatraemia.
- ▶ **Not truly euvoelaemic** but *subclinically volume-expanded*; this triggers two adaptive escapes that limit oedema: (1) **secondary natriuresis** (volume expansion, not AVP, drives urinary Na^+ loss → patients reach a new steady state in neutral Na^+ balance — the basis of so-called “renal salt wasting”), and (2) **AVP/renal escape** — hypotonicity downregulates V2-receptor and aquaporin-2 expression.
- ▶ Proximal-tubular urate and urea handling is suppressed by the volume-expanded state → characteristic **hypouricaemia** ($<4 \text{ mg/dL}$) and low BUN ($<10 \text{ mg/dL}$).
- ▶ **Four patterns of AVP secretion** (independent of cause): (1) random/erratic hypersecretion ($\sim 1/3$); (2) non-suppressible basal AVP with normal osmotic response; (3) **reset osmostat** (left-shifted threshold; AVP suppresses and urine dilutes if Na^+ falls low enough); (4) low/undetectable AVP (**nephrogenic SIAD**, constitutive V2R activation). A fifth copeptin-defined “barostat reset” pattern is described.

Clinical features

- ▶ Reflect **cerebral oedema** from osmotic water shift into brain cells, and depend on severity and *rate* of fall in Na^+ .

- ▶ **Acute** (<48 h): headache, nausea/vomiting, lethargy → seizures, obtundation, brainstem herniation, neurogenic (non-cardiogenic) pulmonary oedema, coma, death. Premenopausal women are especially vulnerable.
- ▶ **Chronic** (>48 h): often labelled “asymptomatic” owing to brain organic-osmolyte efflux/volume regulation, but causes subtle gait/cognitive impairment, **falls, fractures** (with reduced bone density) and increased mortality.

Evaluation / Diagnosis

Schwartz–Bartter diagnostic criteria (essential):

- ▶ **Decreased effective plasma osmolality** (<275 mOsm/kg; exclude pseudo- and translocational hyponatraemia).
- ▶ **Inappropriate urinary concentration** — urine osmolality >100 mOsm/kg (not maximally dilute) at some level of hypoosmolality.
- ▶ **Clinical euvolaemia** (no orthostasis/tachycardia/dry membranes; no oedema/ascites).
- ▶ **Elevated urinary sodium** (>30–40 mmol/L) on normal salt and water intake.
- ▶ **Exclusion** of hypothyroidism, glucocorticoid deficiency (secondary/primary adrenal insufficiency), renal failure and diuretic use.

Supportive (non-essential): hypouricaemia (<4 mg/dL), low BUN, failure to excrete a standard water load, and AVP/copeptin inappropriately elevated for osmolality. **Measurement of AVP/copeptin is generally NOT clinically useful** (10–20% have undetectable AVP; levels overlap with hypovolaemic states).

Key investigations: serum osmolality (exclude pseudohyponatraemia from hyperlipidaemia/hyperproteinaemia and translocational from hyperglycaemia/mannitol), paired urine osmolality and urine Na⁺, serum uric acid, BUN/creatinine, glucose, TFT and **0900 cortisol/short Synacthen test**, and imaging (chest CT for occult small-cell lung cancer in smokers; MRI brain) to find the cause.

Critical differentials by urine Na⁺ and volume status:

- ▶ **Cerebral salt wasting (CSW)** — hypovolaemic hyponatraemia with high urine Na⁺ in intracranial disease (esp. SAH); distinguished by *clinical hypovolaemia* and *responds to saline repletion* (the opposite of SIAD). Modern series suggest true CSW is exceedingly rare; most SAH hyponatraemia is SIAD.
- ▶ **Hypovolaemic hyponatraemia** (urine Na⁺ <20–30; hyperuricaemic) corrects with normal saline.
- ▶ **Hypervolaemic hyponatraemia** (heart failure, cirrhosis; urine Na⁺ <10).
- ▶ **Glucocorticoid deficiency and hypothyroidism** mimic SIAD and must be excluded first.

Management

1. Acute / severely symptomatic (seizures, coma) — medical emergency:

- ▶ **Hypertonic 3% NaCl (513 mmol/L):** a 100-mL bolus over ~10–15 min, repeated up to 2–3 times until symptoms abate; each bolus raises Na^+ by ~1–2 mmol/L. Aim for a prompt rise of only 4–6 mmol/L — sufficient to relieve cerebral oedema. Less severe symptoms: 3% saline 0.5–2 mL/kg/h.
- ▶ Monitor serum Na^+ every 1–2 h; supplemental O_2 /ventilatory support for neurogenic pulmonary oedema.

2. Chronic hyponatraemia — treat the cause + raise Na^+ safely:

- ▶ Withdraw causative drugs; treat tumour/pneumonia; replace glucocorticoid/thyroid if deficient.
- ▶ **Fluid restriction (500–1000 mL/day, all fluids)** is first-line but often fails. The **Furst ratio** ($\text{UNa} + \text{UK})/\text{PNa} > 1$ (i.e. urine osmolality > 500 mOsm/L) predicts failure → escalate.
- ▶ **Increase solute load:** oral salt tablets $\pm$ furosemide 20 mg BD (blunts the medullary gradient); oral urea 30–60 g/day (osmotic aquaresis; palatable bicarbonate/citrate formulations).
- ▶ **AVP-receptor antagonists (vaptans):** **tolvaptan** (oral V_2 antagonist; low-dose 7.5 mg preferred to limit overcorrection) and **conivaptan** (IV $\text{V}_1\text{A}/\text{V}_2$). Start in hospital, liberalise fluids > 2 L/day, monitor closely; limit duration to < 1 –2 months (hepatotoxicity); avoid in cirrhosis.
- ▶ **SGLT2 inhibitors** (glycosuric osmotic diuresis) raise Na^+ in SIAD and **demeclocycline** (induces nephrogenic DI; nephrotoxic, photosensitivity — avoided in cirrhosis) are alternatives.

3. Avoid osmotic demyelination syndrome (ODS):

- ▶ Do **not** correct Na^+ by > 8 mmol/L in 24 h (and < 18 mmol/L over 48 h); high-risk patients ($\text{Na}^+ < 120$, alcoholism, malnutrition, **hypokalaemia**, liver disease) target only 4–6 mmol/L/day.
- ▶ Correct hypokalaemia cautiously (raises Na^+ independently). If overcorrection occurs/anticipated, **re-lower** with IV 5% dextrose and/or a **DDAVP “clamp”** (desmopressin) to prevent aquaresis.
- ▶ ODS (central pontine + extrapontine myelinolysis) presents 2–6 days later with dysarthria, dysphagia, para-/quadriplegia, “locked-in” syndrome.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Diagnostic algorithm for hyponatraemia** (flowchart): Box “Hyponatraemia ($\text{Na}^+ < 135$) → measure serum osmolality” → branches: *Pseudo/translocational* (normal/high osm) vs *True hypotonic* (< 275). Hypotonic branch → assess **volume status**: **Hypovolaemic** (Urine $\text{Na}^+ < 20$ = extrarenal loss; > 20 = renal loss/diuretics/Addison/CSW) | **Euvolaemic** (Urine $\text{Na}^+ > 20$ → exclude hypothyroidism, glucocorticoid deficiency → SIAD) | **Hypervolaemic** (CHF, cirrhosis, nephrotic, renal failure). Label each box with the urine Na^+ cut-off.
- ▶ **SIAD pathophysiology loop:** AVP → V_2 receptor → aquaporin-2 $\uparrow$ → water retention → $\downarrow$ plasma Na^+ /osmolality + subclinical volume expansion → secondary natriuresis (high urine

Na^+) + AVP/renal escape (AQP2 down-regulation). Label: AVP, V2 receptor, AQP2, collecting duct, hypouricaemia.

Clinical / Diagnostic significance

- ▶ Hypouricaemia (<4 mg/dL) and low BUN are quick bedside discriminators of SIAD from hypovolaemic hyponatraemia (which is hyperuricaemic).
- ▶ New-onset unexplained SIAD in a smoker mandates **CT thorax** to exclude **small-cell lung cancer**.
- ▶ Always **exclude adrenal insufficiency and hypothyroidism** before labelling SIAD — glucocorticoid replacement alone may correct euvolaemic hyponatraemia from secondary adrenal failure.
- ▶ **Thiazide-induced** hyponatraemia mimics SIAD; defer the SIAD diagnosis until 1–2 weeks after stopping the thiazide.
- ▶ The *rate* of correction, not just the target, governs outcome — ODS is iatrogenic and preventable.

High-yield exam pointers

- ▶ SIAD = euvolaemic hypotonic hyponatraemia + inappropriately concentrated urine + high urine Na^+ + hypouricaemia; a diagnosis of exclusion.
- ▶ **Schwartz–Bartter (1967)**: ↓plasma osm <275, urine osm >100, euvolaemia, urine Na^+ >40, exclude thyroid/adrenal/renal/diuretic causes.
- ▶ **SCLC** = commonest malignant cause (75%); **SSRIs/carbamazepine** = commonest drug causes; **SAH** classic CNS cause.
- ▶ **Four AVP patterns**, including **reset osmostat** and AVP-negative **nephrogenic SIAD** (V2R gain-of-function).
- ▶ Acute symptomatic: **3% saline 100 mL bolus**, target rise **4–6 mmol/L**; chronic: **fluid restriction** → **urea/tolvaptan 7.5 mg/SGLT2i**.
- ▶ **Never correct >8 mmol/L/24 h** (4–6 in high-risk) → prevents **osmotic demyelination** (central pontine myelinolysis).
- ▶ **Distinguish CSW** (hypovolaemic, saline-responsive) from SIAD; **AVP/copeptin assay is not diagnostically useful**.
- ▶ Overcorrection → re-lower with **D5W ± DDAVP clamp**.

SOURCE & COVERAGE

Etiology, Clinical Features, Diagnosis, Complications and Management of Obesity

Asked in: Paper I Jul 2020 — RGUHS MD General Medicine

Definition / Introduction — Obesity is a chronic, relapsing, multifactorial disease defined as *a state of excess adipose-tissue mass that adversely affects health*. Because direct fat measurement is impractical, the **body-mass index (BMI = weight in kg / height in m²)** is used as a proxy: the WHO classifies BMI ≥ 30 kg/m² as obesity and 25–29.9 kg/m² as overweight. It arises from a sustained imbalance of energy intake over expenditure on a strong genetic and obesogenic-environmental background, and it predisposes to type 2 diabetes, cardiovascular disease, several cancers and reduced life expectancy.

Etiology and Pathogenesis

- ▶ **Fundamental basis — energy imbalance:** Obesity develops when energy intake chronically exceeds expenditure; because it is *cumulative*, a surplus as small as **~7 kcal/day** can produce obesity over years. Excess energy is stored as triglyceride in the unilocular lipid droplet of adipocytes (and ~10% of fat cells turn over yearly).
- ▶ **Genetic predisposition:** Twin/adoption studies show adiposity is strongly heritable (CMDT: genetics explain 40–90% of weight variation). Up to **20% of children with severe obesity** carry a chromosomal abnormality or highly penetrant mutation. Most common obesity is **polygenic**.
- ▶ **Leptin–melanocortin (central) pathway** — the hypothalamus integrates signals of energy stores:
 - **Leptin** (from adipose tissue) rises with fat mass; a *fall* below habitual level is a powerful drive to eat. It stimulates **POMC** neurons in the arcuate nucleus and inhibits **AGRP/NPY/GABA** neurons.
 - POMC-derived **α -/β-MSH act on the MC4 receptor** in the paraventricular nucleus → ↓intake and ↑expenditure; **AGRP** antagonises MC4R. *BDNF/TrkB* and *SIM1* act downstream.

- “**Leptin resistance**” at high levels (blunted response to leptin excess) explains why leptin does not prevent obesity.
- ▶ **Gut/pancreatic (peripheral) signals:** Ghrelin (stomach) increases hunger pre-meal; GLP-1, GIP, PYY, oxyntomodulin, CCK and insulin/amylin promote satiety after a meal — the rationale for incretin-based drugs.
- ▶ **Monogenic obesity** (severe, early-onset, hyperphagic): mutations in **leptin** (treatable with recombinant leptin), **leptin receptor**, **POMC** (with red hair, ACTH deficiency), **PCSK1**, **carboxypeptidase E**, **MC4R** (the *commonest* — heterozygous variants in 5–6% of severe early-onset obesity, ~1 in 300 of the population), **SIM1**, **BDNF**, **TrkB**, **SH2B1**.
- ▶ **Syndromic obesity:** **Prader-Willi** (commonest syndrome, ~1 in 25,000; paternal chromosome-15 deletion; hypotonia, hyperphagia, hypogonadism), **Bardet-Biedl** (AR ciliopathy; polydactyly, retinal dystrophy, renal disease), **Albright hereditary osteodystrophy** / **pseudohypoparathyroidism** (*GNAS1*), Cohen, Carpenter, Alström, Tubby.
- ▶ **Secondary / acquired causes** — always exclude:
 - Endocrine: **hypothyroidism**, **Cushing’s syndrome**, **PCOS**, **insulinoma**, **hypothalamic damage** (craniopharyngioma, trauma, inflammation).
 - **Drug-induced:** insulin, sulfonylureas, thiazolidinediones; glucocorticoids; antipsychotics (clozapine, olanzapine, risperidone); lithium; antidepressants (tricyclics, MAOIs, paroxetine, mirtazapine); antiepileptics (valproate, gabapentin, carbamazepine).
- ▶ **Obesogenic environment:** cheap, energy-dense, aggressively-marketed food in large portions, plus mechanisation, sedentary work and reduced thermoregulatory expenditure — drives the population-level rise.

Clinical Features

- ▶ **Anthropometric:** raised BMI; **central (android) adiposity** — increased waist circumference and waist-to-hip ratio **>0.9 in women, >1.0 in men** (independent marker of metabolic risk).
- ▶ **Symptoms of excess mass:** exertional dyspnoea, fatigue, mechanical low-back pain and knee pain, immobility, daytime somnolence/snoring (sleep apnoea).
- ▶ **Skin:** **acanthosis nigricans** (velvety hyperpigmentation of axilla/groin/nape — marker of hyperinsulinaemia), skin tags (acrochordons), striae distensae, intertrigo/fungal infection, **hidradenitis suppurativa**, stasis pigmentation, lymphoedema.
- ▶ **Reproductive:** in women — irregular menses, anovulatory infertility, hirsutism (PCOS); in men — **central hypogonadism** with low testosterone and inappropriately low/normal LH-FSH.
- ▶ **Distribution matters:** visceral/central obesity carries far higher cardiometabolic risk than gluteofemoral (lower-body) fat — the latter being relatively protective.

Diagnosis and Evaluation

The four steps are: (1) obesity-focused **history**, (2) **physical examination** for degree and type of obesity, (3) assessment of **complications/comorbidities**, and (4) assessment of **readiness to change** (motivational interviewing, 0–10 confidence/importance scale). Use neutral language (“weight,” “BMI,” “unhealthy weight”).

Classification	BMI (kg/m ²)	Obesity class	Disease risk
Underweight	<18.5	—	—
Healthy weight	18.5–24.9	—	—
Overweight	25.0–29.9	—	Increased
Obesity	30.0–34.9	I	High
Obesity	35.0–39.9	II	Very high
Extreme obesity	≥40	III	Extremely high

- ▶ **BMI limitations:** measures size, not body composition/fat distribution; over-estimates fat in the very muscular; **lower thresholds apply to Asia-Pacific populations** (risk at lower BMI).
- ▶ **Waist circumference** (surrogate for visceral fat; measure horizontally above iliac crest, most useful when BMI ≤35) — **ethnic-specific cut-offs:** Europeans — men >94 cm, women >80 cm; **South Asians & Chinese** — men >90 cm, women >80 cm; Japanese — men >85 cm, women >90 cm.
- ▶ **Routine investigations for all:** fasting lipid profile (total, LDL, HDL, triglycerides), chemistry panel, HbA1c, blood pressure; thyroid function (TSH) and, where suspected, screening for Cushing’s (24-h urine free cortisol / dexamethasone suppression), PCOS work-up and obstructive-sleep-apnoea screening.
- ▶ **Severity staging (beyond BMI):**
 - **AACE/ACE staging:** Stage 0 = obesity by BMI, no complications; Stage 1 = ≥1 mild–moderate complication; Stage 2 = ≥1 severe complication — guides aggressiveness of therapy.
 - **Edmonton Obesity Staging System (EOSS):** five grades (0–4) across **medical, functional and psychological domains**, *independent of BMI*.

Complications

- ▶ **Metabolic/endocrine:** insulin resistance/hyperinsulinaemia, **metabolic syndrome**, **type 2 diabetes**, atherogenic **dyslipidaemia** (high triglycerides, low HDL), hyperuricaemia/**gout**, PCOS, male hypogonadism.
- ▶ **Cardiovascular:** hypertension, coronary artery disease, stroke, **heart failure (diastolic dysfunction/HFpEF)**, atrial fibrillation, varicose veins, venous thromboembolism.

- ▶ **Respiratory:** obstructive sleep apnoea, obesity-hypoventilation (**Pickwickian**) syndrome, asthma, cor pulmonale, exertional dyspnoea.
- ▶ **Hepato-gastrointestinal:** MAFLD/NAFLD → NASH → fibrosis/cirrhosis/HCC, GERD/reflux oesophagitis, cholelithiasis (and cholecystitis, pancreatitis, gallbladder cancer), hernias.
- ▶ **Musculoskeletal:** osteoarthritis of knees/hips, low back pain, carpal tunnel syndrome, immobility.
- ▶ **Malignancy:** colorectal, kidney, pancreatic, oesophageal adenocarcinoma, and (in women) endometrial and breast cancer — each 5 kg/m² BMI rise raises cancer mortality ~10%.
- ▶ **Neuro-psychological:** idiopathic intracranial hypertension, meralgia paraesthetica, increased dementia and stroke risk; depression, low self-esteem, body-image disturbance, social stigmatisation.
- ▶ **Renal/GU:** obesity-related glomerulopathy, stress incontinence, pregnancy complications.
- ▶ **Other:** worse outcomes from infection (e.g., SARS-CoV-2), surgical-wound infection; rare association with thrombotic thrombocytopenic purpura.

Management

Therapy is escalated by BMI category and comorbidity (Table 414-4): lifestyle for all, drugs from BMI ≥27 with comorbidity / ≥30, surgery from BMI ≥35 with comorbidity / ≥40. A realistic initial goal is 8–10% loss over 6 months; even 5–10% loss yields dose-related improvement in glycaemia, BP and lipids.

- ▶ **1. Lifestyle management** (modest ~3–5 kg loss; the foundation):
 - **Diet:** create a deficit of **500–750 kcal/day** (≈1200–1500 kcal/day for women, 1500–1800 for men) targeting ~1–2 lb/week loss; macronutrient ratio matters less than total calorie reduction and adherence; use low-energy-density foods, meal replacements; **very-low-calorie diets** (≤800 kcal/day) for selected motivated patients (e.g., DiRECT trial achieved diabetes remission).
 - **Physical activity:** **150 min/week moderate (or 75 min vigorous); >300 min/week** often needed to lose and maintain; key role in *maintenance*; reduce sedentary time.
 - **Behavioural therapy / CBT:** self-monitoring, stimulus control, stress management, problem-solving, cognitive restructuring.
- ▶ **2. Pharmacotherapy** (BMI ≥30, or ≥27 with comorbidity; adjunct to lifestyle):

Drug	Mechanism	Note (placebo-subtracted weight loss)
Phentermine	Sympathomimetic (↑CNS noradrenaline)	Short-term use only; ~4.4%
Orlistat 120 mg tid	GI lipase inhibitor (blocks ~30% dietary fat)	Steatorrhea; supplement fat-soluble vitamins; ~4.1%

Drug	Mechanism	Note (placebo-subtracted weight loss)
Phentermine/topiramate	Sympathomimetic + GABA/carbonic-anhydrase	~8.0%; teratogenic (oral cleft)
Naltrexone SR/bupropion SR	Opioid antagonist + DA/NA reuptake inhibitor (POMC activation)	~5.1%
Liraglutide 3.0 mg SC daily	GLP-1 receptor agonist	~5.4%
Semaglutide 2.4 mg SC weekly	GLP-1 receptor agonist	~12.5%; SELECT trial: 20% ↓ MACE
Tirzepatide SC weekly	Dual GLP-1/GIP agonist	~17.8% (SURMOUNT) — most effective
Setmelanotide SC	MC4R agonist	For monogenic/syndromic obesity (POMC, PCSK1, LEPR, Bardet-Biedl)

GLP-1/GIP agonists are contraindicated with personal/family history of medullary thyroid carcinoma or MEN-2; pancreatitis is a caution. Common adverse effects are gastrointestinal (nausea, vomiting, diarrhoea, constipation).

- ▶ **3. Bariatric/metabolic surgery** (BMI ≥40, or ≥35 with comorbidity):
 - **Restrictive:** laparoscopic adjustable gastric banding (largely abandoned); sleeve gastrectomy (~80% greater curvature removed).
 - **Restrictive-malabsorptive:** Roux-en-Y gastric bypass, biliopancreatic diversion ± duodenal switch — typically 28–33% total-body-weight loss.
 - Benefits act partly via altered gut hormones (ghrelin, GLP-1, PYY); **Swedish Obese Subjects study:** 78% reduction in incident type 2 diabetes; reduced all-cause and cardiovascular mortality. Mortality usually <1%.
 - Risks: stomal stenosis/marginal ulcer (RYGB), and **lifelong micronutrient deficiency** (vitamin B12, iron, folate, calcium, vitamin D) after malabsorptive procedures.
- ▶ **4. Endoscopic options** (treatment gap / poor surgical candidates): intragastric balloon (6–12% loss, removed at 6 months); endoscopic sleeve gastroplasty (~18% at 2 years).

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Hypothalamic energy-balance circuit:** Adipose tissue → Leptin → Arcuate nucleus (stimulates POMC, inhibits AGRP/NPY) → α/β-MSH → MC4R in Paraventricular nucleus → “↓Food intake, ↑Energy expenditure”; gut hormones into brainstem — label Ghrelin (stomach, hunger), GLP-1, GIP, PYY, CCK, oxyntomodulin, Insulin, Amylin, Vagus nerve.

- **Obesity-complication body map:** central figure labelled with **Dementia/Stroke, Sleep apnoea, Hypertension, Ischaemic heart disease, Heart failure, NAFLD/NASH, Type 2 diabetes, Dyslipidaemia, Gallstones, Reflux oesophagitis, PCOS, Osteoarthritis, Gout, Cancers (oesophagus/colon/endometrium/pancreas/kidney).**

Clinical / Diagnostic significance

- Use **BMI + waist circumference + complication staging** together — BMI alone under-estimates risk in South Asians, hence the lower waist cut-offs (men >90 cm, women >80 cm) relevant to Indian practice.
- **Acanthosis nigricans** at the bedside flags insulin resistance and warrants HbA1c/lipids.
- Always **screen for and treat secondary/iatrogenic causes** (thyroid, Cushing's, obesogenic drugs) before labelling "simple" obesity.
- Weight loss is **disease-modifying**: 5–10% improves glycaemia/BP/lipids; semaglutide (SELECT) and bariatric surgery (SOS) provide *hard cardiovascular and diabetes outcome* benefit.

High-yield exam pointers

- BMI ≥ 30 = obesity; ≥ 40 = extreme (class III); Asia-Pacific thresholds are lower.
- Waist-hip ratio **>0.9 (women), >1.0 (men)** = adverse risk; visceral > subcutaneous fat for metabolic harm.
- **MC4R** = commonest monogenic obesity gene; **Prader-Willi** = commonest syndromic cause.
- **Leptin deficiency is the only fully treatable monogenic obesity** (recombinant leptin); leptin-receptor deficiency is not.
- **Setmelanotide** (MC4R agonist) for POMC/PCSK1/LEPR/Bardet-Biedl obesity.
- Drug ladder potency: **tirzepatide > semaglutide > phentermine-topiramate > liraglutide $\approx$ naltrexone-bupropion > orlistat/phentermine.**
- GLP-1/GIP agonists contraindicated in **MEN-2 / medullary thyroid cancer**.
- Surgery thresholds: **BMI ≥ 40 , or ≥ 35 with comorbidity**; RYGB/sleeve give 28–33% weight loss; supplement **B12, iron, folate, Ca, vitamin D** lifelong.
- Treatment target: **8–10% loss over 6 months**; even 5% improves comorbidities.

SOURCE & COVERAGE

- **Harrison's Principles of Internal Medicine, 22e** — "*Pathobiology of Obesity*" (O'Rahilly & Farooqi; etiology, leptin-melanocortin pathway, monogenic/syndromic causes, complications) and "*Evaluation and Management of Obesity*" (Kushner; classification tables, AACE/ACE & Edmonton staging, antiobesity drugs, bariatric surgery).

- ▶ **CMDT 2026** — “*Nutrition, Nutritional Disorders, & Obesity*” (diagnostic approach, weight-loss thresholds, pharmacotherapy and surgical/endoscopic referral criteria).
- ▶ Coverage note: All specifics (BMI/waist cut-offs, drug doses and placebo-subtracted weight-loss figures, trial names — DiRECT, SELECT, SURMOUNT, STEP, SOS) are verbatim from the Harrison and CMDT obesity chapters. The dedicated subspecialty text (Williams Textbook of Endocrinology, “Obesity and Neuroendocrine Control of Energy Stores”) was consulted but added no specifics beyond those already grounded above; corpus coverage of this topic is thorough.

Evaluation and Treatment of Diabetic Peripheral Neuropathy

Asked in: Paper III Jul 2020 — RGUHS MD General Medicine

Definition / Introduction — Diabetic neuropathy is a group of clinically distinct syndromes resulting from damage to peripheral somatic and autonomic nerves by chronic hyperglycaemia and associated metabolic-syndrome factors. It occurs in roughly **50% of individuals with long-standing type 1 or type 2 DM** and is the most common cause of peripheral neuropathy in the developed world. **Distal symmetric polyneuropathy (DSPN)** is by far the commonest form. Diagnosis is essentially clinical and is one of *exclusion* — other causes (B12 deficiency, paraproteinaemia, hypothyroidism, alcohol) must be ruled out before attributing neuropathy to diabetes.

Classification (ADA / Toronto Consensus)

- ▶ **A. Diffuse neuropathy** (commonest group)
 - **Distal symmetric polyneuropathy (DSPN)** — small-fibre predominant, large-fibre predominant, or *mixed* (most common).
 - **Autonomic neuropathy** — cardiovascular (CAN), gastrointestinal, urogenital, sudomotor, hypoglycaemia unawareness, abnormal pupillary function.
- ▶ **B. Mononeuropathy / mononeuritis multiplex** — isolated cranial (III, IV, VI, VII) or peripheral nerve (median, ulnar, peroneal, femoral); entrapment syndromes.
- ▶ **C. Radiculopathy / polyradiculopathy** — lumbosacral radiculoplexus neuropathy (*diabetic amyotrophy / Bruns–Garland syndrome*), thoracic (truncal) radiculopathy.
- ▶ Special form: **treatment-induced neuropathy of diabetes (TIND / “insulin neuritis”)** — acute painful small-fibre neuropathy after rapid glycaemic correction.

Risk factors and pathogenesis

- ▶ **Risk factors:** duration of diabetes and poor glycaemic control (HbA1c); high BMI/central obesity; smoking; coexistent retinopathy and nephropathy; hypertension, hypertriglyceridaemia and ASCVD. In T2D the wider **metabolic syndrome** drives neuropathy as much as glucose itself.
- ▶ **Pathogenesis** — hyperglycaemia-driven microvascular and metabolic injury to both myelinated and unmyelinated fibres, with a unifying theme of mitochondrial **oxidative stress / bioenergetic failure**:
 - **Polyol pathway** — aldose reductase (AKR1B1) reduces glucose to **sorbitol** (then fructose via sorbitol dehydrogenase), consuming NADPH and depleting glutathione.
 - **Advanced glycation end-products (AGEs)** — the dicarbonyl **methylglyoxal** modifies proteins and, via Nav1.8 sodium channels on C-fibres, contributes to neuropathic pain; AGE–RAGE signalling activates inflammation.
 - **Protein kinase C (PKC)** activation and flux through the **hexosamine pathway**.
 - Defective resolution of inflammation and nerve ischaemia (vasa nervorum) — relevant to acute mononeuropathies.

Clinical features

- ▶ **DSPN:** insidious **stocking-and-glove** sensory loss beginning in the toes, ascending up the legs and later into the fingers (“length-dependent”). Small-fibre symptoms — burning, tingling, lancinating/stabbing pain, hyperaesthesia, dysaesthesia — typically *worse at rest and at night*. Up to 50% are **asymptomatic**, making screening essential. As it progresses pain may subside, leaving sensory deficit, **loss of protective sensation (LOPS)**, and later motor signs (foot-drop, small-muscle wasting, clawing of toes).
- ▶ **Signs:** reduced 10-g monofilament/vibration perception, **absent ankle reflexes**, impaired proprioception, distal weakness, foot deformity.
- ▶ **Autonomic:** resting tachycardia, reduced heart-rate variability, **orthostatic hypotension**, gastroparesis, diabetic diarrhoea/constipation, neurogenic bladder (cystopathy), erectile dysfunction/retrograde ejaculation, anhidrosis of feet with hyperhidrosis of trunk, **hypoglycaemia unawareness**, prolonged QTc and risk of sudden death.
- ▶ **Mononeuropathy:** acute painful **third-nerve palsy** that is *pupil-sparing* (ptosis + ophthalmoplegia, pupil intact), or VI/IV/VII (Bell’s) palsy; self-limiting over 6–12 weeks.
- ▶ **Diabetic amyotrophy (Bruns–Garland):** severe unilateral low-back/hip/thigh pain with proximal quadriceps wasting and weakness, often heralded by marked weight loss; raised CSF protein and ESR; gradual self-limited recovery over 6–18 months.
- ▶ **Diabetic neuropathic cachexia:** symmetric painful neuropathy with profound weight loss; good prognosis, recovers within ~1 year.

Evaluation and diagnosis

- ▶ **When to screen:** annual examination beginning **5 years after diagnosis of T1DM** and at **diagnosis of T2DM**, aimed at detecting LOPS (the major risk factor for ulceration, falls and amputation).
- ▶ **Bedside small-fibre tests** — pinprick (sharp/dull discrimination on dorsum of toe), temperature (cool tuning-fork on cheek vs toe), cotton-wisp light touch.
- ▶ **Bedside large-fibre tests** — **128-Hz tuning-fork** vibration at the great toe, ankle (Achilles) reflexes, proprioception at the first MTP joint.
- ▶ **10-g Semmes–Weinstein monofilament (5.07 filament)** — assesses LOPS / ulcer risk; recommended as a **three-site test** (plantar great toe, 3rd and 5th metatarsal heads).
- ▶ **Validated screening scores:** Michigan Neuropathy Screening Instrument (MNSI), Modified Toronto Clinical Neuropathy Score, Neuropathy Impairment Score, Utah Early Neuropathy Score; questionnaires (DN4, LANSS) help identify *neuropathic pain*.
- ▶ **Confirmatory / atypical-case tests:**
 - **Nerve conduction studies (NCS)** — gold standard for **large-fibre** neuropathy; reduced amplitudes with mild–moderate slowing (sural, peroneal, tibial). Sural abnormality plus one other nerve = large-fibre neuropathy.
 - **Intra-epidermal nerve-fibre density (IENFD)** on 3-mm skin punch biopsy (PGP 9.5 staining) — gold standard for **small-fibre** neuropathy.
 - Quantitative sensory testing, autonomic testing (heart-rate variability, QSART/sudomotor, sympathetic skin response), corneal confocal microscopy (research).
- ▶ **Toronto Consensus severity grading:** *possible* → *probable* (≥ 2 of: neuropathic symptoms, decreased distal sensation, reduced/absent ankle reflexes) → *confirmed* (symptom/sign **plus** abnormal NCS or validated small-fibre measure) → *subclinical* (abnormal tests, no symptoms/signs).
- ▶ **Exclude mimics (AAN):** serum protein electrophoresis with immunofixation, **vitamin B12** (metformin lowers B12), TFTs; consider HIV, alcohol, paraneoplastic. Up to **10% of neuropathy in diabetics is non-diabetic** (Rochester study). *Red flags for an alternative diagnosis:* asymmetry, motor > sensory involvement, or rapid/aggressive course.

Treatment

- ▶ **A. Disease-modifying / preventive (the foundation):**
 - **Glycaemic control** — tight, near-normal glycaemia *prevents and slows* DSPN dramatically in T1DM (DCCT). In T2DM intensive glucose control alone is only **modestly effective**; multifactorial risk-factor control is required.
 - **Treat the metabolic syndrome** — dyslipidaemia, hypertension, hypertriglyceridaemia, obesity; smoking and alcohol cessation; exercise and weight loss; correct B12/folate deficiency.

- **Caution:** lower HbA1c gradually — a fall >1% **per month** risks treatment-induced neuropathy (TIND) and accelerated retinopathy.
- **Foot protection** — daily foot inspection, appropriate footwear/accommodative insoles, callus/ulcer prevention, podiatry referral; mechanical off-loading and debridement for neuropathic ulcers.
- ▶ **B. Symptomatic treatment of painful DSPN** — start one agent, titrate to effect or side-effects, then add a second from a different class; ~two-thirds obtain relief:
 - **Voltage-gated $\alpha 2\delta$ ligands** — **pregabalin** (50–100 mg tid; FDA-approved) and **gabapentin** (300–1200 mg tid).
 - **SNRIs** — **duloxetine** (30–60 mg/day; FDA-approved), **venlafaxine** (37.5–150 mg/day).
 - **Tricyclic antidepressants** — secondary amines preferred: **amitriptyline** / **nortriptyline** / **desipramine** (10–100 mg qhs); limited by anticholinergic effects.
 - **Topical** — 5% **lidocaine** patch, **capsaicin** 0.075% cream; **alpha-lipoic acid** 600 mg/day (antioxidant, used in Europe); TENS as adjuvant.
 - **Sodium-channel blockers** (carbamazepine, mexiletine) as later-line; treat coexistent sleep and mood disorders.
 - **Tapentadol** is FDA-approved but, like other **opioids**, is **discouraged** (modest efficacy, addiction risk) — refer to a pain clinic if uncontrolled.

Class	Examples	Typical dose
$\alpha 2\delta$ ligand	Pregabalin / Gabapentin	50–100 mg tid / 300–1200 mg tid
SNRI	Duloxetine / Venlafaxine	30–60 mg/day / 37.5–150 mg/day
TCA	Amitriptyline / Nortriptyline	10–100 mg qhs
Topical	Lidocaine 5% patch / Capsaicin 0.075%	Apply to painful area

- ▶ **C. Autonomic neuropathy (organ-directed):**
 - **Orthostatic hypotension** — adequate salt/fluids, compression stockings, head-up tilt, slow standing; **fludrocortisone** 0.1–0.2 mg/day, **midodrine** 10 mg tid, **droxidopa**.
 - **Gastroparesis** — small, frequent low-fat/low-fibre meals; **metoclopramide** (short-term), **erythromycin** 250 mg tid (motilin agonist); avoid opioids/GLP-1 agonists; gastric electrical stimulation in refractory cases.
 - **Diabetic diarrhoea** — rifaximin/metronidazole if bacterial overgrowth, loperamide; constipation — stimulant laxatives.
 - **Cystopathy** — scheduled voiding, bethanechol, self-catheterisation.
 - **Erectile dysfunction** — **PDE5 inhibitors** (sildenafil, tadalafil, vardenafil); contraindicated with nitrates.

- ▶ **D. Focal forms:** mononeuropathies and amyotrophy are largely self-limiting (analgesia + glycaemic control); entrapment (carpal tunnel) — wrist splint, NSAIDs, surgical decompression; glucocorticoids are sometimes used for severe radiculoplexus pain (unproven).

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Stocking-and-glove sensory loss diagram** — outline of a body with shaded distal lower limbs (feet/calves) and hands/fingers; labels: *Distal symmetric “stocking-and-glove” pattern, length-dependent (longest nerves first), small fibres (pain/temperature) before large fibres (vibration/proprioception).*
- ▶ **Foot examination / screening sites** — sole of foot showing the **three monofilament test sites** (plantar great toe, 3rd metatarsal head, 5th metatarsal head); add labels: *10-g Semmes–Weinstein monofilament (LOPS), 128-Hz tuning fork at great toe (vibration), Achilles reflex, pinprick/temperature (small fibre).*

Clinical / Diagnostic significance

- ▶ DSPN with LOPS is the leading cause of **foot ulceration**, **Charcot neuroarthropathy** (“**rocker-bottom**” foot) and **non-traumatic lower-limb amputation** — annual foot screening is mandatory.
- ▶ **Cardiovascular autonomic neuropathy (CAN)** predicts silent ischaemia, perioperative instability, prolonged QTc and **sudden death** — assess heart-rate variability and orthostatic BP.
- ▶ Always exclude mimics (B12, paraproteinaemia, hypothyroidism) — ~10% of “diabetic” neuropathy is non-diabetic; atypical features mandate neurology referral and NCS.
- ▶ Pre-operative cardiac evaluation is prudent because **silent ischaemia** is common in autonomic neuropathy.

High-yield exam pointers

- ▶ Occurs in ~50% of long-standing DM; DSPN is the commonest form; up to 50% **asymptomatic**.
- ▶ Screen **annually**: from 5 years after T1DM diagnosis and **at diagnosis** of T2DM.
- ▶ **10-g Semmes–Weinstein monofilament (5.07)** detects LOPS; **128-Hz tuning fork** tests large fibre; **IENFD on skin biopsy** = gold standard for small-fibre; **NCS** = gold standard for large-fibre.
- ▶ **Toronto Consensus**: possible → probable → confirmed → subclinical.
- ▶ Diabetic 3rd-nerve palsy is **pupil-sparing**; diabetic amyotrophy = **Bruns–Garland syndrome**.
- ▶ Tight glycaemic control prevents DSPN strongly in T1DM, only modestly in T2DM.
- ▶ Painful DSPN first-line classes: **$\alpha 2\delta$ ligands** (pregabalin/gabapentin), **SNRIs** (duloxetine), **TCAs**; FDA-approved = pregabalin, duloxetine, tapentadol; **avoid opioids**.

- ▶ Avoid lowering HbA1c >1%/month — risk of **treatment-induced neuropathy** (TIND / “insulin neuritis”).
- ▶ Orthostatic hypotension: **midodrine** / **fludrocortisone**; gastroparesis: **metoclopramide** / **erythromycin**; ED: PDE5 inhibitors.

SOURCE & COVERAGE

- ▶ **Harrison’s Principles of Internal Medicine, 22e** — “Diabetes Mellitus: Complications” and “Peripheral Neuropathy” (including Table: *Treatment of Painful Sensory Neuropathies*).
- ▶ **Williams Textbook of Endocrinology, 15e** — “Complications of Diabetes Mellitus” (diabetic neuropathies — classification per ADA/Pop-Busui position statement, Toronto Consensus criteria, Box 38.3 diagnosis, disease-modifying and painful-DSPN treatment, pathogenesis: polyol pathway/AGEs/PKC/hexosamine).

Gestational Diabetes Mellitus

Asked in: Paper IV Dec 2023 · Paper IV Jul 2020 (2×) — RGUHS MD General Medicine

Definition / Introduction — **Gestational diabetes mellitus (GDM)** is glucose intolerance with onset or first recognition during the **second or third trimester** of pregnancy that is not clearly overt (pre-existing) diabetes. It complicates roughly **8% of pregnancies** (the International Diabetes Federation estimated in 2021 that ~**16% of pregnancies worldwide** are affected by GDM or pre-existing diabetes), and it arises when maternal pancreatic β -cell insulin secretion fails to compensate for the physiological insulin resistance of pregnancy. By current **ADA** convention, hyperglycaemia *diagnosed in the first trimester* is reclassified as **pre-existing (pregestational) diabetes**, not GDM. GDM matters because it is both an immediate threat to mother and fetus and a powerful marker of future maternal type 2 diabetes (T2DM) and cardiovascular disease.

Classification and definitional boundaries

- ▶ **ADA aetiologic classification of diabetes** places GDM as a distinct category (Type IV) alongside: I — Type 1 DM; II — Type 2 DM; III — Specific/”other” types (MODY/monogenic, exocrine pancreatic disease, endocrinopathies, drug-/chemical-induced, etc.); IV — **Gestational diabetes mellitus**.
- ▶ **Pregestational (pgDM)** = type 1 or type 2 diabetes antedating pregnancy (complicates ~1% of pregnancies; prevalence is higher in obese vs normal-weight women, ~2.2% vs 0.5%). The crucial clinical separation: **pgDM is teratogenic** because hyperglycaemia is present during

organogenesis (first 5–8 weeks), whereas **GDM** appears after organogenesis and so chiefly causes *fetal overgrowth* rather than malformation.

- ▶ Glucose tolerance in GDM is typically **bidirectional** — most women revert to normal (or impaired) glucose tolerance postpartum.

Pathophysiology and risk factors

- ▶ **Physiology of normal pregnancy:** the fetoplacental unit drives major metabolic change — glucose and amino acids are shunted to the fetus while the mother shifts to ketones/triglycerides, producing “**accelerated starvation**” / **accelerated ketosis** on fasting (lower glucose, higher β -hydroxybutyrate and acetoacetate). Progressive **insulin resistance** develops, mediated by placental production of **steroids, a placental growth-hormone variant, and human placental lactogen** (other candidates: placenta-derived pro-inflammatory exosomes and miRNAs).
- ▶ **β -cell compensation:** to maintain euglycaemia, maternal insulin secretion rises by up to **~250%**. **GDM develops when this β -cell compensation is inadequate** for the rising insulin resistance.
- ▶ That the driver is *placental* (not merely weight gain) is shown by the fact that **euglycaemia returns within days of delivery** once the placenta is removed.
- ▶ **Risk factors:** prepregnancy **obesity** (a major risk factor), excessive gestational weight gain, advancing age, ethnicity (South Asian, etc.), prior GDM, prior macrosomic infant, family history of T2DM, PCOS/insulin-resistant states, and offspring of women who had diabetes in pregnancy (intergenerational transmission).

Screening and diagnosis

- ▶ **Universal screening** of asymptomatic pregnant women at **24–28 weeks** is routine prenatal care (USPSTF grade **B** recommendation). Women with high-risk features may be screened earlier; if hyperglycaemia meets standard non-pregnant diabetes criteria in the **first trimester**, label as pre-existing diabetes.
- ▶ Two validated approaches exist. The **two-step (ACOG-preferred)** strategy is detailed in the corpus; the **one-step (IADPSG/ADA)** 75-g test is the widely-used alternative.

Strategy	Test	Diagnostic thresholds	Rule for diagnosis
Two-step — Step 1 (screen)	50-g oral glucose challenge, non-fasting; 1-h plasma glucose	≥ 130 – 140 mg/dL (7.2–7.8 mmol/L)*	If abnormal $\rightarrow$ proceed to Step 2
Two-step — Step 2 (diagnostic)	100-g 3-h OGTT (fasting) — <i>Carpenter–Coustan</i>	Fasting ≥ 95 ; 1-h ≥ 180 ; 2-h ≥ 155 ; 3-h ≥ 140 mg/dL	GDM if ≥ 2 values met/exceeded
One-step (IADPSG/ADA)	75-g 2-h OGTT (fasting)	Fasting ≥ 92 ; 1-h ≥ 180 ; 2-h ≥ 153 mg/dL	GDM if ≥ 1 value met/exceeded

- ▶ The 50-g screen cut-off is given as >130 mg/dL (Harrison) or ≥ 140 mg/dL* (CMDT/ACOG); 135 mg/dL is also used — higher cut-offs trade sensitivity for specificity.
- ▶ The 100-g OGTT is performed after an **overnight fast (8–14 h)**, following ≥ 3 days of unrestricted diet (>150 g carbohydrate/day); the patient stays seated and does not smoke.
- ▶ HbA1c is **unreliable for monitoring** in pregnancy (high red-cell turnover gives falsely low values), so it is not used for serial glycaemic monitoring.

Maternal, fetal and neonatal complications

- ▶ The mechanistic link is the **Pedersen hypothesis**: maternal hyperglycaemia crosses the placenta → fetal hyperinsulinaemia → fetal overgrowth and, at delivery, neonatal hypoglycaemia.

Domain	Complications
Maternal	Preeclampsia, polyhydramnios, increased caesarean delivery , birth trauma/lacerations; long-term T2DM and cardiovascular disease
Fetal / obstetric	Macrosomia (birth weight >4000 g) → shoulder dystocia , brachial plexus injury (Erb palsy) and birth trauma; large-for-gestational-age fetus, polyhydramnios
Neonatal	Hypoglycaemia (fetal hyperinsulinaemia), hyperbilirubinaemia , polycythaemia , respiratory distress syndrome

- ▶ In **pgDM** (contrast for the exam) add: spontaneous abortion, **congenital malformations** (cardiac, skeletal, neural-tube defects; *caudal regression/sacral agenesis* is the classically associated anomaly), stillbirth and worsening of maternal nephropathy/retinopathy. These reflect first-trimester hyperglycaemia and are **not** features of pure GDM.

Management

- ▶ **Goal-directed glycaemic targets (pregnancy)**: fasting <95 mg/dL (5.3 mmol/L), 1-h postprandial <140 mg/dL (7.8 mmol/L), 2-h postprandial <120 mg/dL (6.7 mmol/L); aim HbA1c $<6\%$. Self-monitor capillary glucose ~ 4 times/day (fasting + post-meals).
- ▶ **Step 1 — Medical nutrition therapy (MNT)** and appropriate gestational weight gain control normalise glucose in the **majority** of women; combine with physical activity.
- ▶ **Step 2 — Pharmacotherapy if targets exceeded**: **insulin is the preferred/first-line agent** (does not cross the placenta, low treatment-failure rate). Use a **basal–bolus regimen** — intermediate/short-acting combinations such as **NPH + regular**, or rapid analogues **lispro/aspart** (placenta-impermeant).
- ▶ **Oral agents — metformin and glyburide** are alternatives when insulin is declined or impractical. Contemporary data show **metformin** gives **lower mean birth weight**, **less gestational weight gain** and **less preeclampsia** than glyburide or insulin; however, both are **off-label**, cross the

placenta, and metformin's uncertain long-term offspring effects (higher childhood adiposity) keep insulin first-line.

- ▶ **Insulin requirements** rise through gestation in diabetic pregnancy: ~0.7–0.8 U/kg/day (1st trimester) → 0.8–1.0 (2nd) → 0.9–1.2 U/kg/day (3rd) as placental insulin resistance increases.
- ▶ **Fetal surveillance:** serial ultrasound for growth/macrosomia and polyhydramnios (markers of suboptimal control). **Timing/mode of delivery:** induction often in the early-term window (37–39 weeks) when indicated; caesarean considered for estimated fetal weight ≥4500 g to avoid shoulder dystocia. **Tight intrapartum control** minimises neonatal hypoglycaemia.
- ▶ **Benefit of treatment:** randomised data show treating GDM reduces preeclampsia, birth weight >4000 g and shoulder dystocia.

Postpartum and long-term follow-up

- ▶ GDM usually resolves immediately after delivery, but it unmasks a high lifetime risk of dysglycaemia: a 7- to 10-fold increased risk of T2DM, with ~10% developing diabetes within 5 years; ~35–60% develop diabetes over 10–20 years (and 50–70% over 15–25 years in some series — a 10- to 18-fold increase).
- ▶ **Postpartum re-test:** a 75-g 2-h OGTT at 4–12 weeks after delivery to detect persisting diabetes or impaired glucose tolerance, then lifelong screening at least every 3 years.
- ▶ **Risk reduction:** breastfeeding, weight loss, exercise and metformin reduce progression to T2DM; counsel on cardiovascular risk and the need for primary-care follow-up.
- ▶ **Offspring** of GDM pregnancies carry increased risk of childhood obesity, metabolic syndrome and later T2DM — an intergenerational, partly *in-utero-programmed* effect attenuated by good maternal control.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Two-step GDM screening/diagnosis flowchart:** Box 1 “All pregnant women, 24–28 wk” → “50-g GCT (non-fasting), 1-h glucose” → decision node “≥130–140 mg/dL?” → if No “Normal — no GDM”; if Yes → “100-g 3-h OGTT (fasting)” → list thresholds “Fasting 95 / 1-h 180 / 2-h 155 / 3-h 140 mg/dL” → decision “≥2 values exceeded?” → “GDM” vs “Not GDM”. Add a side branch “One-step 75-g OGTT: 92 / 180 / 153 → ≥1 value = GDM”.
- ▶ **Pathophysiology schematic:** “Placenta → human placental lactogen + placental GH-variant + steroids” → arrow “maternal insulin resistance ↑” → “β-cell secretion ↑ up to 250% (compensation)”; a second arrow showing “inadequate compensation → GDM → maternal hyperglycaemia → (placental transfer) → fetal hyperinsulinaemia → macrosomia, and at birth → neonatal hypoglycaemia (*Pedersen hypothesis*)”.

Clinical / Diagnostic significance

- ▶ Distinguishing **GDM from pgDM** changes the whole risk profile: pgDM mandates **preconception** optimisation (target HbA1c <6%, insulin before conception) to cut malformation risk; GDM care centres on third-trimester glycaemia and macrosomia prevention.
- ▶ A positive GDM diagnosis is an **opportunity for cardiometabolic prevention** — the postpartum OGTT and triennial screening identify future diabetes early.
- ▶ HbA1c's unreliability in pregnancy means **SMBG/continuous glucose monitoring**, not HbA1c, guides titration.
- ▶ Ultrasound estimated fetal weight and polyhydramnios are **surrogate alarms** for inadequate control and drive delivery planning.

High-yield exam pointers

- ▶ GDM = glucose intolerance **first recognised in 2nd/3rd trimester**; first-trimester hyperglycaemia = **pre-existing diabetes**, not GDM.
- ▶ Screen **all** women at **24–28 weeks** (USPSTF grade B).
- ▶ **Two-step**: 50-g GCT (≥ 130 – 140 mg/dL) $\rightarrow$ 100-g 3-h OGTT, ≥ 2 of 95/180/155/140 mg/dL = GDM. **One-step**: 75-g 2-h OGTT, ≥ 1 of 92/180/153 mg/dL = GDM.
- ▶ Targets: **fasting <95, 1-h <140, 2-h <120 mg/dL**, HbA1c <6%.
- ▶ **Insulin is first-line** drug therapy; metformin/glyburide are off-label alternatives; lispro, aspart, regular and NPH **do not cross the placenta**.
- ▶ Key sequelae via **fetal hyperinsulinaemia**: macrosomia $\rightarrow$ shoulder dystocia/Erb palsy; neonatal hypoglycaemia, hyperbilirubinaemia, polycythaemia, RDS.
- ▶ **Caesarean** considered at EFW ≥ 4500 g; treating GDM lowers preeclampsia, macrosomia and shoulder dystocia.
- ▶ Postpartum 75-g OGTT at **4–12 weeks**; lifelong screening **every 3 years**; **7–10 $\times$ risk of T2DM** (~10% within 5 years).

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Medical Disorders During Pregnancy” (Endocrine/Metabolic Disorders — Gestational Diabetes); “Diabetes Mellitus: Diagnosis, Classification, and Pathophysiology” (Gestational DM, ADA classification, screening recommendations).
- ▶ **Williams Textbook of Endocrinology, 15e** — “Pathophysiology of Type 2 Diabetes Mellitus” (gestational diabetes / pregnancy insulin resistance, β -cell compensation ~250%, placental drivers) and “Therapeutics of Type 2 Diabetes Mellitus” (pregnancy management, postpartum risk).

- ▶ **CMDT 2026** — “Obstetrics & Obstetric Disorders” (GDM screening/diagnostic criteria table, glycaemic targets, insulin and oral-agent therapy, postpartum 75-g OGTT) and “Diabetes Mellitus & Hypoglycemia” (pregnancy targets).
- ▶ **Coverage note:** The corpus fully supports the two-step (50-g/100-g Carpenter–Coustan) pathway, targets, complications and management. The **one-step IADPSG/ADA 75-g criteria (92/180/153 mg/dL)**, the eponyms **Pedersen hypothesis** and **caudal regression/sacral agenesis**, and **Erb palsy** as the brachial-plexus lesion are universally accepted standard internal medicine added for completeness but are not stated verbatim in these chapters. The historical **White classification** of diabetes in pregnancy is not covered in this corpus and is omitted.

GLP-1 Analogues

Asked in: Paper IV Nov 2020 — RGUHS MD General Medicine

Definition / Introduction — **Glucagon-like peptide-1 (GLP-1) receptor agonists (GLP-1RAs)**, also called *incretin mimetics* or *GLP-1 analogues*, are injectable (and now oral) peptide drugs that are homologs or analogues of the gut incretin hormone GLP-1, engineered to resist degradation by *dipeptidyl peptidase-4 (DPP-4)*. They lower glucose in a **glucose-dependent** manner, produce **weight loss** without intrinsic hypoglycaemia, and several confer proven **cardiovascular and renal protection**. They have transformed the management of type 2 diabetes mellitus (T2DM) and obesity, and now occupy a preferred place in glucose-lowering and weight-management algorithms.

Incretin physiology and rationale (mechanism of action)

- ▶ The “**incretin effect**”: an oral glucose load evokes a far greater insulin response than an equivalent intravenous load, because of gut-derived hormones released with nutrient ingestion — **GLP-1** (from intestinal **L-cells**) and **glucose-dependent insulintropic polypeptide (GIP)**, a 42-amino-acid peptide from duodenal/jejunal **K-cells**. This incretin effect is *blunted* in T2DM.
- ▶ Native GLP-1 is rapidly inactivated by the enzyme **DPP-4** (half-life ~1–2 min) and cleared by the kidney, so it cannot be used as a drug; analogues are made DPP-4-resistant or are given as DPP-4 inhibitors (incretin *enhancers*) instead.
- ▶ **Pleiotropic actions of GLP-1RAs:**
 - **Pancreas** — potentiate *glucose-dependent* insulin secretion from beta cells and suppress postprandial **glucagon** (alpha-cell) secretion; insulintropy ceases as glucose falls toward normal, hence minimal hypoglycaemia.
 - **Stomach** — **delay gastric emptying**, flattening postprandial glucose excursions.

- CNS — stimulate GLP-1 receptors in the hypothalamic **arcuate nucleus**, the brainstem **nucleus tractus solitarius** and connected appetite-relay nuclei to promote **satiety** and reduce energy intake → weight loss.
- Additional benefits: improved lipid profile, lower blood pressure, anti-inflammatory/anti-atherogenic endothelial effects, and reduction of hepatic steatosis.

Classification

Group	Agents	Salient feature
Short-acting GLP-1RA	Exenatide (synthetic <i>exendin-4</i>), Lixisenatide	Dominant effect on <i>postprandial</i> glucose via gastric slowing; more nausea per unit HbA1c fall
Long-acting GLP-1RA	Liraglutide (daily); Dulaglutide, exenatide-ER, Semaglutide (weekly)	Greater <i>fasting</i> glucose & HbA1c reduction; CV outcome benefit; better tolerated
Oral GLP-1RA	Oral semaglutide (with absorption enhancer SNAC)	First peptide GLP-1RA absorbed enterally
Dual incretin (GIP/GLP-1) agonist	Tirzepatide	“Twincretin”; superior HbA1c & weight loss

- **Origin pearl:** *exendin-4* is a naturally occurring peptide in the saliva of the *Gila monster* (*Heloderma suspectum*), shares ~53% sequence identity with human GLP-1, and is intrinsically DPP-4-resistant; **exenatide** is its synthetic form and was the first GLP-1RA approved (2004). **Liraglutide** has 97% homology with human GLP-1.

Individual agents — dosing and pharmacology

Agent	Route / frequency	Typical dose	Half-life	HbA1c fall
Exenatide	SC twice daily (before breakfast & dinner)	5–10 mcg BD	~2.4 h (≤6 h action)	~1.0%
Lixisenatide	SC once daily (before breakfast)	10–20 mcg OD	~3 h	~0.4–0.6%
Liraglutide	SC once daily	0.6 → 1.2 → 1.8 mg (3.0 mg for obesity)	~12–15 h	~0.6–1.5%
Dulaglutide	SC once weekly	0.75 → up to 4.5 mg	~5 days	~1.5–1.8%
Semaglutide (SC)	SC once weekly	0.25 → 0.5 → 1 → 2 mg (2.4 mg for obesity)	~1 week	~1.5–2.1%

Agent	Route / frequency	Typical dose	Half-life	HbA1c fall
Semaglutide (oral)	Oral once daily, fasting, ≥ 30 min before food	3 $\rightarrow$ 7 $\rightarrow$ 14 mg	~1 week	comparable to injectable
Tirzepatide (GIP/GLP-1)	SC once weekly	2.5 $\rightarrow$ up to 15 mg	~117 h	up to ~2.3%

- Doses are **titrated slowly** (over weeks) to limit gastrointestinal intolerance.
- **Fixed-ratio combinations with basal insulin:** *liraglutide/degludec* (*Xultophy*) and *lixisenatide/glargine* (*Soliqua*).
- **Tirzepatide** is engineered from the GIP backbone with agonist activity at both receptors; its GLP-1-receptor affinity is ~5-fold weaker than native GLP-1, while GIP agonism equals native GIP — central GIP action appears to act synergistically with GLP-1 to magnify weight loss.

Clinical efficacy and cardiovascular / renal outcomes

- **Glycaemia & weight:** the most effective non-insulin injectables for HbA1c lowering; consistent weight loss (≈ 2 –6 kg with most agents; ≥ 10 –15% with semaglutide 2.4 mg and tirzepatide). Only **liraglutide 3.0 mg** and **semaglutide 2.4 mg** are licensed specifically for chronic weight management; **tirzepatide** is approved for obesity (and obstructive sleep apnoea in obesity).
- **Head-to-head:** tirzepatide 5/10/15 mg gave superior HbA1c reduction versus semaglutide 1 mg (SURPASS-2); the 15 mg dose lowered HbA1c ~2.3% from a baseline of 8.3% with >10% weight loss in 57%.
- **Cardiovascular outcome trials (CVOTs) — long-acting agents (MACE = CV death, non-fatal MI, non-fatal stroke):**

Trial	Agent	MACE HR (95% CI)	Key extra findings
LEADER	Liraglutide	0.87 (0.78–0.97)	↓CV death (0.78), ↓all-cause death (0.85), ↓albuminuria
SUSTAIN-6	Semaglutide (SC)	0.74 (0.58–0.94)	↓stroke (0.61); transient ↑retinopathy signal
REWIND	Dulaglutide	0.88 (0.79–0.99)	↓stroke (0.76); primary-prevention population
EXSCEL	Exenatide-ER	0.91 (0.83–1.00)	Not statistically significant for MACE
HARMONY	Albiglutide	0.78 (0.68–0.90)	↓MI

- ▶ CV benefit is a **class property of long-acting agents** in high-risk T2DM; *short-acting* agents have not shown it consistently. Notably, GLP-1RAs reduced **atherosclerotic (MI/stroke)** events but **not heart-failure hospitalisation**.
- ▶ **Beyond diabetes:** SELECT showed a 20% reduction in MACE with semaglutide 2.4 mg in patients with established CV disease and obesity/overweight **without** diabetes; STEP-HFpEF improved heart-failure symptoms and exercise capacity in obesity-related HFpEF.
- ▶ **Renoprotection:** GLP-1RAs reduce albuminuria; dedicated trial data (semaglutide in CKD) demonstrate slowing of kidney-disease progression, supporting renal benefit.

Adverse effects, contraindications and precautions

- ▶ **Gastrointestinal (commonest):** nausea (11–40%), vomiting (4–13%), diarrhoea (9–17%), constipation, abdominal pain — dose-related, usually mild/transient, mitigated by slow titration; ~1–5% discontinue.
- ▶ **Hypoglycaemia:** not caused by GLP-1RAs alone, but occurs when combined with a **sulfonylurea or insulin** — pre-emptively reduce the secretagogue, and reduce insulin by ~20% (unless HbA1c >8%).
- ▶ **Pancreatitis:** post-marketing reports; advise patients to stop the drug and seek care for severe, persistent abdominal pain. (Avoid in prior pancreatitis.)
- ▶ **Medullary thyroid carcinoma / MEN-2:** rodent C-cell tumours seen pre-clinically; **contraindicated** with personal/family history of medullary thyroid cancer or MEN type 2.
- ▶ **Renal:** acute kidney injury (usually pre-renal, from volume depletion due to nausea/vomiting) — stop if unable to tolerate fluids >4 h. **Exenatide** is renally cleared and contraindicated at **eGFR <30 mL/min**; liraglutide/dulaglutide/semaglutide are proteolytically metabolised and preferred in renal impairment.
- ▶ **Diabetic retinopathy:** transient worsening (SUSTAIN-6) attributed to rapid glucose lowering.
- ▶ **Others:** cholelithiasis (with rapid weight loss); caution with gastroparesis and drugs that slow GI motility; a regulatory caution regarding mood change/suicidal ideation is under review.
- ▶ **Absolute contraindications:** type 1 DM / DKA, medullary thyroid carcinoma or MEN-2; relative — pancreatitis history, confirmed gastroparesis.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **GLP-1 action diagram** — label: *intestinal L-cell* → *GLP-1 release on nutrient ingestion*; arrows to **pancreatic beta cell** (↑ **glucose-dependent insulin**), **alpha cell** (↓ **glucagon**), **stomach** (↓ **gastric emptying**), **brain/hypothalamus** (↑ **satiety**, ↓ **appetite**); show **DPP-4** degrading native GLP-1 (with GLP-1RA = DPP-4-resistant).

- ▶ **Classification tree** — *GLP-1RA* → branches: **short-acting** (exenatide, lixisenatide) / **long-acting** (liraglutide; dulaglutide, semaglutide, exenatide-ER) / **oral** (semaglutide-SNAC) / **dual GIP-GLP-1** (tirzepatide).

Clinical / Diagnostic significance

- ▶ **Place in therapy (T2DM):** preferred add-on (or first-line with metformin) when **atherosclerotic CVD, high CV risk, CKD, or obesity** predominates; combine with SGLT2 inhibitors for layered cardiorenal benefit.
- ▶ **Do not co-prescribe** a GLP-1RA with a **DPP-4 inhibitor** (mechanistically redundant).
- ▶ **Weight management:** semaglutide 2.4 mg, liraglutide 3.0 mg and tirzepatide give clinically meaningful, durable weight loss with cardiometabolic improvement, including in non-diabetic obesity.
- ▶ **Monitoring/counselling:** titrate slowly; counsel on GI symptoms, dehydration-related AKI, pancreatitis warning signs; screen for MTC/MEN-2 history before starting; review at intervals for efficacy and tolerability.

High-yield exam pointers

- ▶ **Exenatide** = **exendin-4** from *Gila monster* saliva; DPP-4-resistant; first GLP-1RA. **Liraglutide** 97% homologous to human GLP-1.
- ▶ Mechanism quartet: ↑ **glucose-dependent insulin**, ↓ **glucagon**, ↓ **gastric emptying**, ↑ **satiety**.
- ▶ **No hypoglycaemia alone**; cause **weight loss**; effective HbA1c reduction (~1–2%).
- ▶ Weekly long-acting agents: **dulaglutide, semaglutide, exenatide-ER**; daily: **liraglutide**; oral **semaglutide** uses absorption enhancer SNAC.
- ▶ **CVOTs:** LEADER (liraglutide), SUSTAIN-6 (semaglutide), REWIND (dulaglutide) positive; EXSCEL (exenatide) **neutral**; benefit on **atherosclerotic events, not HF hospitalisation**.
- ▶ **Tirzepatide** = dual GIP/GLP-1 agonist (“twincretin”), most potent for HbA1c and weight.
- ▶ Key cautions: **medullary thyroid carcinoma / MEN-2, pancreatitis, exenatide in eGFR <30**, transient **retinopathy** worsening, AKI from volume depletion.
- ▶ **SELECT trial** — CV benefit of semaglutide in obesity **without diabetes**.

SOURCE & COVERAGE

Graves' Disease

Asked in: Paper IV Jul 2021 — RGUHS MD General Medicine

Definition / Introduction — *Graves' disease* is an organ-specific **autoimmune disorder** caused by **thyroid-stimulating immunoglobulins (TSIs)** — IgG antibodies directed against the **TSH receptor (TSH-R)** that mimic TSH and drive unregulated thyroid hormone synthesis. It is the commonest cause of **thyrotoxicosis**, accounting for **60–80%** of cases, and is the only cause that classically combines **goitre**, **ophthalmopathy (thyroid eye disease)**, **dermopathy (pretibial myxoedema)** and **acropachy**. Thyrotoxicosis (thyroid-hormone excess) must be distinguished from hyperthyroidism (excessive *gland function*) — Graves' produces both.

Epidemiology & Pathogenesis

- **Epidemiology:** affects up to **2% of women**, one-tenth as frequent in men; peak onset **20–50 years**; high dietary iodine intake increases prevalence. Concordance in **monozygotic twins** is **20–30%** versus **<5%** in dizygotic twins, confirming a strong genetic component.
- **Susceptibility genes:** polymorphisms in **HLA-DR**, immunoregulatory genes **CTLA-4**, **CD25**, **CD40**, **PTPN22**, **FCRL3**, **CD226**, and the **TSH-R** gene itself.
- **Environmental triggers:** smoking (a moderate risk for Graves' but a **major risk for ophthalmopathy**), stress, sudden iodine load, the **postpartum period** (threefold rise), and immune reconstitution after HAART, **alemtuzumab**, or **immune checkpoint inhibitors** (nivolumab, pembrolizumab).
- **Mechanism of hyperthyroidism:** TSIs / **TRAb** synthesised by intrathyroidal, marrow and lymph-node lymphocytes bind and activate the TSH-R → continuous stimulation of hormone synthesis and gland growth, *unrestrained by feedback*. Coexisting **TPO** and **thyroglobulin (Tg) antibodies** are present in up to **80%**; because lymphocytic thyroiditis coexists, there is **no direct correlation** between TSI titre and hormone level.
- **Ophthalmopathy mechanism:** activated T-cell infiltration of extraocular muscles → release of **IFN- γ** , **TNF**, **IL-1** → fibroblast activation and **glycosaminoglycan** deposition that traps water → muscle swelling; increased orbital fat adds to retrobulbar expansion. The **TSH-R** is a **shared orbital autoantigen**, and aberrant signalling via the **insulin-like growth factor-1 receptor (IGF-1R)** on orbital fibroblasts underpins disease and is the target of **teprotumumab**.

Clinical Features

- ▶ **General thyrotoxic features** (descending frequency): hyperactivity, irritability, **heat intolerance and sweating**, palpitations, fatigue, **weight loss with increased appetite**, diarrhoea, oligomenorrhoea. Signs: **sinus tachycardia / atrial fibrillation** (esp. >50 y), fine **tremor**, goitre, warm moist skin, **proximal myopathy**, lid retraction/lag.
- ▶ In the elderly, presentation may be subtle — **apathetic thyrotoxicosis** (fatigue, weight loss, AF) mistaken for depression or malignancy.
- ▶ **Cardiovascular**: high-output state — bounding pulse, widened pulse pressure, aortic flow murmur; AF reverts to sinus rhythm in up to 75% once euthyroid.
- ▶ **Neuromuscular**: hyperreflexia, proximal myopathy without fasciculation; **thyrotoxic hypokalaemic periodic paralysis** — sudden flaccid paralysis, common in **Asian/American-Indian men** (~15%; up to 30× commoner in men), often after carbohydrate/dextrose load or exercise.
- ▶ **Graves'-specific signs (diagnostic triad clues)**:
 - **Goitre** — diffuse, firm, 2–3× **enlarged**, often with a **bruit/thrill** at the inferolateral poles (hypervascularity).
 - **Ophthalmopathy / thyroid eye disease (TED)** — clinically present in ~**one-third**; grittiness, excess tearing, **proptosis**, periorbital oedema, chemosis, scleral injection, **diplopia**, and, most seriously, **optic-nerve compression** at the orbital apex → visual loss. Occurs **without hyperthyroidism in 10%** (euthyroid Graves' ophthalmopathy); onset within 1 year of thyrotoxicosis in 75%.
 - **Thyroid dermopathy (pretibial myxoedema)** — <5% (CMDT ~3%); non-inflamed indurated plaque, “**orange-peel**” appearance, over anterolateral shins; almost always with moderate-severe eye disease.
 - **Thyroid acropachy** — <1%; clubbing with phalangeal periostitis, virtually always with dermopathy.

Classification of Ophthalmopathy (NO SPECS & CAS)

Class	“NO SPECS” feature (Werner)
0	No signs or symptoms
1	Only signs (lid retraction/lag), no symptoms
2	Soft tissue involvement (periorbital oedema)
3	Proptosis (>22 mm)
4	Extraocular muscle involvement (diplopia)
5	Corneal involvement
6	Sight loss (optic nerve)

- ▶ *NO SPECS* is a useful mnemonic but inadequate for monitoring; activity is better graded by the **7-point Clinical Activity Score (CAS)** of EUGOGO (spontaneous retrobulbar pain, pain on gaze, lid redness, conjunctival redness, lid swelling, caruncle/plica swelling, chemosis). **CAS ≥ 3 = active disease**; the EUGOGO system grades severity (mild / moderate-to-severe / sight-threatening).

Laboratory Evaluation & Differential Diagnosis

- ▶ **First-line:** suppressed TSH with raised free (and total) T4 and T3. In 2–5% only T3 is raised (*T3 toxicosis*); rarely *T4 toxicosis* (iodine-induced).
- ▶ **Confirm aetiology:** measure TRAb/TSI (high sensitivity & specificity for Graves'; also predicts neonatal thyrotoxicosis in pregnancy and GO course). Positive **TPO antibodies** in ~80%.
- ▶ **Radionuclide ($^{24}\text{Tc}/^{123}\text{I}/^{131}\text{I}$) scan & uptake:** *diffuse, high uptake* in Graves' — distinguishes it from **destructive thyroiditis, factitia and iodine excess (low uptake)** and from focal uptake of toxic adenoma/toxic MNG. **Colour-flow Doppler** (increased flow) is a radiation-free alternative.
- ▶ **Ancillary abnormalities:** mild rise in bilirubin, transaminases, ferritin, alkaline phosphatase; mild **hypercalcaemia/hypercalciuria**; microcytic anaemia; thrombocytopenia.
- ▶ **Differential:** toxic MNG, toxic adenoma, subacute/silent thyroiditis, factitious thyrotoxicosis, struma ovarii, TSH-secreting pituitary adenoma (non-suppressed TSH + diffuse goitre), and non-thyroid mimics (panic, pheochromocytoma, malignancy). A **normal TSH excludes Graves'**.

Management

- ▶ **Three definitive options** — antithyroid drug (ATD), radioiodine (^{131}I) and surgery; ATD is first-line in Europe/Japan/India and increasingly the USA.
- ▶ **Antithyroid (thionamide) drugs** — inhibit **thyroid peroxidase** ($\downarrow$ organification); also lower antibody levels:
 - **Methimazole/carbimazole** preferred: start **10–20 mg q12h**, maintenance 2.5–10 mg; PTU 100–200 mg q6–8h. PTU uniquely blocks peripheral **T4 $\rightarrow$ T3 conversion** but has short half-life (90 min vs 6 h) and **hepatotoxicity** — now restricted to **first-trimester pregnancy, thyroid storm, and methimazole intolerance**.
 - **Titration** regimen (most common) or **block-and-replace** (high ATD + LT4). Review at 4–6 weeks (titrate to free T4; TSH stays suppressed for months). **Remission 30–60% by 12–18 months**, higher if TRAb becomes undetectable.
 - **Side effects:** rash/urticaria/arthritis (1–5%); rare major — **agranulocytosis** ($<1\%$, idiosyncratic; **stop drug, urgent CBC for sore throat/fever**), hepatitis (PTU), cholestasis, vasculitis.
- ▶ **β -blockers** for adrenergic relief: **propranolol 20–40 mg q6h** (or atenolol); also for thyrotoxic periodic paralysis.

- ▶ **Radioiodine (^{131}I):** progressive ablation; typical dose 370 MBq (10 mCi) – 555 MBq (15 mCi); stop methimazole 2–3 days prior. Risks: transient worsening of thyrotoxicosis, **GO flare in smokers** (cover with prednisone 0.3–0.5 mg/kg/day), and inevitable **hypothyroidism (10–20% first year, ~5%/yr thereafter)**. **Absolutely contraindicated in pregnancy and lactation** (conceive only ≥ 6 months later); avoid in active moderate-to-severe eye disease.
- ▶ **Surgery (total/near-total thyroidectomy):** for large goitre, relapse, or patient preference. Render euthyroid with ATD, then **potassium iodide (SSKI 1–2 drops tid $\times$ 10 days)** to reduce vascularity. Complications: bleeding, laryngeal oedema, **hypoparathyroidism**, **recurrent laryngeal nerve injury**.
- ▶ **Pregnancy:** PTU until 14–16 weeks (avoids methimazole embryopathy — **aplasia cutis, choanal atresia, tracheo-oesophageal fistula**), then switch to methimazole; titrate to keep free T4 at/just above the upper reference range; monitor TRAb (transplacental TSI $\rightarrow$ fetal/neonatal thyrotoxicosis if $>3\times$ normal).
- ▶ **Ophthalmopathy:** stop smoking, restore euthyroidism, artificial tears, selenium for mild disease. **Active moderate-to-severe GO $\rightarrow$ IV methylprednisolone (cumulative 4.5 g: 500 mg weekly $\times 6$ then 250 mg weekly $\times 6$, $\pm$ mycophenolate).** **Teprotumumab** (anti-IGF-1R) is now first-line for active disease with significant proptosis/diplopia; rituximab/tocilizumab are second-line. **Sight-threatening GO** (optic neuropathy/corneal breakdown) $\rightarrow$ high-dose IV methylprednisolone $\pm$ orbital decompression.

Thyrotoxic Crisis (Thyroid Storm)

- ▶ Life-threatening decompensated thyrotoxicosis precipitated by infection, surgery, trauma, DKA, parturition or ^{131}I in untreated patients; **mortality 4–17%**. Features: hyperpyrexia, delirium/coma, seizures, vomiting, diarrhoea, jaundice, **high-output cardiac failure/arrhythmia**. Severity graded by the **Burch-Wartofsky point scale**.
- ▶ **Treatment (combine all):** PTU 500–1000 mg load then 250 mg q4h (blocks T4 $\rightarrow$ T3); **iodide** (SSKI 5 drops q6h) given ≥ 1 h after PTU (Wolff-Chaikoff block of release); **propranolol** 60–80 mg PO q4h or 2 mg IV q4h; **hydrocortisone** 300 mg IV then 100 mg q8h; plus cooling, oxygen, IV fluids, treat the trigger; **cholestyramine** sequesters hormone.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Pathogenesis of Graves' disease** — draw a thyroid follicular cell with a **TSH receptor**; a plasma cell/B-lymphocyte releasing TSI (TRAb, IgG) binding the receptor $\rightarrow$ arrow to “**unregulated T3/T4 synthesis & goitre**”. Side arrow showing the same antibody/IGF-1R acting on **orbital fibroblast $\rightarrow$ GAG deposition $\rightarrow$ proptosis**. Labels: *TSH receptor, TSI/TRAb, B-cell/plasma cell, T-cell + cytokines (IFN- γ , TNF, IL-1), IGF-1R, orbital fibroblast, glycosaminoglycans, extraocular muscle swelling*.

- ▶ **Evaluation-of-thyrotoxicosis algorithm** — Box 1: “↓TSH, ↑free T4” → Box 2: “Features of Graves’? (diffuse goitre, TRAb+, TPO+, ophthalmopathy, dermopathy)” → Yes = Graves’; No → **radionuclide uptake**: *diffuse high = Graves’, focal/patchy = toxic nodule/MNG, low/absent = thyroiditis, iodine excess, factitia*. Labels: TSH, free T4, free T3, TRAb, RAIU, $^{24}\text{Tc}/^{123}\text{I}$ scan.

Clinical / Diagnostic significance

- ▶ TRAb is the confirmatory autoantibody: clinches Graves’ when eye/skin signs are absent, predicts relapse after ATD, and guides pregnancy monitoring (neonatal thyrotoxicosis risk).
- ▶ Distinguishing Graves’ (high RAIU) from destructive thyroiditis (low RAIU) is decisive — the latter is *not* treated with thionamides.
- ▶ Untreated thyrotoxicosis risks AF, thromboembolism, osteoporosis, high-output failure and thyroid storm; AF often reverts with euthyroidism, so rate control + anticoagulation (CHA₂DS₂-VASc) is interim.
- ▶ New-onset AF, unexplained weight loss, or proximal myopathy in any adult warrants TSH testing.

High-yield exam pointers

- ▶ Commonest cause of thyrotoxicosis (60–80%); autoimmune, driven by TSI/TRAb against TSH-R; F:M ≈ 10:1.
- ▶ Classic tetrad: diffuse goitre + ophthalmopathy + dermopathy + acropachy; goitre bruit signifies hypervascularity.
- ▶ Smoking is the key modifiable risk for ophthalmopathy progression and ^{131}I -induced flare.
- ▶ NO SPECS (0–6) and CAS (≥3 = active) classify eye disease; proptosis cut-off >22 mm.
- ▶ Methimazole first-line; PTU only in first-trimester pregnancy, thyroid storm, methimazole intolerance; watch agranulocytosis (<1%).
- ▶ ^{131}I contraindicated in pregnancy/lactation and active severe GO; causes hypothyroidism.
- ▶ Teprotumumab = anti-IGF-1R monoclonal, first-line for active moderate-severe GO.
- ▶ Thyroid storm: PTU → iodide (≥1 h later) → β-blocker → steroid; mortality up to ~17%.
- ▶ T3 toxicosis in 2–5%; thyrotoxic hypokalaemic periodic paralysis classically in Asian men.

SOURCE & COVERAGE

- ▶ Harrison’s Principles of Internal Medicine, 22e — “Hyperthyroidism and Other Causes of Thyrotoxicosis” (epidemiology, pathogenesis, NO SPECS, antithyroid-drug regimens, radioiodine, surgery, pregnancy, thyroid storm).

Gynaecomastia

Asked in: Paper IV Jul 2021 — RGUHS MD General Medicine

Definition / Introduction — Gynaecomastia is the benign enlargement of the male breast due to proliferation of true **glandular** (ductal–stromal) tissue, clinically palpable as a firm, rubbery, mobile, often tender disc extending concentrically from beneath the nipple–areola. It results from an **increased estrogen-to-androgen ratio** acting on breast tissue and must be distinguished from *pseudogynaecomastia* (excess adipose tissue, soft and diffuse, common in obesity) and from **male breast carcinoma**. It may be a benign physiological variant or the first clue to serious endocrine, systemic or neoplastic disease.

Hormonal basis & pathogenesis

- ▶ **Estrogens** stimulate growth and differentiation of ductal epithelium (ductal hyperplasia); **progesterone** drives acinar/glandular bud formation; **androgens inhibit** breast growth and differentiation. GH, IGF-1, insulin, thyroid hormone and cortisol play permissive roles; prolactin promotes milk production in already-developed glands.
- ▶ The unifying mechanism is a **raised estrogen : androgen ratio** at the breast, achieved by *estrogen excess*, *androgen deficiency/resistance*, or both. Even small rises in serum estradiol (within the normal male range) produce large proportional effects on breast tissue.
- ▶ *Galactorrhoea is rare* even with hyperprolactinaemia, because male progesterone levels are too low for acinar development/lactogenesis.
- ▶ In primary hypogonadism (e.g. *Klinefelter syndrome*), high **LH** stimulates aromatase in Leydig cells → relatively more estradiol than testosterone. In obesity/ageing, increased adipose **aromatase** raises peripheral androgen→estrogen conversion.

Natural history & histological phases

- ▶ **Florid / proliferative (early, <6 months)**: ductal proliferation, periductal inflammation and oedema, subareolar fat accumulation → tender, painful; **responsive to medical therapy**.

- **Inactive / fibrotic (late, >6–12 months):** progressive stromal fibrosis, hyalinisation; non-tender; only partial spontaneous regression and generally **unresponsive to drugs** — requires surgery.
- Absence of breast tenderness usually signals the chronic fibrotic stage that will not remit.

Classification of causes

Category	Representative causes
Physiologic	Neonatal (transplacental maternal/placental estrogens; in 60–90%, resolves in weeks); pubertal (transient ↑estrogen:testosterone, ~60% of boys by age 14, regresses in 1–2 yr); ageing/obesity (↑aromatase, ↓testosterone; up to ~65% of men aged 50–80)
Estrogen excess	Exogenous estrogens (diethylstilbestrol for prostate Ca, estrogen creams/cosmetics, phytoestrogens, lavender/tea-tree oils); ER agonists (marijuana, digitoxin); estrogen-secreting tumours — adrenal carcinoma, Leydig/Sertoli cell tumours (Sertoli ± <i>Peutz-Jeghers</i> , <i>Carney complex</i>); hCG-secreting tumours — germ cell, lung, hepatic, gastric, renal; familial/sporadic aromatase excess syndrome
Androgen deficiency / resistance	Primary or secondary hypogonadism (incl. Klinefelter 47,XXY); androgen insensitivity syndromes; hyperprolactinaemia (suppresses GnRH → hypogonadism)
Drug-induced (~20% of adult cases)	Spirolactone (common), AR antagonists (flutamide, bicalutamide, enzalutamide), 5α-reductase inhibitors (finasteride/dutasteride), ketoconazole, cimetidine/H2 blockers , GnRH agonists, digitalis, HAART/efavirenz , anabolic steroids, ketoconazole, CCBs, amiodarone, TCAs/SSRIs, alcohol, opioids, methadone, isoniazid, metoclopramide, antipsychotics
Systemic disease	Hepatic cirrhosis (↓androstenedione catabolism, ↑SHBG → ↑free E2/T), CKD stage 4–5 (often with dialysis), hyperthyroidism (↑SHBG, ↑LH-driven E2), acromegaly, Cushing syndrome, refeeding after starvation/chronic illness (“second puberty”)

Clinical evaluation

- **History:** speed of onset and growth, pain/tenderness, drugs & substances (above), alcohol, recreational drugs, cosmetics/supplements; symptoms of hypogonadism (low libido, ED); features of liver/renal/thyroid disease, weight change, recent refeeding.

- ▶ **Examination (technique):** with thumb and forefinger as pincers, palpate the subareolar disc both **seated and supine** and compare with nearby fat. **True glandular tissue** is firm, rubbery, finely lobular, mobile, concentric to the nipple; **pseudogynaecomastia** is soft, diffuse, non-discrete adipose tissue.
- ▶ Also assess **virilisation, testicular size and masses** (orchidometer; small/firm testes → Klinefelter; a testicular mass → tumour), penis for hypospadias.
- ▶ **Red flags for carcinoma:** unilateral/markedly asymmetric, eccentric (not directly sub-areolar), rock-hard or fixed, skin dimpling (*peau d'orange*), nipple retraction, bloody discharge, axillary lymphadenopathy.
- ▶ **Thresholds:** glandular tissue **>4 cm** (Harrison) or **≥5 cm** with recent/rapid onset, tenderness or suspicious features warrants work-up; non-tender lesions **≤2.5 cm** are a common normal variant; up to two-thirds of pubertal boys and ~half of hospitalised men have benign palpable glandular tissue.

Investigations

- ▶ **First-line hormonal panel:** total and free testosterone, LH, FSH, estradiol (E2), β -hCG, TSH/FT4, prolactin.
- ▶ **Interpretation:** $\downarrow$ T + $\uparrow$ LH → **primary hypogonadism** (do karyotype for Klinefelter if testes very small); $\downarrow$ T + low/normal LH → **secondary hypogonadism**; $\uparrow$ T + $\uparrow$ LH → partial androgen insensitivity; $\uparrow$ hCG → testicular germ-cell/Sertoli tumour or ectopic (lung, liver); $\uparrow$ E2 with **suppressed LH** → estrogen-secreting testicular/adrenal tumour.
- ▶ **Organ work-up:** liver and renal function; TSH for thyrotoxicosis.
- ▶ **Imaging/biopsy:** **testicular ultrasound** if hCG/E2 elevated; **CT adrenal** for high E2 with normal testes, **CT chest/abdomen** for hCG-source search; **mammography ± ultrasound-guided FNA/biopsy** for any features suspicious of malignancy. (Note: routine commercial E2 assays are inaccurate at male levels — prefer **mass spectrometry**; use an assay detecting total hCG/ β -subunit.)
- ▶ Despite full evaluation, the cause is established in only a minority — many adult cases remain **idiopathic**.

Treatment

- ▶ **Treat the cause:** stop/replace the offending drug; correct hypogonadism, thyrotoxicosis, liver/renal disease, tumour. If addressed early, gynaecomastia usually subsides over months.
- ▶ **Reassurance/observation:** physiological neonatal and pubertal gynaecomastia regress spontaneously (pubertal in ~90% by age 18, within 1–2 yr).
- ▶ **Medical therapy (effective only in the early proliferative phase, <6 months):**

- **SERMs** — *Tamoxifen* 10–20 mg/day (reduces volume >50% in ~60%) and *Raloxifene* 60 mg/day (>50% reduction in ~90%); tamoxifen also prevents/treats antiandrogen-induced gynaecomastia in prostate-cancer patients.
- **Aromatase inhibitors** — *Anastrozole* (e.g. 0.5 mg thrice weekly, titrated to mid-range male E2) helps some early/pubertal cases but in a randomised trial was **no better than placebo** for *established* gynaecomastia; avoid long-term AI in adolescents (risk of osteoporosis and delayed epiphyseal fusion).
- ▶ **Prevention:** prophylactic low-dose breast irradiation ($\approx 10\text{--}15$ Gy over 1–3 days) or tamoxifen before androgen-deprivation therapy in prostate cancer.
- ▶ **Surgery:** definitive for long-standing (>6–12 months), fibrotic, large, painful, disfiguring or drug-refractory disease, or when malignancy is suspected — **subcutaneous mastectomy $\pm$ liposuction (reduction mammoplasty).**

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Hormonal pathophysiology schematic:** central box “ $\uparrow$ Estrogen : Androgen ratio at breast $\rightarrow$ ductal proliferation” with three feeding arrows — (1) *Estrogen excess* (tumour E2 / hCG-driven aromatisation / exogenous estrogen / $\uparrow$ peripheral aromatase in fat); (2) *Androgen deficiency* (primary & secondary hypogonadism, hyperprolactinaemia); (3) *Drugs* (spironolactone, AR blockers, 5-ARIs, cimetidine). Label “Estrogen $\rightarrow$ ductal hyperplasia”, “Progesterone $\rightarrow$ acini”, “Androgen $\perp$ inhibits”.
- ▶ **Evaluation algorithm (Harrison Fig. 403-7):** Breast enlargement $\rightarrow$ *true glandular* vs *adipose (pseudogynaecomastia)* $\rightarrow$ if glandular, measure **Total/Free T, SHBG, LH, FSH, E2, TSH, hCG** $\rightarrow$ four branches: $\downarrow T + \uparrow E2:T$ ratio = T-deficiency; $\uparrow E2$ with low/normal T = search testis/adrenal tumour; $\uparrow \beta\text{-hCG}$ = ultrasound testis + CT for hCG tumour; very high SHBG = check free T/E2.

Clinical / Diagnostic significance

- ▶ New, rapidly growing, tender gynaecomastia **in a lean adult** demands evaluation — may signal a testicular/adrenal tumour or hCG-secreting malignancy.
- ▶ **Klinefelter syndrome (47,XXY):** classic gynaecomastia with small firm testes; carries an **increased risk of male breast cancer** $\rightarrow$ periodic **mammographic surveillance** is recommended.
- ▶ Gynaecomastia is a sensitive physical sign of **chronic liver disease** and **chronic kidney disease**, and a flag for drug toxicity (spironolactone, digoxin, antiretrovirals).
- ▶ The relative risk of **male breast carcinoma** is increased in men with gynaecomastia (absolute risk small) — unilateral, hard, eccentric or bloody-discharge lesions must be imaged/biopsied.

High-yield exam pointers

- ▶ Core mechanism = ↑ **estrogen : androgen ratio**; estrogen → ducts, progesterone → acini, androgen inhibits.
- ▶ **True (glandular, ≥4 cm, tender, mobile disc)** vs **pseudogynaecomastia (fatty, soft, obese)** vs **carcinoma (hard, fixed, eccentric, peau d'orange, nipple bleed)**.
- ▶ Three physiological peaks: **neonatal, pubertal, ageing/obesity**.
- ▶ ~20% of adult cases are **drug-induced**; remember **spironolactone, ketoconazole, cimetidine, 5-ARIs, AR antagonists, digoxin, marijuana, efavirenz/HAART, anabolic steroids**.
- ▶ First-line tests: **testosterone, LH, FSH, estradiol, β-hCG, TSH, prolactin**; karyotype if small testes (Klinefelter).
- ▶ ↑hCG → **germ-cell/ectopic tumour**; ↑E2 + suppressed LH → **estrogen-secreting tumour**.
- ▶ Drugs (SERMs/AI) work only in the **early proliferative phase (<6 months)**; **tamoxifen 10–20 mg/day, raloxifene 60 mg/day**; fibrotic disease needs **subcutaneous mastectomy**.
- ▶ **Refeeding gynaecomastia** — first described in liberated WWII prisoners of war; “second puberty” mechanism.
- ▶ **Familial aromatase excess syndrome** — CYP19 activation (chromosome 15q21) → prepubertal gynaecomastia, advanced bone age, short stature.
- ▶ Spironolactone causes it; **eplerenone does not**.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Disorders of the Testes and Male Reproductive System” (Gynecomastia section; evaluation Fig. 403-7).
- ▶ **Williams Textbook of Endocrinology, 15e** — “Testicular Disorders” (Gynecomastia: pathophysiology, Table 17.3 Causes of Gynecomastia, evaluation and treatment).
- ▶ **CMDT 2026** — “Male Hypogonadism & Gynecomastia” (Essentials of diagnosis, Table 31–3, current SERM/aromatase-inhibitor regimens).

Hirsutism

Asked in: Paper IV Jun 2024 — RGUHS MD General Medicine

Definition / Introduction — **Hirsutism** is the presence of excessive **terminal hair** (long, coarse, pigmented) growing in a **male (androgen-dependent) pattern** in a woman — face (upper lip, chin), chest, upper abdomen, midline, and back. It affects roughly **10%** of reproductive-age women and is most often **idiopathic** or due to **androgen excess from polycystic ovary syndrome (PCOS)**; less commonly it reflects **nonclassic congenital adrenal hyperplasia (NCCAH)** or, rarely, an **androgen-secreting tumour**. It must be distinguished from **hypertrichosis** (androgen-independent, generalised vellus hair) and from **virilization** (a more severe androgenic state with masculinising features).

Hair biology and androgen physiology

- ▶ Hair is **vellus** (fine, soft, non-pigmented) or **terminal** (long, coarse, pigmented). Androgens drive the conversion of vellus to terminal hair within the **pilosebaceous unit (PSU)** at androgen-sensitive sites (face, chest, upper abdomen, back).
- ▶ Hair-growth cycle has three phases: **anagen** (growth), **catagen** (involution) and **telogen** (rest). Paradoxically, scalp androgen excess shortens anagen, causing **androgenetic alopecia/thinning**.
- ▶ **Testosterone** is the principal circulating androgen in hirsutism, but it is a *precursor*: it is converted in the PSU by **5 α -reductase** to **dihydrotestosterone (DHT)** — a more potent androgen (higher affinity, slower dissociation from the androgen receptor) that is the **primary local mediator**. Two isoenzymes: **type 2** (prostate, hair follicles) and **type 1** (sebaceous glands).
- ▶ Ovaries and adrenals contribute about **equally** to testosterone; $\sim\frac{1}{2}$ from direct glandular secretion, $\frac{1}{2}$ from peripheral conversion of **androstenedione** and **DHEA/DHEAS**. Ovarian androgen is driven by **LH**, adrenal androgen by **ACTH**.
- ▶ **Sex hormone-binding globulin (SHBG)** governs the *free* (bioavailable) fraction. Hyperinsulinaemia and androgen excess suppress hepatic SHBG, so **free testosterone** rises even when total testosterone is high-normal — central to PCOS and obesity-related hirsutism.

Causes / Classification

Category	Representative causes
Ovarian hyperandrogenism	PCOS (commonest, $\sim 50\text{--}70\%$ of cases), hyperthecosis, ovarian steroidogenic blocks, severe insulin-resistance syndromes, ovarian neoplasms (arrhenoblastoma/Sertoli–Leydig, hilar cell tumours)
Adrenal hyperandrogenism	Nonclassic & classic CAH (chiefly 21-hydroxylase deficiency), premature adrenarche, functional adrenal hyperandrogenism, adrenal neoplasms
Other endocrine	Cushing's syndrome, hyperprolactinaemia, acromegaly
Peripheral overproduction	Obesity, idiopathic hirsutism
Pregnancy-related	Hyperreactio luteinalis, luteoma/thecoma of pregnancy
Drug-induced	Androgens/anabolic steroids, androgenic progestins (norgestrel, levonorgestrel), minoxidil, phenytoin, diazoxide, cyclosporine, valproate

- ▶ **AES prevalence (Azziz cohort, Williams):** PCOS 72%, idiopathic hyperandrogenism 16%, idiopathic hirsutism 7.6%, NCCAH (21-OHD) 4.3%, androgen-secreting tumours 0.2%.

- ▶ **Idiopathic hirsutism** = hirsutism with **cyclic ovulatory menses** and **normal serum testosterone**; reflects increased end-organ 5 α -reductase sensitivity (elevated androstenediol/androsterone glucuronide).

Clinical assessment

- ▶ **History:** age at onset and **rate of progression**. Onset in 2nd–3rd decade, slow and progressive favours PCOS/idiopathic; **sudden onset with rapid progression and virilization** suggests an **androgen-secreting neoplasm**. Menstrual history (**oligomenorrhoea** <8 cycles/year points to ovarian excess), galactorrhoea (prolactin/thyroid), family history of hirsutism/infertility (NCCAH), and **drug history**.
- ▶ **Examination:** height, weight, **BMI** (>25 overweight; >30 commonly associated with hirsutism via peripheral conversion), blood pressure (adrenal causes), and cutaneous markers of insulin resistance — **acanthosis nigricans**, **skin tags**. Look for Cushingoid features (striae, bruising, centripetal obesity).
- ▶ **Quantification** — **modified Ferriman–Gallwey (mFG) score**: **9 androgen-sensitive sites** (upper lip, chin, chest, upper abdomen, lower abdomen/pelvis, upper arms, thighs, upper back, lower back), each graded **0 (none) to 4 (frankly virile)**; **maximum 36**. **Score >8** = abnormal in most non-Hispanic white and African-American women (~95% score <8) and warrants hormonal work-up. Asian and Native-American women manifest hirsutism less readily (acne and scalp thinning may be the only clues).
- ▶ **Hirsutism vs virilization vs hypertrichosis:**
 - **Virilization** (markedly higher androgens — think tumour/hyperthecosis): deepening voice, temporal/frontal balding, breast atrophy, $\uparrow$ muscle bulk, loss of female contour, **clitoromegaly** (clitoral length >10 mm or **clitoral index** >35 mm² abnormal), $\uparrow$ libido.
 - **Hypertrichosis:** androgen-independent, diffuse **vellus** hair (non-sexual distribution) from drugs (phenytoin, minoxidil, cyclosporine) or systemic disease — not a sign of androgen excess.

Hormonal evaluation and investigations

- ▶ **First-line:** **total testosterone $\pm$ free testosterone** (calculated from total testosterone and SHBG, or by LC-MS/MS) and DHEAS. Free testosterone is the more sensitive index given SHBG suppression.
- ▶ **“Tumour” thresholds (red flags):**

Test	Value	Implication
Total testosterone	>7 nmol/L (>2 ng/mL)	Suggests tumour or hyperthecosis

Test	Value	Implication
Total testosterone	>12 nmol/L (>3.5 ng/mL)	Strongly indicates androgen-producing tumour (CMDT: >200 ng/dL → image)
Androstenedione	>1000 ng/dL (>34.9 nmol/L)	Ovarian/adrenal neoplasm
DHEAS	>18.5 µmol/L (>7000 µg/L; CMDT >700 µg/dL)	Adrenal source/tumour
17-hydroxyprogesterone (morning, follicular)	<6 nmol/L (<2 µg/L)	Excludes 21-OHD; >300 ng/dL suggests NCCAH

- ▶ **PCOS:** ↑LH:FSH ratio (>2) is characteristic but *random LH/FSH is unreliable* (pulsatile); transvaginal ultrasound shows enlarged ovaries with multiple peripheral follicles, but 25–30% of normal women have “cystic” ovaries, so imaging has low specificity — PCOS is a clinical/biochemical diagnosis of exclusion (Rotterdam: 2 of 3 — hyperandrogenism, oligo-anovulation, polycystic morphology).
- ▶ **NCCAH:** screen high-risk women with **morning follicular 17-OHP**; if borderline, ACTH (cosyntropin) 250 µg IV stimulation test confirms 21-hydroxylase deficiency.
- ▶ **Adrenal vs ovarian source:** dexamethasone androgen-suppression test (0.5 mg every 6 h × 4 days) — suppression of free testosterone to normal = adrenal source; incomplete suppression = ovarian.
- ▶ **Cushing’s:** overnight 1-mg dexamethasone suppression test if clinical suspicion. **Imaging:** CT/MRI adrenals for adrenal mass; transvaginal USG for ovarian mass; selective venous sampling for occult small virilizing tumours.

Management

- ▶ **Set expectations:** suppression slows *new* hair growth only — benefit not evident for 4–6 months, maximal at 9–12 months (hair-cycle length); existing terminal hair needs mechanical removal. Treat any **underlying cause** (stop offending drugs; surgery for tumours/Cushing’s).
- ▶ **Non-pharmacological (adjunct or sole therapy):** bleaching; shaving (does **not** increase growth rate/density); chemical depilatories; **plucking/waxing/electrolysis**; **laser and intense pulsed light (IPL)** photothermolysis for permanent reduction of pigmented terminal hair; **topical eflornithine 13.9% cream** (slows facial hair, esp. with laser).
- ▶ **Pharmacological — interrupt androgen synthesis/action:**

Drug class	Agent / dose	Mechanism / notes
Combined OCP (first-line)	Ethinyl-estradiol 30–35 µg + low-androgenic progestin	↓LH → ↓ovarian androgen; ↑SHBG; choose non-androgenic progestins (norgestimate) or antiandrogenic

Drug class	Agent / dose	Mechanism / notes
		drospirenone /cyproterone; avoid androgenic levonorgestrel/norgestrel
Androgen-receptor antagonist	Spirolactone 100–200 mg/day	Most-used antiandrogen; also inhibits 5 α -reductase; monitor K ⁺ /BP; menstrual irregularity; teratogenic (feminises male fetus) — needs contraception; synergistic with OCP
Antiandrogen + progestin	Cyproterone acetate (50–100 mg days 1–15) + EE — reverse-sequential	Competitive AR blockade + $\uparrow$ testosterone clearance; not available in USA
5 α -reductase inhibitor	Finasteride 5 mg/day	Inhibits type 2 (PSU has type 1 too $\rightarrow$ partial efficacy); teratogenic; dutasteride blocks types 1 & 2
Non-steroidal antiandrogen	Flutamide	Effective but hepatotoxic $\rightarrow$ not preferred
Insulin sensitiser	Metformin ($\pm$ lifestyle)	Modest hirsutism benefit in PCOS; aids ovulation
Glucocorticoid	Dexamethasone 0.2–0.5 mg / prednisone 5–10 mg at bedtime	Second-line in CAH (OCP preferred); suppresses nocturnal ACTH surge
Newer (CAH)	Crinicerfont 100 mg BD	CRF-receptor antagonist; $\downarrow$ androstenedione in 21-OHD CAH

- **Preferred regimen for the common causes (PCOS, NCCAH, idiopathic): combined OCP + spironolactone** plus weight loss (500 kcal/day deficit + exercise) — an ovary-suppressing agent combined with a peripheral antiandrogen; continue ≥ 2 years before reassessing.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- **Modified Ferriman–Gallwey scoring chart:** a female body outline with the **9 androgen-sensitive sites** labelled — *Upper lip, Chin, Chest, Upper abdomen, Lower abdomen (pelvis), Upper arms, Thighs, Upper back, Lower back* — each scored 0–4 (*max 36; abnormal >8*).
- **Androgen physiology / site of drug action flow diagram:** Ovary (LH) + Adrenal (ACTH) $\rightarrow$ Androstenedione/DHEA $\rightarrow$ Testosterone $\rightarrow$ [5 α -reductase] $\rightarrow$ DHT $\rightarrow$ Androgen receptor in pilosebaceous unit $\rightarrow$ terminal hair; label drug targets — OCP ($\downarrow$ LH, $\uparrow$ SHBG); Spirolactone/Cyproterone/Flutamide (AR block); Finasteride/Dutasteride (5 α -reductase); Eflornithine (follicle).

Clinical / Diagnostic significance

- ▶ A normal mFG with menstrual irregularity still warrants screening; **rapid-onset hirsutism + virilization + very high testosterone/DHEAS** mandates urgent tumour search (ovarian USG, adrenal CT/MRI).
- ▶ Free testosterone (not total) best reflects bioactivity because **SHBG is suppressed** by insulin/androgens — explains hirsutism with “normal” total testosterone.
- ▶ PCOS carries **metabolic risk** (insulin resistance, dyslipidaemia, type 2 diabetes, endometrial hyperplasia from unopposed estrogen) — screen accordingly; the cosmetic complaint is a window to systemic disease.
- ▶ All antiandrogens (spironolactone, finasteride, flutamide, cyproterone) are **teratogenic to a male fetus** — reliable contraception is mandatory in reproductive-age women.

High-yield exam pointers

- ▶ **Hirsutism = androgen-dependent terminal hair, male pattern**; hypertrichosis = androgen-independent vellus hair (drugs/systemic illness).
- ▶ **Commonest cause = PCOS**; most cases overall are idiopathic or PCOS-related; tumours are <1%.
- ▶ **DHT (via 5 α -reductase) is the key local mediator**; testosterone is the precursor.
- ▶ **mFG score**: 9 sites $\times$ 0–4, max 36, abnormal >8.
- ▶ **Tumour thresholds**: testosterone >7 nmol/L (>2 ng/mL) suggestive, >12 nmol/L (>3.5 ng/mL) likely tumour; DHEAS >7000 μ g/L = adrenal.
- ▶ **NCCAH screen**: morning follicular 17-OHP (<6 nmol/L excludes); confirm with ACTH/cosyntropin 250 μ g test.
- ▶ **Dexamethasone suppression** (0.5 mg q6h $\times$ 4 days) distinguishes adrenal (suppresses) from ovarian (does not).
- ▶ **First-line drug = combined OCP**; best results = OCP + **spironolactone**; response takes 6–9 months; combine with laser/electrolysis for existing hair.

Hyperaldosteronism

Asked in: Paper IV May 2019 — RGUHS MD General Medicine

Definition / Introduction — Hyperaldosteronism denotes a state of inappropriately high aldosterone secretion relative to volume/sodium status. It is **primary** when aldosterone production by the adrenal zona glomerulosa is *autonomous* of the renin–angiotensin–aldosterone (RAA) system (low/suppressed renin), and **secondary** when aldosterone rises appropriately in response to an *activated* RAA system (high renin). Primary aldosteronism (PA), first described by *Jerome W. Conn* in 1955, is now recognised as the commonest *curable/specifically-treatable* endocrine cause of hypertension, present in ~5–12% of all hypertensives and a higher proportion of resistant/hypokalaemic hypertension. Its clinical hallmark is **hypokalaemic hypertension** with metabolic alkalosis, though most patients are normokalaemic.

Physiology & pathogenesis

- ▶ **Normal control:** aldosterone synthesis (via *aldosterone synthase*, *CYP11B2*) is driven mainly by **angiotensin II** and **serum potassium**, with only a permissive role for ACTH; volume/salt loading suppresses renin and hence aldosterone. Aldosterone acts on the **mineralocorticoid receptor (MR)** in the distal nephron, increasing ENaC-mediated Na⁺ reabsorption and K⁺/H⁺ secretion.
- ▶ **In PA**, autonomous aldosterone → Na⁺/water retention, plasma-volume expansion, hypertension, renal K⁺ and H⁺ wasting (→ hypokalaemia, metabolic alkalosis), and feedback **suppression of renin**.
- ▶ “**Mineralocorticoid escape**” (pressure natriuresis + atrial natriuretic peptide) limits sodium retention, so overt oedema is uncharacteristic.
- ▶ Aldosterone also exerts **direct, blood-pressure-independent target-organ injury** — cardiac fibrosis/remodelling, vascular stiffening, and glomerular damage — explaining the excess cardiovascular, renal, metabolic and bone morbidity in PA versus essential hypertension of equal severity.

Classification & causes

Category	Renin	Aldosterone	Principal causes
Primary	Low / suppressed	High	Bilateral idiopathic adrenal hyperplasia (IHA); aldosterone-producing adenoma (<i>Conn's adenoma</i>); unilateral (primary) adrenal hyperplasia; familial forms; rarely adrenocortical carcinoma

Category	Renin	Aldosterone	Principal causes
Secondary	High	High	Renovascular (renal artery stenosis), renin-secreting (juxtaglomerular) tumour, malignant/accelerated hypertension, oedematous states (CHF, cirrhosis, nephrotic syndrome), diuretics, <i>Bartter</i> / <i>Gitelman</i> syndromes (normotensive)
Pseudo-aldosteronism (mimics, low renin and low aldosterone)	Low	Low	Liddle syndrome; apparent mineralocorticoid excess (AME)/liquorice; CAH (11 β - & 17 α -OHase deficiency); Cushing syndrome; DOC-secreting tumour

Subtypes of primary aldosteronism (approximate frequency):

- ▶ **Bilateral idiopathic hyperplasia (IHA)** — ~60% (60–70%); the commonest cause; treated medically.
- ▶ **Aldosterone-producing adenoma (Conn's syndrome)** — ~30–40%; usually a small (<2 cm), lipid-rich, golden-yellow unilateral nodule; surgically curable.
- ▶ **Unilateral (primary) adrenal hyperplasia** — ~2%.
- ▶ **Aldosterone-producing adrenocortical carcinoma** — <1% (suspect if tumour $\geq$ 4 cm, heterogeneous).
- ▶ **Familial hyperaldosteronism (FH)** — ~1–6%.

Genetics — somatic mutations drive most APAs by upregulating CYP11B2: *KCNJ5* (potassium channel *GIRK4*, ~40–70% of APAs; commoner in women, larger adenomas, overproduce hybrid steroids), *ATP1A1* (Na⁺/K⁺-ATPase), *ATP2B3* (Ca²⁺-ATPase), *CACNA1D* / *CACNA1H* (voltage-gated Ca²⁺ channels), *CLCN2* (chloride channel) and *CTNNB1* (β -catenin).

Familial hyperaldosteronism:

- ▶ **FH type I — Glucocorticoid-remediable aldosteronism (GRA / dexamethasone-suppressible):** autosomal dominant; a *CYP11B1/CYP11B2* chimeric gene places aldosterone synthesis under ACTH control. Severe early-onset hypertension, high risk of haemorrhagic stroke from ruptured

intracranial aneurysm; high urinary **18-oxocortisol & 18-hydroxycortisol**; aldosterone suppressible by glucocorticoid.

- ▶ **FH type II**: germline **CLCN2**; the commonest familial form (<6%); early-onset hypertension; *not* dexamethasone-suppressible.
- ▶ **FH type III**: germline **KCNJ5**; severe childhood hypertension with **massive bilateral adrenal hyperplasia**.
- ▶ **FH type IV**: germline **CACNA1H**; early-onset hypertension ± developmental disorders.
- ▶ **PASNA**: de novo **CACNA1D**; Primary Aldosteronism with Seizures and Neurologic Abnormalities.

Clinical features

- ▶ **Hypertension** — moderate-to-severe, often drug-resistant; commonest curable secondary cause in young/middle-aged adults.
- ▶ **Hypokalaemia** — present in only ~10–40% (≈37%); ~72% are normokalaemic. May be unmasked/worsened by thiazide or loop diuretics. Manifestations: muscle weakness, cramps, fatigue, **hypokalaemic periodic paralysis** (notably in Asians), polyuria/nocturia (nephrogenic diabetes insipidus from a renal concentrating defect), arrhythmias, rhabdomyolysis.
- ▶ **Metabolic alkalosis** (raised HCO_3^-); severe alkalosis → tetany/cramps. **Hypomagnesaemia** common.
- ▶ **High-normal serum sodium** (reset osmostat) — a useful clue; oedema usually absent (escape).
- ▶ **End-organ disease** out of proportion to BP: LVH/diastolic dysfunction, atrial fibrillation, stroke, CKD/proteinuria (masked early by glomerular hyperfiltration), osteoporosis, type 2 diabetes, impaired quality of life.
- ▶ “**Connshing**” syndrome — concurrent mild autonomous cortisol secretion (MACS) in a subset.

Diagnostic approach

A three-step pathway — **case detection** → **confirmation** → **subtyping**.

- ▶ **Whom to screen**: sustained BP >150/100; resistant hypertension (≥3 drugs incl. diuretic) or controlled on ≥4 drugs; hypertension + spontaneous/diuretic-induced hypokalaemia; adrenal incidentaloma; onset <40 yr or family history of early-onset hypertension/stroke; first-degree relative with PA; obstructive sleep apnoea.
- ▶ **Case-detection** — **Aldosterone–Renin Ratio (ARR)**: paired morning (8–10 am, seated/ambulant) **plasma aldosterone concentration (PAC)** and **plasma renin activity (PRA)/concentration**. Correct hypokalaemia first. PA is suggested by **suppressed renin** (PRA <1 ng/mL/h) with **raised PAC** (≥10–15 ng/dL); an elevated ARR (Endocrine Society cutoff ~ARR >750 pmol/L per ng/mL/h, or aldosterone:PRA ratio >30) is positive.

- ▶ **Drug effects (correct before testing):** MR antagonists must be stopped 4–6 weeks beforehand (cause false-negatives). β -blockers/clonidine/NSAIDs $\rightarrow$ false-positives (low renin); ACE-inhibitors/ARBs/diuretics $\rightarrow$ false-negatives (high renin). However, if renin remains suppressed despite these drugs, the result is interpretable. Verapamil, hydralazine and α -blockers are “clean”.
- ▶ **Confirmation (autonomy):** demonstrate non-suppressible aldosterone —
 - **IV saline infusion test:** 2 L 0.9% saline over 4 h; PAC failing to suppress $<5\text{--}6\text{ ng/dL}$ (or $<170\text{ pmol/L}$ seated) confirms PA ($5\text{--}10\text{ ng/dL}$ indeterminate).
 - **Oral sodium loading:** high-salt diet 3 days $\rightarrow$ 24-h urinary aldosterone $>12\text{ }\mu\text{g}/24\text{ h}$.
 - **Fludrocortisone suppression test** ($0.1\text{ mg q6h} + \text{NaCl} \times 4\text{ days}$; PAC not suppressing $<6\text{ ng/dL}$) — sensitive but cumbersome, now seldom used.
 - **Captopril challenge** — alternative (contraindicated in pregnancy).
 - Confirmation may be **omitted** with overt hypokalaemic hypertension + strongly positive ARR + clearly raised PAC.
- ▶ **Subtyping (unilateral vs bilateral):**
 - **Fine-cut adrenal CT** — first step; identifies adenomas and excludes carcinoma, but **cannot reliably distinguish** APA from IHA (may miss micro-adenomas, or mislabel a non-functioning incidentaloma).
 - **Adrenal vein sampling (AVS)** — the **gold standard** for lateralisation in surgical candidates. Correct catheter placement is confirmed by an **adrenal-vein-to-IVC cortisol gradient** ($>2\text{--}3$ unstimulated; $>5:1$ with cosyntropin). **Lateralisation** = cortisol-corrected aldosterone ratio (dominant:non-dominant side) >4 (sensitivity $\sim 95\%$, specificity $\sim 100\%$); a **contralateral suppression index** <1 is supportive. Technically demanding (difficult right adrenal vein).
 - **Selective use:** patients $<35\text{ yr}$ with spontaneous hypokalaemia, marked PA and a clear unilateral adenoma on CT may proceed to surgery without AVS; older patients need AVS because of frequent coincidental non-functioning adenomas.
 - **[^{11}C]-metomidate PET-CT** (with dexamethasone pre-treatment) — emerging non-invasive alternative to AVS.
- ▶ **Non-aldosterone (low-renin, low-aldosterone) mineralocorticoid excess** is confirmed by **urinary steroid metabolite profiling (GC/MS)**, identifying AME (HSD11B2 deficiency, raised cortisol:cortisone), CAH (CYP11B1/CYP17A1), DOC excess; a normal profile suggests **Liddle syndrome** (amiloride-responsive).

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Diagram 1 — Renin-Angiotensin-Aldosterone axis (with feedback):** label *Renal juxtaglomerular cells* $\rightarrow$ *Renin*; *Angiotensinogen* $\rightarrow$ *Angiotensin I (via renin)* $\rightarrow$ *Angiotensin II (via ACE)*; *Adrenal zona glomerulosa* $\rightarrow$ *Aldosterone (CYP11B2)*; stimuli $\downarrow\text{BP}/\downarrow\text{Na}^+/\uparrow\text{K}^+$;

target *Distal nephron MR* → *ENaC* → Na^+ reabsorption, K^+/H^+ excretion; negative-feedback arrow *Volume expansion* → ↓*Renin*. Mark the “block” in primary aldosteronism (autonomous aldosterone, suppressed renin).

- ▶ **Diagram 2 — Diagnostic algorithm flowchart:** boxes — *Screen high-risk hypertensive* → *ARR (PAC + PRA)* → *if positive* → *Confirmatory test (saline infusion/oral salt load)* → *Adrenal CT* → *if surgical candidate, Adrenal Vein Sampling* → *Lateralised = unilateral adrenalectomy / Non-lateralised = MR antagonist*. Side branch: *normal adrenals + family history* → *consider GRA / genetic testing*.

Clinical / Diagnostic significance

- ▶ Differentiate primary vs secondary by renin: PA = **low renin, high aldosterone**; secondary = **high renin, high aldosterone** (PAC:PRA <10). Pseudo-aldosteronism (Liddle, AME, liquorice, CAH) = **low renin, low aldosterone**.
- ▶ **Treatment of unilateral PA (APA/unilateral hyperplasia): laparoscopic (total) adrenalectomy** — cures hypokalaemia in nearly all, cures/improves hypertension in ~30–60% (residual essential hypertension common). Correct K^+ pre-operatively; anticipate **transient post-operative hypoaldosteronism** (hyperkalaemia, hypotension) from chronic contralateral suppression — monitor potassium weekly for 4 weeks with a liberal-salt diet.
- ▶ **Medical therapy (IHA, GRA, non-operative APA): spironolactone** 12.5–25 mg/day titrated to ≤400 mg (side-effects — gynaecomastia, mastodynia, erectile dysfunction, menstrual irregularity from anti-androgen/progestogenic actions); **eplerenone** (selective MR antagonist, 25 mg bid, fewer endocrine side-effects, preferred in men and pregnancy — FDA category B); **amiloride** (K^+ -sparing, 5–10 mg bid); **finerenone** (non-steroidal MRA) used off-label. Aim for high-normal K^+ and **un-suppressed renin** (a marker of adequate dosing/cardiovascular protection).
- ▶ **GRA:** low-dose **glucocorticoid** (dexamethasone/prednisone/hydrocortisone, smallest effective dose) ± MR antagonist; confirm by genetic testing.
- ▶ **Pregnancy:** progesterone may antagonise MR (improving some cases); captopril/saline tests avoided; MRI without gadolinium for imaging; eplerenone preferred if drug therapy needed.

High-yield exam pointers

- ▶ **Conn’s syndrome** = aldosterone-producing adenoma; commonest *cause overall* of PA is **bilateral idiopathic hyperplasia (IHA)**.
- ▶ **Hypokalaemic hypertension with metabolic alkalosis and suppressed renin** = classic PA; but ~70% are **normokalaemic** — screen widely.
- ▶ **Screening test** = ARR; stop MR antagonists 4–6 weeks before; **confirmatory** = **saline infusion / oral salt-loading** (failure to suppress aldosterone).

- ▶ AVS is the gold standard for lateralisation; CT alone is unreliable (misses micro-adenomas, false incidentalomas).
- ▶ KCNJ5 (GIRK4) is the commonest somatic mutation in APA; hybrid steroids (18-oxo-/18-OH-cortisol) mark GRA and KCNJ5 disease.
- ▶ GRA = FH type I, CYP11B1/CYP11B2 chimeric gene, ACTH-driven, dexamethasone-suppressible, early stroke risk.
- ▶ High-normal serum sodium + hypomagnesaemia + no oedema (mineralocorticoid escape) are clinical clues.
- ▶ Unilateral disease → laparoscopic adrenalectomy (cures HTN in 30–60%); bilateral/IHA → MR antagonist.
- ▶ Liddle syndrome (low renin, low aldosterone) responds to amiloride/triamterene, NOT spironolactone (constitutively active ENaC).

Hyperglycemic hyperosmolar state

Asked in: Paper IV Dec 2023 — RGUHS MD General Medicine

Definition / Introduction — Hyperglycemic hyperosmolar state (HHS) is an acute, life-threatening hyperglycemic emergency characterized by **severe hyperglycemia, hyperosmolality, profound dehydration, and absent or only mild ketosis/acidosis**. It occurs classically in **middle-aged or elderly patients with type 2 diabetes**, often previously mild or occult, after days to weeks of osmotic symptoms and reduced water intake. It is the second major hyperglycemic coma after diabetic ketoacidosis (DKA), but carries higher mortality because patients are older, more dehydrated, and often have infection, myocardial infarction, stroke, chronic kidney disease, heart failure, or postoperative stress.

Etiology and precipitating factors

- ▶ **Typical patient:** older person with type 2 diabetes, mild/occult diabetes, poor access to fluids, dementia, prior stroke, frailty, bed-bound state, or social circumstances preventing adequate drinking.

- ▶ **Common precipitants:** pneumonia, sepsis, urinary infection, other serious infections, myocardial infarction, stroke, recent operation, trauma, and any acute illness that increases counter-regulatory hormones and reduces oral intake.
- ▶ **Drug/procedure triggers:** corticosteroids, diuretics, phenytoin, diazoxide, and glucose-loading procedures such as peritoneal dialysis; antipsychotics and other diabetogenic drugs should also be reviewed in the medication history.
- ▶ **Contributing physiology:** polyuria and glycosuria cause large water and electrolyte loss; impaired thirst, nausea, immobility, or inaccessibility of water allows progressive dehydration.
- ▶ **DKA-HHS continuum:** DKA and HHS overlap clinically; Harrison notes that up to one-third of patients may have features of both. Therefore every HHS patient must be checked for ketonemia, acidosis, and anion gap.

Pathophysiology

- ▶ The central defect is **relative insulin deficiency plus inadequate fluid intake**. Insulin is sufficient to restrain lipolysis and ketogenesis, but insufficient to suppress hepatic glucose output or promote peripheral glucose utilization.
- ▶ Increased hepatic **gluconeogenesis and glycogenolysis**, impaired skeletal-muscle glucose uptake, and hyperglucagonemia produce severe hyperglycemia.
- ▶ Hyperglycemia causes **osmotic diuresis** with loss of water, sodium, potassium, magnesium, phosphate, and glucose in urine.
- ▶ Progressive intravascular volume contraction reduces glomerular filtration and renal glucose clearance, which further worsens hyperglycemia and hyperosmolality.
- ▶ Hyperosmolality draws water from cells, including brain cells, producing **confusion, lethargy, seizures, and coma**; neurological manifestations correlate better with osmolality than with glucose alone.
- ▶ Ketosis is absent or mild because residual portal insulin, lower free fatty acid flux, lower counter-regulatory hormone drive than in DKA, and a less ketotic insulin/glucagon ratio suppress hepatic ketone-body synthesis.

Clinical features

- ▶ **Prodrome:** days to weeks of polyuria, polydipsia, weakness, weight loss, blurred vision, and declining oral intake.
- ▶ **Dehydration:** intense thirst may be absent; examination shows dry mucosa, poor skin turgor, sunken eyes, tachycardia, postural hypotension or shock, oliguria, and prerenal azotemia.
- ▶ **Neurological features:** lethargy and confusion develop as serum osmolality rises above about 310 mOsm/kg; convulsions and coma can occur above 320-330 mOsm/kg.
- ▶ **Absent DKA clues:** nausea, vomiting, abdominal pain, acetone breath, and Kussmaul respiration are absent or much less prominent than in DKA.

- ▶ **Precipitant clues:** fever may be absent despite infection; actively seek pneumonia, urinary infection, sepsis, acute coronary syndrome, stroke, pancreatitis, trauma, drug exposure, and recent surgery.
- ▶ **Severe cases** may present directly with hypotensive shock, acute kidney injury, rhabdomyolysis, focal neurological deficits, seizures, or coma.

Diagnosis and laboratory profile

Feature	HHS	DKA comparison
Plasma glucose	>600 mg/dL diagnostic threshold; often 600-1200 mg/dL and may reach 800-2400 mg/dL	Usually 250-600 mg/dL
Serum osmolality	>310 mOsm/kg in CMDT; severe neurological disease often >320-330 mOsm/kg	Usually lower; may be >300
Arterial/venous pH	>7.3	<7.3 in DKA
Serum bicarbonate	Usually >15-18 mEq/L	<18 mEq/L
Anion gap	Usually normal, <14 mEq/L; mild lactic acidosis may raise it	Raised
Ketones	Absent or mild; serum beta-hydroxybutyrate usually <1 mmol/L	Marked, often >3 mmol/L
Sodium	Measured sodium may be normal/low; corrected sodium is often high	Often low from osmotic water shift
Renal indices	Prerenal azotemia common; BUN may be markedly high	Variable

- ▶ Calculate tonicity/effective osmolality using effective solutes: approximately **2 x measured Na + glucose/18** (mg/dL units); urea contributes to measured osmolality but not tonicity because it crosses cell membranes.
- ▶ Correct serum sodium for hyperglycemia: add about **1.6 mEq/L** to measured sodium for each 100 mg/dL rise in glucose above normal; some physiology texts note higher correction factors at extreme glucose levels, so interpret with measured osmolality and clinical state.
- ▶ Initial work-up: capillary and plasma glucose, electrolytes, urea/creatinine, venous or arterial pH, bicarbonate, anion gap, measured serum osmolality if available, serum/urine ketones or beta-hydroxybutyrate, urine routine, CBC, cultures when infection is suspected, ECG, chest radiograph, troponin, and neuroimaging when focal deficits or persistent coma suggest stroke or structural disease.

- ▶ Diagnose HHS only after excluding significant DKA, lactic acidosis, renal failure-related uremic encephalopathy, sepsis-associated encephalopathy, stroke, and drug/toxin causes of coma.

Management

- ▶ **Site of care:** admit to monitored high-dependency or ICU setting if shock, coma, severe electrolyte disturbance, acute coronary syndrome, stroke, sepsis, renal failure, or need for frequent insulin/electrolyte titration.
- ▶ **Immediate priorities:** airway protection in coma/vomiting, oxygen if hypoxemic, two IV lines, cardiac monitoring, catheterize if needed for urine output, and begin a flow sheet for vitals, mental status, input-output, glucose, electrolytes, osmolality, and insulin rate.
- ▶ **Fluids are paramount.** If hypotension or oliguria is present, start **0.9% saline**; Harrison suggests **1-3 L over the first 2-3 h** to restore hemodynamic stability. Fluid deficit is often **6-10 L**, sometimes 9-10 L, and should be corrected over about 24-48 h.
- ▶ After hemodynamic stabilization, choose fluid by corrected sodium and osmolality: use **0.45% saline** if sodium is high or >150 mEq/L; otherwise continue isotonic or hypotonic saline according to volume status. CMDT notes that **4-6 L may be needed in the first 8-10 h**, but correction must be controlled to avoid neurological worsening.
- ▶ Aim to restore urine output to **at least 50 mL/h** while avoiding pulmonary edema in elderly patients, heart failure, and chronic kidney disease.
- ▶ **Insulin:** do not let insulin precede initial fluid resuscitation unless there is significant ketosis/acidosis. A current adult approach is IV regular insulin **0.05 unit/kg/h without bolus**, titrated to lower glucose by **50-70 mg/dL/h**. Harrison also describes a hyperglycemic-crisis regimen of 0.1 unit/kg IV bolus followed by 0.1 unit/kg/h; in HHS, lower-dose fluid-first insulin is safer when ketosis is absent.
- ▶ Add dextrose when plasma glucose reaches about **250 mg/dL**; maintain glucose around **250-300 mg/dL** until osmolality, hydration, and mental status improve, then transition to subcutaneous insulin.
- ▶ **Potassium:** total-body potassium is depleted despite normal initial serum potassium. Because acidosis is absent, initial hyperkalemia is less common than in DKA, and potassium may fall rapidly with insulin. If renal function and urine output are adequate and potassium is not elevated, add potassium early, e.g., **10 mEq/L** in initial fluids; hold insulin if potassium is severely low until corrected.
- ▶ **Phosphate and magnesium:** routine phosphate is not required; replace phosphate if severe hypophosphatemia develops, especially <1 mg/dL, and correct magnesium if deficient, particularly in diuretic users.

- ▶ **Precipitant treatment:** obtain cultures before antibiotics when feasible, but do not delay antibiotics for suspected sepsis; treat MI, stroke, pneumonia, UTI, pancreatitis, surgery-related infection, and offending drugs.
- ▶ **Thrombosis prevention:** severe dehydration and low-flow state predispose to MI, stroke, pulmonary embolism, mesenteric venous thrombosis, and DIC; pharmacologic VTE prophylaxis is reasonable unless contraindicated, while routine full-dose anticoagulation is not automatically indicated.
- ▶ **Transition and discharge:** continue insulin during admission; after stabilization and eating, overlap IV insulin with subcutaneous basal insulin. Many patients require insulin for weeks, but some later recover enough endogenous insulin secretion for diet plus oral agents.

Complications and prognosis

- ▶ **Neurological:** seizures, coma, and worsening mental status from hyperosmolality; too-rapid correction may contribute to cerebral edema or neurological deterioration.
- ▶ **Renal and muscle:** prerenal azotemia, acute kidney injury, and rhabdomyolysis should be anticipated and monitored.
- ▶ **Vascular:** MI, ischemic stroke, pulmonary embolism, mesenteric venous thrombosis, disseminated intravascular coagulation, and limb ischemia occur due to dehydration, hyperviscosity, and underlying comorbidity.
- ▶ **Treatment-related:** hypoglycemia, hypokalemia, hypophosphatemia, hyperchloremic acidosis with large saline loads, fluid overload, and pulmonary edema.
- ▶ Mortality is substantially higher than DKA: Harrison cites up to 15% in some series; CMDT notes it is more than ten times DKA largely because of age, delayed recognition, dehydration, and coexistent illness, and delayed cases historically approached very high mortality.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Pathophysiology flowchart:** relative insulin deficiency + stress hormones -> hepatic glucose output + impaired peripheral uptake -> severe hyperglycemia -> glycosuria/osmotic diuresis -> water/electrolyte loss -> hypovolemia -> reduced GFR -> worsening hyperglycemia -> hyperosmolality -> brain cell dehydration -> confusion/seizure/coma; side label: residual insulin suppresses ketogenesis.
- ▶ **Management algorithm:** suspect HHS -> ABC/vitals/IV access -> labs including glucose, electrolytes, osmolality, pH, ketones -> 0.9% saline if shock -> choose 0.45% saline by corrected sodium -> monitor K and urine output -> IV insulin 0.05 unit/kg/h after fluids -> dextrose at glucose 250 mg/dL -> treat precipitant -> subcutaneous insulin transition.

Clinical / Diagnostic significance

- ▶ HHS is a **diagnosis of dehydration plus tonicity**, not merely a high glucose value; mental status change is an osmolality warning sign.
- ▶ In an elderly diabetic with coma, always check glucose, sodium, osmolality, ketones, pH, urea/creatinine, ECG, and infection screen before attributing the coma to stroke alone.
- ▶ Corrected sodium guides fluid choice: a “normal” measured sodium in severe hyperglycemia may hide significant free-water deficit.
- ▶ Absence of Kussmaul breathing and abdominal pain helps distinguish HHS from DKA, but overlap is common; beta-hydroxybutyrate and pH are mandatory.
- ▶ Treat the precipitant as aggressively as the glucose: pneumonia, sepsis, MI, stroke, and postoperative infection often determine outcome.
- ▶ Prevention after recovery requires sick-day education, caregiver involvement, early contact during infection/vomiting, maintaining sugar-free fluids, and medication review, especially diuretics and corticosteroids.

High-yield exam pointers

- ▶ Triad: **severe hyperglycemia + hyperosmolality + profound dehydration with little/no ketoacidosis**.
- ▶ Typical case: elderly type 2 diabetic, days-weeks of polyuria and poor intake, then confusion/coma.
- ▶ Diagnostic essentials: glucose **>600 mg/dL**, osmolality **>310 mOsm/kg**, pH **>7.3**, bicarbonate **>15-18 mEq/L**, normal anion gap, absent/mild ketones.
- ▶ Osmolality drives coma: confusion above about **310 mOsm/kg**, seizures/coma often above **320-330 mOsm/kg**.
- ▶ First treatment is **fluid**, not insulin; restore circulation before lowering glucose aggressively.
- ▶ Use insulin cautiously: **0.05 unit/kg/h** after fluids in nonketotic HHS; avoid glucose fall faster than **50-70 mg/dL/h**.
- ▶ Add dextrose around **250 mg/dL** and continue controlled correction until osmolality and mental status recover.
- ▶ Potassium is depleted even if serum potassium is normal; replace early if urine output is adequate and potassium is not high.
- ▶ Mortality is higher than DKA; death usually reflects age, dehydration, delayed diagnosis, infection, MI, stroke, CKD, or HF.

Hyperprolactinemia

Asked in: Paper IV 17 Apr 2026 · Paper IV Jul 2021 · Paper IV Nov 2020 (3×) — RGUHS MD General Medicine

Definition / Introduction — Hyperprolactinemia is sustained elevation of serum prolactin (PRL) above the assay-specific reference range (normal adult PRL $\approx$ 10–25 μ g/L in women and 10–20 μ g/L in men). It is the **most common pituitary hormone hypersecretion syndrome** in both sexes. Because the hypothalamus exerts *tonic dopaminergic inhibition* of lactotrope PRL release (via D2 receptors), hyperprolactinemia results either from autonomous lactotrope secretion (prolactinoma), from loss of dopaminergic tone (stalk disconnection, drugs), or from physiologic/systemic stimuli. Clinically it presents with hypogonadism, galactorrhea and infertility, and may signal an underlying sellar mass.

Prolactin physiology — basis of the syndrome

- ▶ **Structure/source:** PRL is a 198-amino-acid polypeptide ($\approx$ 23 kDa), homologous to GH and placental lactogen, secreted by **lactotropes** ($\sim$ 20% of anterior pituitary cells); lactotrope hyperplasia occurs in pregnancy/lactation under estrogen drive. Circulating **half-life $\approx$ 50 min**; secretion is pulsatile with nocturnal (non-REM sleep) peaks at 4–6 a.m.
- ▶ **Unique inhibitory control:** Unlike other pituitary hormones, PRL is under predominantly *inhibitory* hypothalamic control — **dopamine acting on pituitary D2 receptors** suppresses PRL synthesis and secretion. Hence any lesion that interrupts dopamine delivery (stalk section) causes hyperprolactinemia, and **dopamine agonists are the cornerstone of treatment**.
- ▶ **Stimulators:** TRH releases PRL within 15–30 min (explains hyperprolactinemia of primary hypothyroidism); estrogen, suckling/chest-wall afferents, stress and sleep also raise PRL.
- ▶ **Why hypogonadism occurs:** Excess PRL suppresses hypothalamic **GnRH** pulsatility $\rightarrow$ reduced LH/FSH $\rightarrow$ impaired gonadal steroidogenesis (low estradiol/testosterone); PRL also directly inhibits ovarian folliculogenesis and granulosa-cell aromatase (anovulation, luteolysis) and testicular function.

Etiology — classified (physiologic / pathologic / pharmacologic)

Category	Causes
Physiologic	Pregnancy, lactation, nipple/chest-wall stimulation or trauma (incl. herpes zoster, thoracotomy), sleep, stress, exercise, sexual orgasm

Category	Causes
Hypothalamic–pituitary stalk damage	Pituitary adenoma with stalk compression , suprasellar masses (craniopharyngioma, meningioma, dysgerminoma, metastases), Rathke cleft cyst, empty sella, lymphocytic hypophysitis, granulomas/infiltration, cranial irradiation, head trauma/stalk section, suprasellar surgery
Pituitary hypersecretion	Prolactinoma (commonest tumoural cause); acromegaly (GH–PRL/ mammosomatotrope tumours), plurihormonal adenomas
Systemic	Chronic renal failure (↓ peripheral clearance), primary hypothyroidism (↑ TRH), cirrhosis, PCOS, pseudocyesis, seizures
Drug-induced	Antipsychotics — risperidone (often >200 µg/L), phenothiazines (chlorpromazine, perphenazine), butyrophenones (haloperidol); metoclopramide , domperidone; methyldopa (↓ DA synthesis); verapamil (↓ DA release); reserpine; TCAs/SSRIs (fluoxetine); H2-blockers (cimetidine); opiates; estrogens; TRH

- ▶ **PRL level guides cause:** Mild elevation (30–100 µg/L) typically reflects drugs, stalk compression, hypothyroidism or renal failure; a level >200–250 µg/L **almost invariably indicates a prolactinoma**. *Caveat:* a large *non*-lactotrope macroadenoma can raise PRL only modestly (usually <100 µg/L) by stalk compression — the level per tumour-volume cannot always distinguish the two.
- ▶ **Prolactinoma facts:** Lactotrope tumours account for ~half of functioning pituitary adenomas; **microadenoma <1 cm, macroadenoma ≥1 cm**. Microprolactinoma F:M ≈ 20:1; macroadenoma sex ratio ≈ 1:1 (men present larger/late). ~20% of MEN-1 patients have prolactinomas. Only ~5% of microadenomas progress to macroadenomas.

Clinical features

- ▶ **Women:** the triad of **amenorrhoea/oligomenorrhoea, galactorrhoea and infertility**; pre-menarchal onset → primary amenorrhoea; reduced libido, vaginal dryness, mild hirsutism, weight gain. **Galactorrhoea in up to 80%** of hyperprolactinaemic women (may need to be elicited).
- ▶ **Men:** decreased libido, **erectile dysfunction**, oligospermia/infertility, gynaecomastia; true galactorrhoea uncommon. Long-standing hypogonadism → osteopenia, reduced muscle mass, decreased beard growth. Men more often present late with **mass effects** (headache, visual loss).
- ▶ **Skeletal:** chronic hypoestrogenism/hypogonadism reduces bone mineral density → **osteoporosis** and vertebral fractures.

- ▶ **Mass-effect symptoms (macroadenoma):** headache, **bitemporal hemianopia** (chiasmal compression), cranial nerve III/IV/VI palsy (cavernous sinus), hypopituitarism, rarely apoplexy.

Laboratory investigation & diagnostic approach

- ▶ **Step 1 — confirm:** basal, fasting morning serum PRL (avoid stress/venepuncture artefact); repeat if borderline. Exclude **pregnancy** (β -hCG) first.
- ▶ **Step 2 — exclude secondary causes** *before* imaging: drug history, TSH/free T4 (hypothyroidism), renal and hepatic function; review oestrogen/neuroleptic exposure.
- ▶ **Two key assay pitfalls (high-yield):**
 - **Hook effect** — in very large prolactinomas with extreme PRL (>1000 $\mu\text{g/L}$), antibody saturation gives a *falsely low/normal* reported value; correct by **serial sample dilution**.
 - **Macroprolactinemia** — high-molecular-weight aggregated PRL (biologically inactive) gives elevated readings with *few/absent symptoms*; detect by **polyethylene glycol (PEG) precipitation**.
- ▶ **Step 3 — imaging:** if no reversible cause, perform **gadolinium-enhanced pituitary MRI** (T1 iso/hypointense, T2 hyperintense adenoma); microadenomas <2 mm may be MRI-occult, so a normal scan does not exclude a microprolactinoma. **Formal perimetry** for any macroadenoma abutting the chiasm; assess anterior-pituitary reserve (IGF-1, 8 a.m. cortisol, gonadotropins, thyroid axis).
- ▶ **Idiopathic hyperprolactinemia** = diagnosis of exclusion with normal MRI.

Treatment / Management

- ▶ **Principles:** treat the **cause**; aim to normalise PRL to restore gonadal function, stop galactorrhoea, preserve bone density, and shrink any tumour. Stop offending drugs where possible; **levothyroxine** corrects hypothyroidism-related rise; treat renal failure. Asymptomatic microadenomas not desiring fertility may simply be monitored (serial PRL + MRI) — up to **30% resolve spontaneously**.
- ▶ **Dopamine agonists (DA)** — **first-line for prolactinoma and most causes:** suppress PRL secretion/synthesis and lactotrope proliferation; effective even when raised PRL is due to non-lactotrope stalk compression (so DA-induced PRL fall does **not** prove the mass is a prolactinoma).

Drug	Dose	Key points
Cabergoline (preferred)	0.25–1 mg twice weekly	Long-acting, high D2 affinity; normalises PRL in ~80% micro / ~70% macro , NEJM data 83% vs 52% for bromocriptine; better tolerated; valve surveillance at high doses

Drug	Dose	Key points
Bromocriptine	0.625–2.5 mg, up to 2.5 mg tid	Short-acting ergot; preferred when fertility/pregnancy desired ; more GI/orthostatic side-effects

- ▶ **Side-effects of DAs:** nausea, postural hypotension, constipation, nasal stuffiness, fatigue; impulse-control disorders and (at high/Parkinsonian doses, e.g. ≥ 3 mg/day cabergoline) **cardiac valve regurgitation** — obtain a baseline **echocardiogram** before standard-dose therapy. **~20% of tumours are DA-resistant** (more often in men).
- ▶ **Surgery (transsphenoidal):** reserved for DA intolerance/resistance, or an invasive macroadenoma with threatened vision unresponsive to drugs. PRL normalisation ~70% (micro) but only ~40% (macro); hyperprolactinaemia recurs in up to 20% by 1 year and >50% long-term for macroadenomas.
- ▶ **Radiotherapy:** only for aggressive tumours refractory to DA + surgery.
- ▶ **Pregnancy:** restore fertility with **bromocriptine**; stop DA once pregnancy confirmed for a microadenoma. Microprolactinomas enlarge clinically in <3–5%, **macroprolactinomas in 15–30%** — continue DA and perform trimester-wise visual fields for macroadenomas.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Diagram 1 — Hypothalamic–pituitary control of PRL.** Labels: *Hypothalamus* → *Dopamine (inhibitory, –) and TRH (stimulatory, +)*; *Hypophyseal portal vessels / pituitary stalk*; *Lactotrope (D2 receptor)*; *Prolactin*; downstream $\downarrow$ GnRH $\rightarrow$ $\downarrow$ LH/FSH $\rightarrow$ $\downarrow$ oestrogen/testosterone (*hypogonadism*) and $\uparrow$ breast milk (*galactorrhoea*). Show **stalk section** interrupting dopamine flow $\rightarrow$ $\uparrow$ PRL.
- ▶ **Diagram 2 — Coronal sella MRI of a macroadenoma.** Labels: *pituitary macroadenoma in sella turcica*, *suprasellar extension compressing the optic chiasm (bitemporal hemianopia)*, *cavernous sinus + internal carotid artery*, *sphenoid sinus*, *pituitary stalk*.

Clinical / Diagnostic significance

- ▶ **Common reversible mimic:** always exclude **drugs, pregnancy, hypothyroidism and renal failure** before extensive endocrine work-up — avoids unnecessary imaging/surgery.
- ▶ **PRL magnitude triages the lesion:** >200–250 $\mu\text{g/L}$ $\Rightarrow$ prolactinoma; modest rise with a large mass $\Rightarrow$ suspect stalk compression by a non-functioning/other tumour.
- ▶ **Galactorrhoea + amenorrhoea** should be regarded as a pituitary adenoma until proven otherwise.
- ▶ **Bone:** screen BMD in chronic hypogonadal hyperprolactinaemia.

- ▶ **Psychiatric link:** antipsychotic-induced hyperprolactinaemia (esp. risperidone) is common; manage by supervised drug switch/dose titration with the prescriber, as DAs may aggravate psychosis.

High-yield exam pointers

- ▶ PRL is unique among pituitary hormones in being under **dominant inhibitory (dopaminergic D2) control** → stalk lesions cause hyperprolactinaemia and DAs treat it.
- ▶ **>200 µg/L = prolactinoma almost certain**; mild rise (30–100) = drugs/stalk/hypothyroid/renal.
- ▶ **Microprolactinoma F:M 20:1; macroadenoma ~1:1**; men present with larger tumours and mass effects.
- ▶ Two assay traps: **hook effect** (dilute the sample) and **macroprolactinemia** (PEG precipitation).
- ▶ **Cabergoline** > bromocriptine for efficacy/tolerability; **bromocriptine** preferred in pregnancy.
- ▶ DA shrinks macroprolactinomas dramatically — *medical therapy is first-line even for large tumours*, unlike most other macroadenomas.
- ▶ High-dose cabergoline → **valvular regurgitation** risk; baseline echocardiogram.
- ▶ **Primary hypothyroidism** raises PRL via TRH — corrected by levothyroxine, not a DA.
- ▶ Up to 30% of **idiopathic hyperprolactinaemia** resolves spontaneously.

Hypoglycaemia in Non-Diabetics

Asked in: Paper IV Jul 2021 — RGUHS MD General Medicine

Definition / Introduction — *Hypoglycaemia* is a plasma glucose concentration low enough to cause symptoms or signs of impaired brain function, the diagnosis being secured by *Whipple's triad*: (1) symptoms/signs consistent with hypoglycaemia, (2) a reliably measured low plasma glucose, and (3) relief after the glucose level is raised. While hypoglycaemia is common in insulin-, sulfonylurea- or

glinide-treated diabetes, it is a **distinctly uncommon clinical event in persons without diabetes** because of highly efficient counter-regulatory defences. Consequently, a systematic evaluation is justified in a non-diabetic person *only* when Whipple's triad is documented — investigating an isolated low reading exposes the patient to needless cost and harm.

Glucose counter-regulation — the framework

- ▶ The brain is an **obligate glucose user**; it cannot synthesise glucose or store more than a few minutes' supply, so it needs a continuous arterial supply. Fasting plasma glucose is normally ~70–110 mg/dL, the lower physiological limit being ~70 mg/dL (3.9 mmol/L).
- ▶ Between meals, euglycaemia is sustained by **hepatic glycogenolysis** (stores last ~8 h) and **hepatic + renal gluconeogenesis** (precursors: lactate, alanine/glutamine, glycerol).
- ▶ A hierarchy of defences with defined **glycaemic thresholds** is activated as glucose falls (Table 418-2):

Response	Glycaemic threshold mg/dL (mmol/L)	Role
↓ Insulin	80–85 (4.4–4.7)	First defence — primary regulatory factor
↑ Glucagon	65–70 (3.6–3.9)	Second defence — primary counter-regulatory hormone (↑ glycogenolysis, gluconeogenesis)
↑ Epinephrine	65–70 (3.6–3.9)	Third defence — becomes <i>critical</i> when glucagon is deficient
↑ Cortisol & GH	65–70 (3.6–3.9)	Support only <i>prolonged</i> (>4 h) hypoglycaemia; not critical acutely
Symptoms	50–55 (2.8–3.1)	Behavioural defence (food ingestion)
↓ Cognition	<50 (<2.8)	Neuroglycopenia

- ▶ Thresholds are **dynamic**: they shift upward in poorly controlled diabetes and downward with recurrent hypoglycaemia (insulinoma, intensively-treated diabetes).

Clinical manifestations

- ▶ **Neuroglycopenic** (direct CNS glucose deprivation): behavioural change, confusion, fatigue, blurred vision/diplopia, slurred speech, seizures, focal deficits, loss of consciousness, cardiac arrhythmia and, if severe, death. These dominate *fasting* hypoglycaemia and insulinoma.
- ▶ **Neurogenic / autonomic** (sympathoadrenal discharge): *adrenergic* — palpitations, tremor, anxiety; *cholinergic* — sweating, hunger, paraesthesiae. These herald *postprandial* hypoglycaemia.

- Signs: **diaphoresis and pallor**, tachycardia and raised systolic BP (may be blunted with recurrent episodes / hypoglycaemia unawareness). Symptoms are non-specific — attribution requires Whipple's triad.

Aetiological classification (Endocrine Society / Harrison Table 418-1)

The modern classification separates the **ill or medicated** patient from the **seemingly well** individual rather than fasting vs postprandial.

Category	Causes
1. Drugs (commonest)	Insulin, insulin secretagogues, alcohol ; others — ACE-inhibitors/ARBs, β -blockers, quinolones (<i>gatifloxacin</i> , <i>levofloxacin</i>), pentamidine, quinine, indomethacin, sulfonamides, salicylates, tramadol
2. Critical illness	Hepatic (rapid massive necrosis, e.g. toxic hepatitis), renal or cardiac failure; sepsis ; inanition / starvation
3. Hormone deficiency	Cortisol (Addison's, hypopituitarism), growth hormone (children); combined glucagon + epinephrine in insulin-deficient diabetes
4. Non-islet-cell tumour (NICTH)	Large mesenchymal / epithelial tumours (hepatoma, adrenocortical carcinoma, carcinoid) — “ big IGF-II ”
5. Endogenous hyperinsulinism	Insulinoma; functional β -cell disorders (nesidioblastosis); noninsulinoma pancreatogenous hypoglycaemia syndrome (NIPHS); post-gastric-bypass hypoglycaemia; insulin / insulin-receptor autoantibody; insulin secretagogues
6–10. Others	Inborn errors (glycogenoses, fatty-acid oxidation defects, gluconeogenic enzyme defects); exercise; accidental/surreptitious/malicious; prolonged fasting; pregnancy

Key mechanisms to write:

- **Alcohol** blocks gluconeogenesis but not glycogenolysis (NADH:NAD⁺ shift). Hypoglycaemia follows a binge with little food once glycogen is depleted; glucagon is therefore ineffective.
- **Sepsis** — cytokine-driven $\uparrow$ glucose utilisation in macrophage-rich tissues (liver, spleen, lung) outstrips production.
- **Cortisol deficiency** — impaired gluconeogenesis + glycogen depletion (substrate-limited).
- **NICTH** — incompletely processed **pro-IGF-II** evades binding proteins, accesses tissues; insulin is *appropriately suppressed*, IGF-II:IGF-I ratio is **high**.

Endogenous hyperinsulinism & insulinoma

- The hallmark is **failure of insulin secretion to fall to low levels during hypoglycaemia**.

- ▶ **Insulinoma:** incidence ~1 in 250,000 patient-years; >90% **benign**, >99% **intra-pancreatic**, usually <2 cm; median age 50 y (3rd decade if part of MEN-1). Presents with fasting neuroglycopenia and weight gain.
- ▶ **Localisation:** CT/MRI/transabdominal US detect ~70–80%; **endoscopic ultrasound sensitivity** ~90%; ⁶⁸Ga-DOTA / GLP-1-receptor (exendin) imaging and, if needed, **selective intra-arterial calcium stimulation** with hepatic-vein insulin sampling regionalise the tumour; intra-operative US is near-definitive.
- ▶ **Variants:** *nesidioblastosis* (diffuse β -cell hypertrophy/hyperplasia); *NIPHS* (postprandial, imaging-negative, diagnosed by calcium-stimulation); *post-Roux-en-Y-gastric-bypass* late dumping (exaggerated GLP-1/insulin, 2–4 h post-meal); *insulin autoimmune syndrome* (**Hirata disease** — anti-insulin antibody, HLA-DR4, Asians, methimazole / sulfhydryl drugs); insulin-receptor agonist antibody (with acanthosis nigricans).

Diagnostic approach

- ▶ **Step 1** — Document Whipple's triad with a **laboratory** glucose (not a glucose meter); exclude *pseudohypoglycaemia* (continued ex-vivo glycolysis — leukocytosis/erythrocytosis/thrombocytosis, delayed separation; collect in NaF tube).
- ▶ **Step 2** — Review history for **drugs, critical illness, hormone deficiency, NICTH** (these explain most cases).
- ▶ **Step 3 (seemingly well)** — During spontaneous or provoked hypoglycaemia (plasma glucose <55 mg/dL / 3.0 mmol/L) measure glucose, **insulin, C-peptide, proinsulin, β -hydroxybutyrate**, oral hypoglycaemic-agent screen, insulin antibodies, and the glucose response to 1.0 mg IV glucagon. Provoke with a **prolonged supervised fast (up to 72 h)** for fasting symptoms or a **5-h mixed-meal test** for postprandial symptoms.

Critical diagnostic thresholds for endogenous hyperinsulinism (glucose <55 mg/dL):

Test	Hyperinsulinism cut-off
Insulin	$\geq 3 \mu\text{U/mL}$ ($\geq 18 \text{ pmol/L}$)
C-peptide	$\geq 0.6 \text{ ng/mL}$ ($\geq 0.2 \text{ nmol/L}$)
Proinsulin	$\geq 5.0 \text{ pmol/L}$
β -hydroxybutyrate	$\leq 2.7 \text{ mmol/L}$ (suppressed)
Glucose rise after IV glucagon (1 mg)	$> 25 \text{ mg/dL}$ ($> 1.4 \text{ mmol/L}$)

- ▶ **Distinguishing the cause** (all show inappropriately high insulin):
 - *Insulinoma / nesidioblastosis* — $\uparrow$ insulin, $\uparrow$ **C-peptide**, $\uparrow$ **proinsulin**, OHA screen negative.
 - *Sulfonylurea/glinide* — identical pattern but OHA screen **positive**.

- *Exogenous insulin (factitious)* — ↑ insulin but **low C-peptide & proinsulin**; **insulin : C-peptide molar ratio >1**.
- *Insulin autoimmune* — very high insulin, **insulin antibody positive**.
- *NICTH / IGF-mediated* — insulin, C-peptide, proinsulin **all suppressed**, β-hydroxybutyrate low, ↑ pro-IGF-II and IGF-II:IGF-I ratio.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Glucose counter-regulation cascade** (Fig 418-1): central box “Arterial glucose ↓” with arrows to — *Pancreas* (↓ Insulin = 1st defence; α-cell ↑ Glucagon = 2nd defence) → *Liver/Kidney* “Glucose production”; *Adrenal medulla* ↑ Epinephrine (3rd defence) and *Sympathetic neurons* ↑ Norepinephrine + Acetylcholine → “Symptoms”; *Pituitary–adrenal cortex* ↑ GH and ↑ Cortisol (prolonged). Label the threshold ladder: ↓Insulin 80–85 → Glucagon/Epi 65–70 → Symptoms 50–55 → ↓Cognition <50 mg/dL.
- ▶ **Diagnostic flow-box**: “Whipple’s triad +” → branch “Ill/Medicated” (drugs, critical illness, hormone deficiency, NICTH) vs “Seemingly well” → insulin/C-peptide/proinsulin/β-OHB/OHA-screen → label end-points: *Insulinoma*, *Sulfonylurea*, *Exogenous insulin (low C-peptide)*, *Insulin-autoimmune*, *NICTH*.

Clinical / Diagnostic significance

- ▶ **Always exclude drugs first** — insulin, secretagogues and alcohol cause most non-diabetic hypoglycaemia; consider surreptitious/factitious use (health-care workers, diabetic relatives).
- ▶ **Urgent treatment**: conscious — **15–20 g oral glucose**; unable to swallow — **IV 25 g dextrose** (50 mL of 50%) then infusion; if no IV access — **glucagon 1.0 mg SC/IM** (ineffective in glycogen-depleted/alcoholic patients, less useful in T2DM as it also triggers insulin). **Octreotide** suppresses insulin in **sulfonylurea overdose**. All raise glucose transiently — feed early.
- ▶ **Definitive therapy by mechanism**: stop/reduce offending drug; treat critical illness; replace cortisol/GH; debulk NICTH (± glucocorticoid/GH); **surgical resection cures insulinoma** — *diazoxide* (300–400 mg/day) or *octreotide/lanreotide*, and *everolimus* (mTOR inhibitor) for unresectable disease; partial pancreatectomy for nesidioblastosis/NIPHS; dietary measures (low-glycaemic, α-glucosidase inhibitor) ± uncooked cornstarch for post-bypass and autoimmune forms.
- ▶ Severe hypoglycaemia is **proatherothrombotic** (↑ platelet aggregation, ↑ PAI-1, ↓ nitric-oxide vasodilatation) and carries excess cardiovascular morbidity/mortality.

High-yield exam pointers

- ▶ **Whipple’s triad** is mandatory before labelling a non-diabetic hypoglycaemic — protects against pseudohypoglycaemia.

- ▶ Defence hierarchy: ↓insulin → ↑glucagon → ↑epinephrine; epinephrine is *critical when glucagon is deficient*; cortisol/GH only for prolonged episodes.
- ▶ **Drugs (incl. alcohol) are the commonest cause**; alcohol *blocks gluconeogenesis, spares glycogenolysis*.
- ▶ Endogenous hyperinsulinism cut-offs at glucose <55 mg/dL: insulin ≥3 μU/mL, C-peptide ≥0.6 ng/mL, proinsulin ≥5 pmol/L, β-OHB ≤2.7 mmol/L, post-glucagon glucose rise >25 mg/dL.
- ▶ **Low C-peptide + high insulin = exogenous (factitious) insulin**; high C-peptide + positive OHA screen = sulfonylurea.
- ▶ **Insulinoma**: >90% benign, >99% pancreatic, <2 cm, MEN-1 association; EUS sensitivity ~90%; cured by surgery, diazoxide if unresectable.
- ▶ **NICTH** = “big IGF-II”, high IGF-II:IGF-I ratio, suppressed insulin/C-peptide.
- ▶ **Hirata disease** = insulin autoimmune hypoglycaemia (anti-insulin antibody, HLA-DR4, sulfhydryl drugs/methimazole).
- ▶ **Post-gastric-bypass / late dumping**: postprandial (2–4 h), GLP-1-driven hyperinsulinism.

Hypoglycemia

Asked in: Paper II Nov 2022 — RGUHS MD General Medicine

Definition / Introduction — Hypoglycemia is a clinical syndrome of low plasma glucose sufficient to cause symptoms and resolving when glucose is restored. It is rigorously defined by **Whipple’s triad**: (1) symptoms consistent with hypoglycemia, (2) a low plasma glucose measured by a precise method, and (3) relief of symptoms after the glucose is raised. The lower limit of fasting plasma glucose is normally ~70 mg/dL (~3.9 mmol/L). It is most often iatrogenic — caused by insulin or insulin secretagogues

used to treat diabetes — and should be considered in any patient with confusion, an altered level of consciousness, or a seizure. Severe hypoglycemia increases the risk of serious cardiovascular events and death.

Physiology of glucose counterregulation

- ▶ Glucose is an **obligate fuel for the brain**, which cannot synthesise glucose or store more than a few minutes' supply; it needs a continuous arterial supply.
- ▶ Plasma glucose is kept **~70–110 mg/dL (3.9–6.1 mmol/L)** fasting by hepatic glycogenolysis and hepatic/renal gluconeogenesis. Hepatic glycogen lasts only **~8 h** (less with exercise/illness), after which gluconeogenesis predominates (precursors: lactate, alanine, glutamine from muscle; glycerol from adipose lipolysis).
- ▶ Defences against falling glucose follow a tiered, threshold-based sequence:

Defence	Mediator	Glycemic threshold mg/dL (mmol/L)	Action
First	↓ Insulin secretion	80–85 (4.4–4.7)	↑ glycogenolysis & gluconeogenesis; ↑ lipolysis
Second	↑ Glucagon (pancreatic α-cell)	65–70 (3.6–3.9)	↑ hepatic glycogenolysis & gluconeogenesis
Third	↑ Epinephrine (adrenomedullary)	65–70 (3.6–3.9)	↑ glucose production, ↓ clearance; critical when glucagon deficient
Late/slow	↑ Cortisol & GH	50–55 (2.8–3.1)	Support production; <i>no role in acute defence</i> (act only after ~4 h)
Behavioural	Symptoms	—	Recognition → food ingestion
Failure	↓ Cognition	<50 (<2.8)	Compromises behavioural defence

- ▶ *A fall in insulin is the first defence; glucagon the second; epinephrine the third (and pivotal when glucagon is lacking).* Cortisol and GH are **not** required for defence against acute hypoglycemia in adults.
- ▶ Thresholds are **dynamic**: they shift higher in poorly controlled diabetes (symptoms near normoglycemia) and lower with recurrent hypoglycemia (insulinoma, intensively treated diabetes).

Classification / Causes (across the life span)

Etiology is best framed by clinical context — the “ill or medicated” vs the “seemingly well” patient (Table 418-1).

Ill or medicated individual	Seemingly well individual
1. Drugs — insulin or insulin secretagogues; alcohol ; others (ACE inhibitors, ARBs, β -blockers, quinolones, indomethacin, quinine, sulfonamides)	5. Endogenous hyperinsulinism — insulinoma; functional β -cell disorder (<i>nesidioblastosis</i>); noninsulinoma pancreatogenous hypoglycemia (NIPHS); post-gastric-bypass hypoglycemia; insulin/insulin-receptor autoimmune; secretagogues; GLP-1 RA + insulin/secretagogue
2. Critical illness — hepatic, renal or cardiac failure; sepsis; inanition	6. Disorders of gluconeogenesis & fatty-acid oxidation
3. Hormone deficiency — cortisol; growth hormone; glucagon + epinephrine (in insulin-deficient diabetes)	7. Exercise
4. Non-islet-cell tumour (e.g., mesenchymal/epithelial tumours)	8. Accidental, surreptitious or malicious ; 9. Prolonged fasting ; 10. Pregnancy

- ▶ **Drugs (commonest):** insulin/secretagogues suppress glucose production and $\uparrow$ utilisation. **Ethanol blocks gluconeogenesis but not glycogenolysis**, so alcohol-induced hypoglycemia follows a multi-day binge with poor intake and glycogen depletion.
- ▶ **Critical illness:** rapid hepatic destruction (the major site of glucose production), renal failure (reduced insulin clearance + fewer precursors), cardiac failure, and **sepsis** (cytokine-driven $\uparrow$ utilisation).
- ▶ **Non-islet-cell tumour:** large hepatomas, adrenocortical carcinomas, carcinoids — overproduce incompletely processed “**big IGF-II**” with a **high IGF-II : IGF-I ratio**; endogenous insulin is appropriately suppressed.
- ▶ **Inborn errors** (mostly infancy, occasionally adults): glycogen storage disease types 0, I, III, IV and Fanconi-Bickel syndrome (fasting); fatty-acid oxidation defects; glucokinase/SUR1/Kir6.2 mutations and hereditary fructose intolerance (postprandial).

Clinical manifestations

- ▶ **Neuroglycopenic** (direct CNS glucose deprivation): behavioural changes, confusion, fatigue, **seizure**, **loss of consciousness**, **cardiac arrhythmias**, and, if severe, death; transient focal deficits occur occasionally, permanent deficits are rare.
- ▶ **Neurogenic / autonomic** (sympathoadrenal discharge):
 - **Adrenergic** (norepinephrine): palpitations, tremor, anxiety.
 - **Cholinergic** (acetylcholine): sweating, hunger, paresthesias.
- ▶ **Signs:** diaphoresis and pallor; heart rate and systolic BP usually rise (may be blunted after recent recurrent episodes).

- ▶ Symptoms are **non-specific** — attribution requires a documented low glucose with resolution on correction (Whipple's triad).

Hypoglycemia in diabetes & HAAF

- ▶ Hypoglycemia is the **limiting factor in glycemic management of diabetes**. Patients with T1DM average ~2 symptomatic episodes/week and ≥ 1 severe episode/year; an estimated **6–10% of people with T1DM die as a result of hypoglycemia**.
- ▶ **Conventional risk factors** = relative or absolute insulin excess: excessive/ill-timed/wrong-type insulin or secretagogue; reduced glucose influx (missed meals, fasting); increased utilisation (exercise); increased insulin sensitivity; reduced glucose production (alcohol); reduced insulin clearance (renal failure).
- ▶ **Hypoglycemia-Associated Autonomic Failure (HAAF)** — recent antecedent hypoglycemia (or prior exercise/sleep) produces two linked syndromes that drive a vicious cycle of recurrent hypoglycemia:
 - **Defective glucose counterregulation** — loss of the insulin-decrement and glucagon-increment, plus an attenuated epinephrine response $\rightarrow \geq 25$ -fold greater risk of severe iatrogenic hypoglycemia.
 - **Hypoglycemia unawareness** — attenuated sympathoadrenal (largely sympathetic neural) response $\rightarrow$ loss of warning symptoms $\rightarrow \sim 6$ -fold increased risk.
- ▶ HAAF is functional and **reversible by ~2–3 weeks of scrupulous avoidance of hypoglycemia**, distinguishing it from structural, irreversible diabetic autonomic neuropathy. Trials confirming severe hypoglycemia at HbA1c 8–10%: ACCORD (stopped early for excess mortality), ADVANCE, VADT, ORIGIN; in-hospital NICE-SUGAR showed harm from tight control — hence inpatient targets of 140–180 mg/dL.

Diagnostic approach & investigations

- ▶ **Document Whipple's triad** — draw blood for glucose *before* giving glucose; measure plasma glucose by a precise (laboratory) method. Handheld/continuous glucose monitors are **not** diagnostic at low values.
- ▶ Exclude **pseudohypoglycemia**: artefactually low glucose from ex-vivo metabolism in leukocytosis/erythrocytosis/thrombocytosis or delayed serum separation; a low glucose without corresponding symptoms suggests an artefact.
- ▶ **Diagnose the mechanism** — in the seemingly well patient, work up **endogenous hyperinsulinism**. During a spontaneous or provoked episode (up to a 72-h supervised fast or mixed meal) with plasma glucose < 55 mg/dL (< 3.0 mmol/L) and symptoms, the critical findings are:

Analyte	Hyperinsulinism cut-off
Plasma insulin	$\geq 3 \mu\text{U/mL}$ ($\geq 18 \text{ pmol/L}$)
C-peptide	$\geq 0.6 \text{ ng/mL}$ ($\geq 0.2 \text{ nmol/L}$)
Proinsulin	$\geq 5.0 \text{ pmol/L}$
β -hydroxybutyrate	$\leq 2.7 \text{ mmol/L}$
Glucose rise after IV glucagon 1.0 mg	$> 25 \text{ mg/dL}$ ($> 1.4 \text{ mmol/L}$)
Sulfonylurea/glinide screen	Negative

- **Differentiating hyperinsulinism:** secretagogue ingestion $\rightarrow$ **high** C-peptide (positive drug screen distinguishes it); **exogenous insulin** $\rightarrow$ hypoglycemia with **low** C-peptide (suppressed endogenous secretion); non-islet-cell tumour $\rightarrow$ **suppressed** insulin/C-peptide with high big-IGF-II.
- **Insulinoma:** yearly incidence ~ 1 in 250,000; **>90% benign**; median age 50 (third decade and multiple if part of MEN-1); **>99% intrapancreatic**, usually $< 2 \text{ cm}$. Imaging: CT/MRI detect $\sim 70\text{--}80\%$, endoscopic ultrasound sensitivity $\sim 90\%$, somatostatin-receptor scintigraphy $\sim$ half; selective arterial calcium stimulation regionalises diffuse disease; intra-operative ultrasound localises non-palpable tumours.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- **Tiered counterregulation cascade (vertical arrow of falling glucose):** label glucose levels $80\text{--}85 \text{ mg/dL} \rightarrow \downarrow$ Insulin (1st defence); $65\text{--}70 \text{ mg/dL} \rightarrow \uparrow$ Glucagon (2nd) and $\uparrow$ Epinephrine (3rd); $50\text{--}55 \text{ mg/dL} \rightarrow \uparrow$ Cortisol & GH; $< 50 \text{ mg/dL} \rightarrow$ Neuroglycopenia / $\downarrow$ Cognition. Side-label Symptoms (autonomic warning) between the epinephrine and cognition tiers.
- **HAAF vicious-cycle loop:** label *Recurrent hypoglycemia* $\rightarrow \downarrow$ *Adrenomedullary epinephrine* + $\downarrow$ *Sympathetic neural response* $\rightarrow$ *Defective glucose counterregulation* + *Hypoglycemia unawareness* $\rightarrow$ (back to) *Recurrent hypoglycemia*; annotate inputs *Antecedent hypoglycemia* / *Exercise* / *Sleep*.

Clinical / Diagnostic significance

- **Urgent treatment:** if conscious, oral $15\text{--}20 \text{ g}$ glucose (tablets/juice/candy); if neuroglycopenic, IV glucose 25 g then an infusion titrated to serial glucoses. If no IV access, **SC/IM glucagon 1.0 mg** — but glucagon is *ineffective in glycogen-depleted states* (alcohol) and *less useful in T2DM* (it also stimulates insulin secretion). **Octreotide** suppresses insulin secretion in **sulfonylurea-induced** hypoglycemia. All raise glucose only transiently — the patient must eat to replenish glycogen.

- ▶ **Prevention of recurrence** is mechanism-specific: stop/reduce the offending drug (sulfonylurea effect may last **hours-to-days**); treat the critical illness; replace deficient cortisol/GH; debulk a non-islet-cell tumour ($\pm$ glucocorticoid/GH).
- ▶ **Insulinoma**: surgical resection is **curative**; for unresectable tumours or functional β -cell disorders use **diazoxide** (inhibits insulin secretion), **octreotide**, or **everolimus** (mTOR inhibitor); partial pancreatectomy may be needed for diffuse disease. Frequent feeds, **uncooked cornstarch at bedtime**, or overnight intragastric glucose help refractory cases.
- ▶ Risk-reduction in diabetes: second-generation basal/prandial analogue insulins, GLP-1 ($\pm$ GIP) agonists added to basal insulin, **continuous glucose monitoring** with predictive low-glucose suspend / closed-loop “artificial pancreas,” structured patient education, and individualised, incrementally tightened HbA1c goals.

High-yield exam pointers

- ▶ **Whipple’s triad** is mandatory for diagnosis; fasting glucose lower limit ~ 70 mg/dL.
- ▶ Defence order: $\downarrow$ **insulin (1st)** $\rightarrow$ **glucagon (2nd)** $\rightarrow$ **epinephrine (3rd)**; cortisol/GH play *no role* in acute defence.
- ▶ **Ethanol blocks gluconeogenesis, not glycogenolysis** $\rightarrow$ glucagon is useless in alcohol-induced hypoglycemia.
- ▶ **C-peptide high** = secretagogue/insulinoma; **C-peptide low** = exogenous (factitious) insulin; **insulin + C-peptide suppressed + big-IGF-II high** = non-islet-cell tumour.
- ▶ Hyperinsulinism criteria (glucose < 55 mg/dL): insulin ≥ 3 μ U/mL, C-peptide ≥ 0.6 ng/mL, proinsulin ≥ 5 pmol/L, β -OHB ≤ 2.7 mmol/L; **72-h fast** is the classic provocation.
- ▶ **Insulinoma**: $>90\%$ benign, $>99\%$ intrapancreatic, <2 cm; consider **MEN-1**; resection curative.
- ▶ **HAAF** = defective counterregulation (≥ 25 -fold risk) + hypoglycemia unawareness (~ 6 -fold risk); **reversible in 2–3 weeks** of avoidance.
- ▶ Treatment ladder: oral 15–20 g $\rightarrow$ IV 25 g glucose $\rightarrow$ glucagon 1 mg IM/SC; octreotide for sulfonylurea overdose.

SOURCE & COVERAGE

Harrison 22e — Ch 418 “Hypoglycemia” (Stephen N. Davis). Fully covers the asked topic — definition, counterregulatory physiology, etiologic classification (Table 418-1), clinical features, HAAF, diagnostic evaluation including the biochemical criteria for endogenous hyperinsulinism, insulinoma, and treatment. No coverage gap; all numbers, thresholds and drug details above are taken verbatim from the chapter.

Hypoglycemia without diabetes

Asked in: Paper IV Nov 2019 — RGUHS MD General Medicine

Definition / Introduction — Hypoglycemia is a plasma glucose concentration low enough to cause symptoms or signs of impaired brain function and/or sympathoadrenal activation. Unlike in insulin-, sulfonylurea- or glinide-treated diabetes (where it is common and iatrogenic), hypoglycemia in a person **without diabetes is a distinctly uncommon clinical event**, because the normal physiologic and behavioural defences are highly effective. A genuine non-diabetic hypoglycemic disorder is accepted only when **Whipple's triad** is documented: (1) symptoms/signs consistent with hypoglycemia, (2) a low, reliably-measured plasma glucose, and (3) relief of symptoms after the glucose is raised. A plasma glucose **<55 mg/dL (3.0 mmol/L)** is unequivocally low.

Physiology of glucose counterregulation (the framework for diagnosis)

- ▶ Glucose is an **obligate fuel for the brain**, which cannot synthesise glucose, store more than a few minutes' supply as glycogen, or use circulating fuels at physiologic concentrations; brain oxidation accounts for ~25% of basal metabolic rate and >50% of whole-body glucose use.
- ▶ Endogenous glucose comes from **hepatic glycogenolysis** (stores last only ~8 h) and **hepatic + renal gluconeogenesis** (precursors: lactate/pyruvate, alanine and glutamine, glycerol). Only liver and kidney express **glucose-6-phosphatase**.
- ▶ Defences are deployed in a strict hierarchy as glucose falls (glycemic thresholds, Harrison Table 418-2):

Response	Glycemic threshold mg/dL (mmol/L)	Role
↓ Insulin (β -cell)	80–85 (4.4–4.7)	First defence; primary regulatory factor
↑ Glucagon (α -cell)	65–70 (3.6–3.9)	Second defence; primary counterregulatory factor
↑ Epinephrine (adrenomedullary)	65–70 (3.6–3.9)	Third defence; critical when glucagon deficient
↑ Cortisol & growth hormone	65–70 (3.6–3.9)	Support prolonged (>4 h) hypoglycemia; not critical for acute defence
Neurogenic symptoms	50–55 (2.8–3.1)	Behavioural defence (carbohydrate ingestion)
↓ Cognition	<50 (<2.8)	Neuroglycopenia begins

- ▶ In the non-diabetic, these mechanisms are intact, so demonstrating hypoglycemia mandates a search for a pathology that overwhelms them.

Clinical manifestations

- ▶ **Neuroglycopenic** (direct CNS glucose deprivation): behavioural change, confusion, fatigue/drowsiness, blurred vision/diplopia, difficulty speaking, focal deficits, seizure, loss of consciousness, and—if severe—cardiac arrhythmia or death. These are the more compelling features in non-diabetic disease.
- ▶ **Neurogenic (autonomic)** from sympathoadrenal discharge: *adrenergic* (palpitations, tremor, anxiety) and *cholinergic* (sweating, hunger, paraesthesiae). Signs: **diaphoresis and pallor**; modest tachycardia and rise in systolic BP.
- ▶ Symptoms are **non-specific**; their attribution to hypoglycemia requires fulfilment of Whipple's triad.

Aetiological classification (Harrison Table 418-1 / Endocrine Society)

The clinical categorisation separates the **ill or medicated** patient from the **seemingly well** patient.

Category	Causes
Drugs (commonest)	Insulin, insulin secretagogues (covert/accidental), alcohol ; others: ACE inhibitors, ARBs, β -blockers, quinolones (gatifloxacin, levofloxacin), quinine, indomethacin, pentamidine, sulfonamides/cotrimoxazole, IGF-1
Critical illness	Hepatic, renal or cardiac failure; sepsis ; inanition/starvation
Hormone deficiency	Cortisol (Addison's disease, hypopituitarism), growth hormone (in children); combined glucagon + epinephrine (in insulin-deficient diabetes only)
Non-islet cell tumour (NICTH)	Large mesenchymal/epithelial tumours (hepatoma, adrenocortical carcinoma, carcinoid) secreting "big" pro-IGF-II
Endogenous hyperinsulinism	Insulinoma; functional β -cell disorders (nesidioblastosis), NIPHS, post-gastric-bypass hypoglycemia; insulin/insulin-receptor autoantibodies; sulfonylurea/glinide
Other	Inborn errors (glycogenoses, fatty-acid oxidation/gluconeogenesis defects), exercise-induced, prolonged fasting, pregnancy; accidental/surreptitious/malicious

Key mechanisms to write:

- ▶ **Alcohol** inhibits **gluconeogenesis but not glycogenolysis**; hypoglycemia follows a binge with poor food intake (glycogen-depleted state). Ethanol is usually detectable in blood. (Glucagon is therefore ineffective in alcohol-induced hypoglycemia.)

- ▶ **Sepsis/critical illness:** cytokine-driven ↑ glucose utilisation in macrophage-rich tissue (liver, spleen, lung) outstrips production; compounded by hepatic/renal hypoperfusion and inanition. Hepatogenous hypoglycemia needs rapid, massive liver destruction (e.g., toxic hepatitis). Renal failure reduces insulin clearance and gluconeogenic precursor supply.
- ▶ **NICTH:** overproduction of incompletely-processed **pro-IGF-II** (“**big IGF-II**”) that escapes binding proteins, accessing tissue and acting like insulin; endogenous insulin is **appropriately suppressed**; the **IGF-II:IGF-I ratio is high** and GH/IGF-1 are low.
- ▶ **Hormone deficiency:** isolated GH deficiency does **not** cause hypoglycemia in adults; cortisol deficiency causes substrate-limited gluconeogenesis with glycogen depletion (consider Addison’s in a T1DM with worsening hypoglycemia + hyperpigmentation/hyponatraemia).

Endogenous hyperinsulinism and insulinoma (the seemingly-well patient)

- ▶ The hallmark is **failure of insulin secretion to fall** as glucose drops—i.e., insulin, C-peptide and proinsulin are *inappropriately high* for the low glucose.
- ▶ **Insulinoma** is the prototype: incidence ~1 in 250,000 patient-years; >90% **benign, solitary**; >99% **intrapancreatic**; usually small (<2 cm in 90%); median age 50 (sporadic), third decade if part of MEN-1 (~<10% have malignancy, multiplicity or MEN-1). Presents with **fasting** neuroglycopenia (occasionally postprandial) and weight gain.
- ▶ **Nesidioblastosis** – diffuse β-cell hypertrophy/hyperplasia causing fasting hyperinsulinemic hypoglycemia, clinically indistinguishable from insulinoma; imaging negative.
- ▶ **NIPHS** (noninsulinoma pancreatogenous hypoglycemia) – diffuse islet hyperfunction with **postprandial** hypoglycemia; imaging negative, diagnosed by positive **selective arterial calcium stimulation test**.
- ▶ **Post-gastric bypass (late dumping) hypoglycemia** – after Roux-en-Y; exaggerated GLP-1/insulin responses 2–4 h post-meal, usually >6–12 months postoperatively.
- ▶ **Autoimmune:** anti-insulin antibody (late postprandial; very high insulin with **insulin:C-peptide molar ratio >1**, HLA-DR4, Asians) or agonist insulin-receptor antibody.
- ▶ **Factitious/accidental secretagogue or insulin** must always be excluded.

Diagnostic approach

- ▶ **Step 1 – Document Whipple’s triad** with a *laboratory* glucose (never a glucometer); a normal glucose during a typical spell excludes hypoglycemia. Beware **pseudohypoglycemia** (ex-vivo glycolysis with leukocytosis/erythrocytosis/thrombocytosis or delayed separation—use NaF tube on ice).
- ▶ **Step 2 – Review for drugs, critical illness, hormone deficiency, NICTH** (history, examination, routine labs) — these explain most cases.

- ▶ **Step 3** – In a seemingly well patient, during spontaneous (or provoked) hypoglycemia draw the “critical sample”: plasma glucose, insulin, C-peptide, proinsulin, β -hydroxybutyrate, sulfonylurea/meglitinide screen, insulin antibodies; then give **1.0 mg IV glucagon** and measure the glucose response.
- ▶ If no spontaneous event: **72-hour supervised fast** (fasting history) or **5-h mixed-meal test** (postprandial history). ~2/3 of insulinomas declare in <24 h and most within 48 h; an OGTT is of no value.

Diagnostic interpretation when glucose <55 mg/dL (3.0 mmol/L) (Endocrine Society criteria):

Finding	Insulin (μ U/mL)	C-peptide (ng/mL)	Proinsulin (pmol/L)	β -OHB (mmol/L)	Glucose rise after glucagon	Other
Insulinoma / nesidioblastosis	≥ 3	≥ 0.6	≥ 5	≤ 2.7	>25 mg/dL	screens negative
Sulfonylurea/glinide	≥ 3	≥ 0.6	≥ 5	≤ 2.7	>25 mg/dL	agent positive
Exogenous insulin (factitious)	$\gg 3$	low (<0.6)	low (<5)	≤ 2.7	>25 mg/dL	C-peptide suppressed
Insulin autoimmune	$\gg 3$	high	high	≤ 2.7	>25 mg/dL	insulin antibody +
NICTH / IGF-mediated	<3	<0.6	<5	≤ 2.7	>25 mg/dL	$\uparrow$ pro-IGF-II, $\uparrow$ IGF-II:IGF-I
Not insulin/IGF-mediated	<3	<0.6	<5	>2.7	<25 mg/dL	—

- ▶ A >25 mg/dL (1.4 mmol/L) glucose rise after IV glucagon and a suppressed β -OHB (≤ 2.7 mmol/L) indicate preserved glycogen and suppressed ketogenesis from insulin/IGF action.
- ▶ **Localisation of insulinoma** (after biochemical confirmation): CT/MRI/transabdominal USG (~70–80%), **endoscopic ultrasound** (~90%), somatostatin-receptor (or Ga-68 DOTATATE / GLP-1-receptor exendin) imaging, and—if equivocal—**selective intra-arterial calcium stimulation with hepatic-venous insulin sampling**; intraoperative ultrasound localises nearly all.

Treatment

- ▶ **Urgent**: if able to swallow, **15–20 g oral glucose**; if not, **IV 25 g dextrose** (50 mL of 50%) then an infusion guided by serial glucose; **glucagon 1.0 mg SC/IM** (ineffective if glycogen-depleted, e.g., alcohol; less useful in factitious sulfonylurea). Always feed afterwards to replete glycogen.

- ▶ **Cause-specific:** stop/reduce offending drug; treat critical illness; replace cortisol/GH if deficient; debulk/irradiate/chemotherapy ± glucocorticoid for NICTH.
- ▶ **Insulinoma: surgical resection is curative.** If unresectable—**diazoxide** (inhibits insulin secretion; CMDT 300–400 mg/day, up to 800 mg, with hydrochlorothiazide to offset oedema), **octreotide**, or **everolimus** (mTOR inhibitor).
- ▶ **Octreotide** specifically suppresses insulin in sulfonylurea overdose. **NIPHS/post-bypass:** low-glycaemic-index diet, α-glucosidase inhibitor, diazoxide/octreotide, partial pancreatectomy if refractory. **Autoimmune:** glucocorticoids ± immunosuppression; often self-limited. Refractory cases: frequent feeds and **uncooked cornstarch** at night.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Diagram 1 – Glucose counterregulatory cascade:** Falling arterial glucose → pancreas (β-cell ↓insulin = 1st defence; α-cell ↑glucagon = 2nd defence) → adrenal medulla ↑epinephrine (3rd defence) → pituitary/adrenal cortex ↑GH, ↑cortisol → liver/kidney ↑glycogenolysis + gluconeogenesis → ↑glucose production; sympathoadrenal outflow → neurogenic symptoms → carbohydrate ingestion. Label thresholds (↓insulin 80–85; glucagon/epi 65–70; symptoms 50–55 mg/dL).
- ▶ **Diagram 2 – Diagnostic flow at glucose <55 mg/dL:** branch on C-peptide (high → endogenous: insulinoma vs sulfonylurea [screen] vs autoimmune [antibody]; low → exogenous insulin or, with low insulin + high IGF-II:IGF-I → NICTH). Label insulin ≥3 μU/mL, C-peptide ≥0.6 ng/mL, proinsulin ≥5 pmol/L, β-OHB ≤2.7 mmol/L.

Clinical / Diagnostic significance

- ▶ Distinguishing **fasting** (neuroglycopenic, insulinoma/NICTH/drugs) from **postprandial** (autonomic, NIPHS/post-bypass/autoimmune) hypoglycemia directs the provocative test chosen.
- ▶ The **C-peptide/proinsulin pattern** is the single most useful discriminator: high with insulinoma and sulfonylurea, **low with exogenous insulin**—a medicolegally important clue to factitious/malicious illness (commonest in healthcare workers and relatives of diabetics).
- ▶ Insulinoma is rare but **treatable and potentially fatal**; suspect it in a healthy adult with fasting confusion misdiagnosed as epilepsy or psychiatric illness, and screen for **MEN-1** (calcium, gastrin, prolactin).

High-yield exam pointers

- ▶ **Whipple's triad** is mandatory before labelling non-diabetic hypoglycemia; glucose <55 mg/dL (3.0 mmol/L) = unequivocally low.
- ▶ Order of defences: ↓insulin → ↑glucagon → ↑epinephrine (critical when glucagon deficient); cortisol/GH are *not* critical for acute defence.

- ▶ **Drugs** (esp. insulin, secretagogues, alcohol) are the commonest cause; alcohol blocks gluconeogenesis, not glycogenolysis.
- ▶ Endogenous hyperinsulinism criteria (glucose <55): **insulin** $\geq 3 \mu\text{U/mL}$, **C-peptide** $\geq 0.6 \text{ ng/mL}$, **proinsulin** $\geq 5 \text{ pmol/L}$, **β -OHB** $\leq 2.7 \text{ mmol/L}$, **glucagon-induced glucose rise** $>25 \text{ mg/dL}$, negative sulfonyleurea screen.
- ▶ **Exogenous insulin** $\rightarrow$ **low C-peptide** (insulin:C-peptide ratio >1); **sulfonyleurea** $\rightarrow$ **high C-peptide** + **positive drug screen**.
- ▶ **NICTH** = “big” pro-IGF-II, suppressed insulin, **high IGF-II:IGF-I ratio**; mesenchymal tumours.
- ▶ **Insulinoma**: 1/250,000, $>90\%$ benign, $>99\%$ pancreatic, $<2 \text{ cm}$, EUS sensitivity $\sim 90\%$; **surgery curative**, diazoxide/octreotide if unresectable.
- ▶ **72-h supervised fast** for fasting type; **mixed-meal test** for postprandial type; **OGTT has no diagnostic role**.
- ▶ Beware **pseudohypoglycemia** (ex-vivo glycolysis) and always use a **laboratory** (not glucometer) glucose.

Insulin Resistance

Asked in: Paper I May 2022 — RGUHS MD General Medicine

Definition / Introduction — **Insulin resistance (IR)** is the *decreased ability of insulin to act effectively on its target tissues* — chiefly **skeletal muscle, liver and adipose tissue** — so that a normal insulin concentration produces a subnormal biological response. It is *relative* rather than absolute, because supranormal (compensatory hyperinsulinaemic) levels can still normalise plasma glucose. IR results from a combination of **genetic susceptibility, obesity and metabolic inflammation**, is the central and usually earliest lesion in **type 2 diabetes mellitus (T2DM)**, and is the most accepted **unifying hypothesis**

for the **metabolic syndrome** — linking obesity to atherogenic dyslipidaemia, hypertension, steatotic liver disease, PCOS and accelerated atherosclerotic cardiovascular disease (ASCVD).

Physiological basis and target tissues

- ▶ Insulin normally **stimulates glucose uptake in muscle and fat, suppresses hepatic glucose production, inhibits adipose-tissue lipolysis and stimulates lipoprotein lipase**; inhibition of lipolysis is the *most sensitive* pathway of insulin action.
- ▶ In IR these actions fail in a **tissue-selective** manner:
 - **Skeletal muscle** — impaired insulin-stimulated glucose utilisation; whole-body glucose disposal is **30–60% lower** than in non-diabetic individuals → drives *postprandial* hyperglycaemia.
 - **Liver** — failure of hyperinsulinaemia to suppress **gluconeogenesis** → increased hepatic glucose output (drives *fasting* hyperglycaemia) and reduced postprandial glycogen storage.
 - **Adipose tissue** — uninhibited lipolysis → increased **free fatty acid (FFA)** flux to liver and muscle.

Natural history (IR → hyperglycaemia)

- ▶ Onset is heralded by **postprandial hyperinsulinaemia** → **fasting hyperinsulinaemia** → **hyperglycaemia**.
- ▶ Pancreatic beta cells initially **compensate** by raising insulin output, keeping glucose tolerance near-normal despite resistance.
- ▶ When secretion can no longer match the degree of resistance → **IFG/IGT**, and ultimately frank **T2DM** (the *twin-defect* model: IR **plus** progressive beta-cell failure). Diabetes develops *only when insulin secretion becomes inadequate for the prevailing insulin resistance*.
- ▶ IR (reduced skeletal-muscle glucose utilisation) is demonstrable in many **non-diabetic first-degree relatives** of T2DM patients, underscoring a strong heritable component (twin concordance 70–90%).

Molecular and cellular mechanisms

- ▶ The precise molecular lesion is **not fully elucidated** but is predominantly a “**post-receptor**” defect:
 - Insulin-receptor number and **tyrosine-kinase activity** in muscle are reduced, but this is largely *secondary* to hyperinsulinaemia, not the primary fault.
 - Defective **insulin-regulated phosphorylation / dephosphorylation** of downstream signalling proteins predominates.
- ▶ **Lipotoxicity** — accumulation of lipid intermediates within myocytes impairs **mitochondrial oxidative phosphorylation**, lowers insulin-stimulated ATP production and generates **reactive oxygen species (lipid peroxides)**.

- ▶ **Metabolic (low-grade) inflammation** — adipose-resident macrophages and adipocytes secrete TNF- α , IL-6, IL-1, IL-18 and resistin and raise CRP; this feeds back and *directly worsens* IR.
- ▶ **Selective (pathway-specific) resistance** — the mitogenic MAP-kinase growth/differentiation pathway remains insulin-sensitive; compensatory hyperinsulinaemia therefore *over-drives* it, potentially **accelerating atherosclerosis**.

Adipose tissue, free fatty acids and adipokines

- ▶ **Central/visceral obesity** (high waist–hip ratio) is pivotal; $\geq 80\%$ of T2DM patients are obese. Visceral fat drains via the **portal vein**, delivering FFAs and adipokines directly to the liver and contributing to hepatic IR. Importantly, **normal-weight South-Asian, Southeast-Asian and Central-American individuals can be insulin-resistant** (“metabolically obese, normal weight”).
- ▶ Excess FFAs impair muscle glucose uptake, promote hepatic gluconeogenesis and **VLDL-triglyceride** synthesis, accumulate as intramuscular/intrahepatic triglyceride, and impair beta-cell function.
- ▶ **Adipokines** modulate sensitivity:
 - **Adiponectin** — insulin-sensitising and anti-inflammatory (activates AMP-kinase, $\uparrow$ fatty-acid oxidation, $\downarrow$ hepatic gluconeogenesis); **reduced** in obesity $\rightarrow$ contributes to hepatic IR.
 - **Leptin** — normally $\downarrow$ appetite, $\uparrow$ energy expenditure, $\uparrow$ insulin sensitivity; obesity produces **hyperleptinaemia with leptin resistance**.
 - Pro-resistance mediators — **resistin, retinol-binding protein-4, visfatin, fetuin-A, asprosin, PAI-1, TNF- α , IL-6**.

Consequences and clinical correlates of insulin resistance

Domain	Mechanism / effect of IR
Type 2 DM / IGT–IFG	Primary, earliest defect; $\sim 75\%$ of patients with T2DM or IGT have the metabolic syndrome
Atherogenic dyslipidaemia	$\uparrow$ Triglyceride/VLDL, $\downarrow$ HDL, small dense LDL , $\uparrow$ apoC-III (inhibits lipoprotein lipase)
Hypertension	Loss of insulin’s NO-mediated vasodilation with <i>preserved</i> renal Na^+ reabsorption; $\uparrow$ sympathetic activity; $\uparrow$ adipose angiotensinogen
Metabolic syndrome	IR is the unifying pathophysiological mechanism (syndrome X / insulin-resistance syndrome)
MASLD / MASH (NAFLD/NASH)	Hepatic triglyceride accumulation from $\uparrow$ FFA flux + VLDL synthesis
PCOS	IR present in 50–80% ; independently raises T2DM risk

Domain	Mechanism / effect of IR
Hyperuricaemia	↓Renal tubular uric-acid excretion; promotes endothelial dysfunction/hypertension
Prothrombotic / proinflammatory state	↑PAI-1, fibrinogen, CRP
ASCVD	Relative risk ~1.5–3×; MI/stroke risk threefold higher in metabolic syndrome

Severe insulin-resistance syndromes

Syndrome	Key features	Underlying defect
Type A insulin resistance	Young women; severe hyperinsulinaemia, obesity, hyperandrogenism, acanthosis nigricans	Undefined defect in the insulin-signalling pathway
Type B insulin resistance	Middle-aged women; severe hyperinsulinaemia, hyperandrogenism, autoimmune disease	Autoantibodies to the insulin receptor (block → hyperglycaemia; stimulate → intermittent hypoglycaemia)
Insulin-receptor mutations	Rare; features of T2DM/IGT	Impaired insulin binding or signal transduction
Leprechaunism (Donohue) / Rabson-Mendenhall	Severe congenital IR	Genetic defects in insulin action
Lipodystrophies	Selective loss of adipose tissue → severe IR + hypertriglyceridaemia	Inherited (Berardinelli-Seip congenital generalised; Dunnigan familial partial) or acquired (HIV-related)
PCOS	Chronic anovulation + hyperandrogenism	IR in a major subset; independent T2DM risk

- ▶ *Acanthosis nigricans* and signs of hyperandrogenism (hirsutism, acne, oligomenorrhoea) are the physical hallmarks of **severe IR**.
- ▶ Secondary IR also accompanies **endocrinopathies** (acromegaly, Cushing's syndrome, glucagonoma, pheochromocytoma) and **drugs** (glucocorticoids, calcineurin/mTOR inhibitors, certain antiretrovirals, nicotinic acid, thiazides).

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Pathophysiology of IR / metabolic syndrome (central-obesity hub)**: draw an expanded adipocyte at the centre releasing FFAs, TNF- α / IL-6 / **resistin** / PAI-1 and *reduced adiponectin*; arrows to **Liver** (↑gluconeogenesis, ↑VLDL-triglyceride → fasting hyperglycaemia + dyslipidaemia), **Muscle** (↓glucose uptake → postprandial

hyperglycaemia), **Pancreas** (compensatory **hyperinsulinaemia**), **Vessels** ($\downarrow$ NO, $\uparrow$ Na⁺ reabsorption, $\uparrow$ SNS $\rightarrow$ hypertension) and **Blood** ($\uparrow$ CRP/fibrinogen $\rightarrow$ prothrombotic state).
Labels: FFA, *adiponectin* $\downarrow$, *TNF- α* , *IL-6*, *PAI-1*, *VLDL/TG*, *small dense LDL*, *HDL* $\downarrow$, *hyperinsulinaemia*, *NO* $\downarrow$, *ASCVD*.

- **Beta-cell compensation curve (insulin secretion vs insulin sensitivity):** hyperbolic curve with points A (normal) $\rightarrow$ B (insulin-resistant, $\uparrow$ secretion) $\rightarrow$ C (IGT) $\rightarrow$ D (Type 2 DM).
Labels: *insulin sensitivity (M value)*, *insulin secretion*, *NGT*, *IGT*, *Type 2 DM*.

Clinical / Diagnostic significance

- **Clinical clues** — **acanthosis nigricans**, skin tags, central obesity ($\uparrow$ waist circumference), and hyperandrogenism (hirsutism, acne, oligomenorrhoea) flag significant IR.
- **Assessment of IR:**
 - *Surrogate indices* — fasting insulin and **HOMA-IR** (homeostasis model assessment) are the practical clinical surrogates; the chapter notes that fasting insulin / HOMA only *partially* capture IR.
 - *Quantitative gold standard* — the **hyperinsulinaemic-euglycaemic clamp**, expressing whole-body glucose disposal as the “M value” ($\mu\text{mol}/\text{min per kg}$) = insulin sensitivity.
 - *Clinical surrogate* — meeting **metabolic-syndrome criteria** (NCEP:ATP III 2001 / Harmonizing definition: central obesity + ≥ 2 of $\uparrow$ TG ≥ 150 mg/dL, HDL $< 40 / < 50$ mg/dL, BP $\geq 130 / 85$ mmHg, FPG ≥ 100 mg/dL).
- **Management — reduce/reverse IR (insulin sensitisation):**
 - **Lifestyle is first-line** — weight loss (target ≥ 5 –7% body weight), saturated-fat restriction and ≥ 150 min/week physical activity. The **Diabetes Prevention Program (DPP)** showed intensive lifestyle change reduced incident T2DM by **58%**.
 - **Metformin (biguanide)** — enhances hepatic insulin action and suppresses endogenous glucose production; DPP reduction **31%**; benefits IR in PCOS.
 - **Thiazolidinedione (pioglitazone)** — improves insulin-mediated glucose uptake in muscle/adipose tissue *and* hepatic action; a meta-analysis (9 trials, 12,026 participants) showed $\downarrow$ **ASCVD events**; caution — weight gain, oedema/CHF, fractures.
 - **GLP-1 receptor agonists / tirzepatide** — improve insulin sensitivity largely via weight loss.
 - Treat the clustered components — statins/fibrates for dyslipidaemia, antihypertensives, and urate-lowering where indicated.

High-yield exam pointers

- IR = **reduced insulin action on muscle, liver and fat**; *relative* (overcome by hyperinsulinaemia); central lesion of T2DM and **unifying mechanism of metabolic syndrome**.

- ▶ Sequence: **postprandial** → **fasting hyperinsulinaemia** → **hyperglycaemia**; T2DM only when **beta-cell compensation fails**.
- ▶ Predominantly a **post-receptor signalling defect**; lipotoxicity + ROS + metabolic inflammation; **MAP-kinase pathway spared** → hyperinsulinaemia promotes atherosclerosis.
- ▶ **FFA excess** and **low adiponectin / high resistin**, **TNF- α** , **IL-6**, **leptin resistance** drive IR.
- ▶ **Type A** = insulin-signalling defect (young women); **Type B** = **anti-insulin-receptor antibodies** (autoimmune, middle-aged women).
- ▶ **Acanthosis nigricans + hyperandrogenism** = clinical markers of severe IR; lipodystrophy (Berardinelli-Seip, Dunnigan) causes severe IR with hypertriglyceridaemia.
- ▶ **PCOS**: IR in 50–80%, independent T2DM risk.
- ▶ Best quantified by **hyperinsulinaemic-euglycaemic clamp**; HOMA-IR is the practical surrogate.
- ▶ Sensitisers = **metformin and pioglitazone**; lifestyle/weight loss is most effective (DPP 58% vs metformin 31%).

SOURCE & COVERAGE

Harrison 22e — Ch 415 “Diabetes Mellitus: Diagnosis, Classification, and Pathophysiology” + Ch 420 “The Metabolic Syndrome”. Coverage note: The HOMA-IR formula (fasting insulin $\times$ fasting glucose $\div$ 22.5) and the use of the hyperinsulinaemic-euglycaemic clamp as the quantitative gold standard are universally accepted standard internal medicine; the provided chapters reference “homeostasis model assessment”, fasting insulin, and the clamp-derived “M value” (insulin sensitivity) but do not print the HOMA-IR formula explicitly. Drug doses are deliberately not stated, as the source chapters cite drug classes rather than specific doses (detailed dosing is in Ch 416, not provided).

Insulin Sensitizers

Asked in: Paper IV May 2019 — RGUHS MD General Medicine

Definition / Introduction — *Insulin sensitizers* are glucose-lowering agents that act by enhancing the responsiveness of target tissues (liver, skeletal muscle, adipose) to circulating insulin, thereby reducing insulin resistance, rather than by stimulating insulin secretion. Two oral classes form this group: the **biguanides** (metformin) and the **thiazolidinediones / glitazones** (pioglitazone, rosiglitazone). Because their action is insulin-dependent and does not augment β -cell secretion, they **do not cause hypoglycaemia as monotherapy** and are central to the management of type 2 diabetes mellitus (T2DM), where insulin resistance is a defining lesion.

Classification and rationale

- ▶ **Biguanides** — metformin (the only biguanide in current use; *phenformin* and *buformin* were withdrawn from most markets in the 1970s after deaths from lactic acidosis). Acts predominantly on the **liver** to lower hepatic glucose output.
- ▶ **Thiazolidinediones (TZDs)** — *pioglitazone* and *rosiglitazone*; the first agent, *troglitazone* (1997), was withdrawn in 2000 because of rare fatal hepatotoxicity. Act predominantly on **adipose tissue** (PPAR- γ) with secondary benefit at liver and muscle.
- ▶ Both classes lower glucose without directly raising insulin levels; circulating insulin actually **falls** with effective therapy, confirming improved sensitivity.
- ▶ They target the *insulin-resistance* arm of T2DM pathophysiology and so are complementary to secretagogues, incretins and SGLT-2 inhibitors in combination regimens.

Biguanides — Metformin

- ▶ **Mechanism (incompletely defined):** principally **reduces hepatic gluconeogenesis** and hepatic insulin resistance; less consistently improves peripheral (muscle) glucose uptake; influences gut function (alters microbiome, increases GLP-1 release). At the molecular level it **activates AMP-activated protein kinase (AMPK)** (a sensor of depleted cellular energy), and more recent work implicates **inhibition of mitochondrial glycerophosphate dehydrogenase** and a direct effect on the intestinal mucosa signalling to brain/liver.
- ▶ **Pharmacokinetics:** half-life ~1.5–3 h; **not protein-bound, not metabolised, excreted unchanged by the kidney** (hence the dependence of safety on renal function).
- ▶ **Efficacy:** lowers **HbA1c** by ~1–2%; reduces fasting plasma glucose and insulin; modestly improves the lipid profile ($\downarrow$ LDL, $\downarrow$ triglycerides) and procoagulant factors; **weight-neutral to modest weight loss**; no hypoglycaemia; inexpensive — hence the **first-line agent** in most T2DM algorithms (ADA/EASD, IDF, AACE).
- ▶ **Dosing:** start low (500 mg once–twice daily *with food*) and titrate every 1–2 weeks; maximally tolerated dose **2000 mg/day** (formal maximum 2550 mg, little extra benefit beyond 2000 mg). IR: 500 mg tid or 850–1000 mg bid; **extended-release (ER)** once daily has fewer upper-GI effects and better adherence.
- ▶ **Adverse effects:** GI intolerance (nausea, anorexia, abdominal cramps, diarrhoea, metallic taste) in up to 20–30%, often transient and dose-related; **vitamin B12 deficiency** (interferes with calcium-dependent absorption of the B12–intrinsic-factor complex in the terminal ileum — monitor periodically, especially if neuropathy or macrocytosis); **lactic acidosis** — the major but *very rare* toxicity (incidence <10/10,000 patient-years), almost confined to patients with predisposing illness.
- ▶ **Contraindications / cautions:** **eGFR <30 mL/min/1.73 m² (contraindicated)**; do not *initiate* if eGFR <45, and halve the dose ($\approx$ 1000 mg/day) if eGFR 30–45; hepatic insufficiency, excess alcohol intake, unstable/decompensated CHF, any acidosis, severe hypoxaemia. **Withhold for**

iodinated radiographic contrast (halt on the day in patients with eGFR 30–60, restart after 48 h once renal function is confirmed stable) and in hospitalised/NPO/acutely ill patients (substitute insulin).

- ▶ **Cardiovascular / outcome data:** in overweight patients in the UKPDS (UKPDS 34), metformin reduced *any diabetes-related endpoint* by 32%, *myocardial infarction* by 39% and *all-cause mortality* by 36%; benefit persisted at 10-year post-trial follow-up (a “legacy”/metabolic-memory effect). Metformin also **reduces progression from prediabetes to diabetes** (Diabetes Prevention Program). It is the insulin sensitiser with the best long-term outcome record.

Thiazolidinediones (Glitazones)

- ▶ **Mechanism:** bind and activate the nuclear transcription factor **peroxisome proliferator-activated receptor- γ (PPAR- γ)**, which forms a **heterodimer with the retinoid X receptor (RXR)**. PPAR- γ is expressed at highest levels in **adipocytes**. Activation regulates many genes $\rightarrow$ promotes **adipocyte differentiation**, **redistributes fat from central/visceral to peripheral/subcutaneous depots**, reduces hepatic fat, promotes fatty-acid storage and **lowers circulating free fatty acids**, thereby improving whole-body insulin sensitivity. Onset is **slow (weeks–months)**.
- ▶ **Efficacy:** HbA1c reduction **~ 0.5 – 1.4%** (up to 1–2%); effective as monotherapy or with metformin/sulfonylurea/insulin. When combined with insulin they **lower insulin requirement by 30–50%**. **No hypoglycaemia** as monotherapy. **Preserve β -cell function** — in ADOPT, rosiglitazone gave the slowest rate of secondary glycaemic failure vs metformin and glyburide.
- ▶ **Pioglitazone (preferred TZD):** dose 15–45 mg once daily (start 15 mg; 30 mg $\approx$ 80% of maximal glucose-lowering; 45 mg least well tolerated); **favourable lipid effect** — $\downarrow$ triglycerides (~ 9 –20%), $\uparrow$ HDL, neutral/ $\downarrow$ LDL; reduces hepatic fat and can **reverse hepatic fibrosis (benefit in NASH/MASH)**; lowers blood pressure and urinary albumin. Metabolised by CYP2C8 / CYP3A4.
- ▶ **Rosiglitazone:** raises LDL and triglycerides; embroiled in a still-unresolved controversy over possible increased myocardial-infarction risk (meta-analyses), leading to a **shift away from its use worldwide** (RECORD trial showed no excess CV death/hospitalisation but did not settle the dispute).
- ▶ **Cardiovascular data (pioglitazone):** PROactive (5238 T2DM with macrovascular disease) — the broad primary endpoint was negative but a tighter secondary composite (death/MI/stroke) fell by **16%**; the IRIS study showed pioglitazone reduced recurrent **stroke or MI** in insulin-resistant, non-diabetic patients after stroke/TIA. Overall, **pioglitazone appears to reduce recurrent cardiovascular events**, partly offset by fluid retention/heart failure.
- ▶ **Adverse effects:** **weight gain (2–4 kg)** — from both fluid retention and an increase in subcutaneous fat; **fluid retention / peripheral oedema** (~ 5 –10%, rising to 10–15% with concomitant insulin or sulfonylurea) which may precipitate **congestive heart failure** — TZDs are **contraindicated in NYHA class III/IV heart failure**; **bone fractures** (especially distal long bones in postmenopausal women — PPAR- γ diverts mesenchymal stem cells from osteoblastic to

adipocytic lineage and reduces lumbar BMD); **macular oedema**; mild **anaemia** (dilutional, small fall in haematocrit); **hepatotoxicity** caution (check LFTs; contraindicated if ALT >2.5× ULN); possible **bladder-cancer** association with pioglitazone (conflicting data — avoid with active or prior bladder cancer). TZDs **induce ovulation in PCOS** — counsel premenopausal women on contraception as safety in pregnancy is unestablished.

Biguanide vs Thiazolidinedione — comparison

Feature	Biguanide (Metformin)	Thiazolidinedione (Pioglitazone)
Primary site / target	Liver; activates AMPK	Adipose tissue; PPAR-γ-RXR heterodimer
Dominant action	↓ Hepatic gluconeogenesis	↑ Peripheral insulin sensitivity, fat redistribution
HbA1c reduction	~1–2%	~0.5–1.4% (up to 2%)
Onset	Days	Weeks–months
Effect on weight	Neutral / slight loss	Gain (2–4 kg)
Hypoglycaemia (mono)	No	No
Key adverse effects	GI upset, B12 deficiency, lactic acidosis	Oedema/CHF, fractures, macular oedema, ?bladder Ca
Major contraindication	eGFR <30, acidosis, hypoxia	NYHA class III/IV heart failure, hepatic disease
Outcome highlight	UKPDS 34 ↓ MI & mortality	PROactive/IRIS ↓ recurrent CV events; benefit in NASH

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- “**Sites of action of insulin sensitizers**”: a central panel with three organs labelled — **Liver** (arrow “Metformin → AMPK → ↓ gluconeogenesis / ↓ hepatic glucose output”), **Skeletal muscle** (“↑ insulin-stimulated glucose uptake”), and **Adipose tissue** (“Pioglitazone → PPAR-γ → adipocyte differentiation, fat redistributed visceral → subcutaneous, ↓ free fatty acids”). Add a peripheral box: “Net result = ↓ insulin resistance, ↓ circulating insulin, no hypoglycaemia.” Labels: *Metformin*, *AMPK*, *hepatic gluconeogenesis*, *PPAR-γ*, *FFA*, *insulin resistance*.
- “**TZD molecular mechanism**”: *TZD* → binds **PPAR-γ**, which dimerises with **RXR**; the **PPAR-γ-RXR heterodimer** binds the **PPRE (PPAR response element)** on **DNA** → gene transcription → adipocyte differentiation / insulin-sensitising genes. Labels: *TZD*, *PPAR-γ*, *RXR*, *PPRE*, *DNA*, *target genes*.

Clinical / Diagnostic significance

- ▶ **Metformin** is the recommended **first-line drug** for T2DM (efficacy, safety, weight neutrality, cardiovascular benefit, low cost) and is continued through combination therapy even after HbA1c falls below target.
- ▶ Check **eGFR before starting and at least annually** for metformin; obtain **vitamin B12** periodically, particularly when peripheral neuropathy or macrocytosis appears (do not misattribute to diabetic neuropathy).
- ▶ **Pioglitazone** is especially useful where insulin resistance, **NASH/MASH**, or hepatic steatosis coexist, and as an inexpensive generic add-on; screen for and avoid in **heart failure** and assess **fracture risk** (BMD) before prescribing, particularly in postmenopausal women.
- ▶ Neither agent causes hypoglycaemia alone, but **dose reduction of insulin/sulfonylurea** is needed when either is added to those drugs.
- ▶ In current ADA/EASD practice, when **ASCVD, heart failure or CKD** dominate, a GLP-1 RA or SGLT-2 inhibitor is layered onto metformin; pioglitazone is favoured for the MASH/ASCVD-risk phenotype provided heart failure is absent.

High-yield exam pointers

- ▶ Two insulin-sensitiser classes: **biguanides (metformin)** and **thiazolidinediones (pioglitazone, rosiglitazone)** — improve sensitivity, **no hypoglycaemia** as monotherapy.
- ▶ **Metformin**: ↓ hepatic gluconeogenesis via **AMPK**; renally excreted unchanged; **B12 deficiency** and **lactic acidosis**; stop if **eGFR <30** and hold for **contrast/surgery**.
- ▶ **UKPDS 34**: metformin ↓ MI 39% and all-cause mortality 36% in overweight T2DM (legacy effect).
- ▶ **TZDs**: activate **PPAR-γ-RXR** heterodimer in adipocytes → fat redistribution and ↓ FFA.
- ▶ **Pioglitazone** ↓ triglycerides, ↑ HDL, benefits **NASH/MASH**; **PROactive/IRIS** suggest reduced recurrent CV/stroke events.
- ▶ **TZD red flags**: fluid retention → **CHF (contraindicated NYHA III/IV)**, **fractures** in postmenopausal women, macular oedema, possible **bladder cancer** (pioglitazone).
- ▶ **Troglitazone** withdrawn (hepatotoxicity); **phenformin** withdrawn (lactic acidosis) — historical safety landmarks.
- ▶ TZDs **preserve β-cell function** (slowest secondary failure in ADOPT) and **induce ovulation** in PCOS.

Investigations and Treatment of Diabetes Insipidus

Asked in: Paper IV Nov 2021 — RGUHS MD General Medicine

Definition / Introduction — Diabetes insipidus (DI) is a hypotonic polyuria–polydipsia syndrome caused by a deficiency of **arginine vasopressin (AVP / antidiuretic hormone)** secretion or by renal resistance to its action, leading to excretion of abnormally large volumes of dilute urine (24-h urine volume >40–50 mL/kg body weight, usually >3 L/day) with compensatory polydipsia. Harrison 22e adopts the revised nomenclature: *AVP deficiency* (formerly central / neurogenic / cranial / pituitary DI) and *AVP resistance* (formerly nephrogenic DI). The core clinical task is to **confirm hypotonic polyuria, exclude osmotic diuresis, and differentiate the three look-alike disorders** — AVP deficiency, AVP resistance, and primary polydipsia — because their treatment differs fundamentally.

Classification and etiology (basis for investigation)

The differential of the polyuria–polydipsia syndrome has four mechanistic groups; investigations are designed to separate them.

Disorder (new term / old term)	Basic defect	Representative causes
AVP deficiency (central DI)	Deficient AVP synthesis/secretion	Trauma/surgery, tumours (craniopharyngioma, germinoma, meningioma, metastases), granulomatous (histiocytosis, sarcoidosis), infective (TB, meningitis), lymphocytic/IgG4 infundibuloneurohypophysitis, idiopathic; genetic — autosomal dominant <i>AVP–neurophysin II</i> mutations, <i>WFS1</i> (Wolfram)
AVP resistance (nephrogenic DI)	Reduced renal sensitivity to AVP	Drugs (lithium , demeclocycline, cisplatin), hypercalcemia , hypokalemia , infiltration (amyloid, myeloma), sickle cell, obstruction/PKD; genetic — X-

Disorder (new term / old term)	Basic defect	Representative causes
		linked <i>AVPR2</i> , autosomal <i>AQP2</i> mutations
Primary polydipsia	Excess fluid intake (low thirst set-point)	Dipsogenic, psychogenic (chronic schizophrenia), compulsive/"health-enthusiast" water drinking
Gestational AVP deficiency	Placental vasopressinase (N-terminal aminopeptidase) degrades AVP	Pregnancy; remits weeks after delivery

Step 1 — Initial clinical and biochemical evaluation

- ▶ **Document true polyuria:** collect a 24-h urine on unrestricted fluid intake. Volume >40–50 mL/kg per day and/or >3 L/day with **urine osmolality** <800 mosm/kg confirms hypotonic polyuria and warrants further work-up. Urine volume <50 mL/kg/24 h points to a genitourinary cause instead.
- ▶ **Exclude osmotic diuresis first:** absence of **glucosuria** (rule out diabetes mellitus); also exclude high solute load.
- ▶ **Measure serum sodium / plasma osmolality** — this triages the patient:
 - Serum Na <135 mmol/L → favours **primary polydipsia** (patients can “drink themselves into” hyponatremia).
 - Serum Na >147 mmol/L (hypernatremia) → favours **AVP deficiency or AVP resistance** (true DI).
 - Normal Na (136–146 mmol/L) — the commonest situation — mandates **provocative testing** (below).
- ▶ A bedside discriminator when Na is high: give **desmopressin 2 µg SC** and repeat urine osmolality — a brisk rise indicates **AVP deficiency**, while failure to concentrate indicates **AVP resistance**. (Done as an inpatient to allow serial osmolality checks.)

Step 2 — Confirmatory tests: water deprivation and desmopressin

The **indirect water deprivation test** (Miller–Moses principle) was the long-standing gold standard — it indirectly assesses AVP activity by measuring urine-concentrating capacity during supervised dehydration, then after a dose of desmopressin. *Limitation flagged by Harrison:* its published criteria gave an overall diagnostic accuracy of only ~70%, and just 41% in **primary polydipsia**, hence the move to copeptin.

Interpretation (per the diagnostic algorithm, Fig. 393-4):

Test result	Interpretation
Water deprivation → urine osmolality >800 mosm/kg	Mild primary polydipsia
Urine osmolality 300–800 mosm/kg, then desmopressin → >9% further rise	Partial central DI (AVP deficiency)
Urine osmolality 300–800, then desmopressin → <9% rise	Primary polydipsia
Urine osmolality <300 mosm/kg, then desmopressin → >50% rise	Complete central DI
Urine osmolality <300, then desmopressin → <50% rise	Nephrogenic DI (AVP resistance)

- ▶ Direct plasma AVP assay was proposed but is **not in routine use** because of technical instability of the AVP assay.

Step 3 — Copeptin-based diagnosis (current preferred approach)

Copeptin is the C-terminal glycopeptide of the AVP prohormone, co-secreted stoichiometrically with AVP but far more **stable ex vivo**, making it a reliable AVP surrogate.

- ▶ **Baseline copeptin >21.4 pmol/L** (without prior water deprivation) **unequivocally identifies AVP resistance (nephrogenic DI)**.
- ▶ For the harder split between AVP deficiency and primary polydipsia, perform a **hypertonic saline infusion test**: a **stimulated copeptin >4.9 pmol/L at a plasma sodium ≥150 mmol/L** diagnoses **AVP deficiency** with an overall accuracy of **96.5–97%** (values <4.9 pmol/L indicate primary polydipsia). Requires **close monitoring of sodium**.
- ▶ **Arginine-stimulated copeptin** is a gentler alternative but with lower diagnostic accuracy. Copeptin assays are commercially available in Europe, Australia, **India**, and Mexico.

Step 4 — Localisation / imaging

- ▶ Once AVP deficiency is confirmed, obtain **MRI of the sella and suprasellar region** to find the underlying lesion (tumour, infiltration, stalk thickening) and assess the posterior pituitary and stalk.
- ▶ The normal **posterior pituitary “bright spot”** (T1 hyperintensity reflecting AVP-laden neurosecretory vesicles) is typically **absent in AVP deficiency**; however, its absence alone is **not diagnostic** (it may persist early in disease or be absent in normal elderly people).
- ▶ Stalk thickening prompts evaluation for infiltrative/inflammatory disease (sarcoid, histiocytosis, IgG4, germinoma) and screening of anterior pituitary function.

Treatment

A. AVP deficiency (central DI) — desmopressin (DDAVP):

- ▶ **DDAVP**, a synthetic AVP analogue, acts **selectively on V2 receptors** to concentrate urine in a dose-dependent fashion; it is **more resistant to degradation** than AVP with a 3- to 4-fold longer **duration of action**.
- ▶ **Adult doses (route-dependent)**: 1–2 µg once or twice daily SC/IV; 10–20 µg twice or thrice daily intranasal spray; 100–400 µg twice or thrice daily orally (tablet/melt). Onset of antidiuresis is rapid — ~15 min after injection to ~60 min after oral dosing.
- ▶ **Main complication — hyponatremia**: mild dilutional fall (Na 131–134 mmol/L) in ~25% of patients with intact thirst; more severe (<130 mmol/L) in ~15%. **Desmopressin escape** — intentionally delaying a DDAVP dose for a few hours to permit a transient aquaresis — reduces this risk.
- ▶ Because DDAVP resists placental vasopressinase, it is the agent of choice for gestational AVP deficiency.

B. AVP resistance (nephrogenic DI) — difficult to treat:

- ▶ **Remove the cause** where possible (most commonly stop **lithium**); correct hypercalcemia/hypokalemia.
- ▶ Partial resistance may respond to **high-dose desmopressin**.
- ▶ Mainstay: **thiazide diuretic and/or amiloride + low-sodium diet + an NSAID** (e.g., indomethacin) — this paradoxically reduces polyuria, but the combination is **nephrotoxic** and demands **renal-function monitoring**.
- ▶ Persistent **lithium-induced** resistance is treated with **hydrochlorothiazide + amiloride**. *Caution*: thiazide-induced volume contraction **reduces lithium excretion and can precipitate lithium toxicity**.

C. Primary polydipsia: graded reduction of fluid intake; relieve mouth dryness with **ice chips / hard candy** to stimulate salivary flow. Drug therapy has been inconsistent; a recent study suggests **GLP-1 analogues** reduce fluid intake, urine output, and thirst. (Desmopressin is *avoided* — it precipitates water intoxication.)

D. Adipsic AVP deficiency and acute hypernatremia:

- ▶ Replace AVP with DDAVP, then **regulate intake by body weight/serum sodium** rather than thirst — monitor input/output as an inpatient to reach **eunatremia**, record the eunatremic weight, prescribe ~1.5–2 L **fluid/day**, weigh daily, and replace deficits when below eunatremic weight (Table 393-2).
- ▶ For established **hypertonic hypernatremia**, estimate the **free-water deficit** from body weight and serum sodium; replace with **hypotonic fluid** (0.45% saline or 5% dextrose) plus ongoing losses over **24–48 h**, ensuring sodium does **not fall too rapidly**; monitor urea/creatinine for rhabdomyolysis-related acute kidney injury.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Diagnostic algorithm of the polyuria–polydipsia syndrome.** Labels: *Confirm polyuria* ($>40\text{--}50\text{ mL/kg/24 h}$) $\rightarrow$ *Measure serum Na / plasma osmolality* $\rightarrow$ branches: Na $<135 \rightarrow$ **primary polydipsia**, Na $>147 \rightarrow$ **central or nephrogenic DI**, Na $136\text{--}146 \rightarrow$ **provocative testing**; under testing — **Water deprivation test** (urine osm >800 = mild primary polydipsia; $300\text{--}800 / <300 \rightarrow$ **Desmopressin test**: $>9\%$ = partial central DI, $<9\%$ = primary polydipsia, $>50\%$ = complete central DI, $<50\%$ = nephrogenic DI) and **Baseline copeptin** ($>21.4\text{ pmol/L}$ = nephrogenic DI; $\leq 21.4 \rightarrow$ **hypertonic saline** $\rightarrow$ **stimulated copeptin** $>4.9\text{ pmol/L}$ at Na ≥ 150 = **AVP deficiency**, <4.9 = primary polydipsia).
- ▶ **AVP–neurophysin II–copeptin prohormone schematic.** Labels: *signal peptide*, *AVP* (*nonapeptide*), *neurophysin II*, *copeptin*; arrow showing co-secretion of copeptin as the stable AVP surrogate.

Clinical / Diagnostic significance

- ▶ The three disorders are clinically indistinguishable on history alone — **biochemistry** (Na, plasma/urine osmolality) and a **provocative test** (**copeptin preferred**) are decisive; misclassification risks dangerous mistreatment (e.g., DDAVP in primary polydipsia $\rightarrow$ water intoxication).
- ▶ **Copeptin** has largely supplanted the inaccurate water-deprivation test and removes the need for an unreliable AVP assay.
- ▶ **MRI** is essential after diagnosing central DI to detect tumour/infiltrative/inflammatory causes and to screen for combined anterior pituitary failure.
- ▶ **Adipsic DI** carries the highest morbidity (rhabdomyolysis, thromboembolism, AKI) because the protective thirst response is lost — these patients need weight/sodium-guided fluid prescriptions.

High-yield exam pointers

- ▶ **DI = hypotonic polyuria** $>40\text{--}50\text{ mL/kg/day}$ ($>3\text{ L/day}$), urine osmolality $<800\text{ mosm/kg}$, glucosuria absent.
- ▶ New terms: **AVP deficiency** (central) and **AVP resistance** (nephrogenic).
- ▶ Na low $\rightarrow$ **primary polydipsia**; Na high $\rightarrow$ **true DI**.
- ▶ **Copeptin** $>21.4\text{ pmol/L}$ baseline = **nephrogenic DI**; stimulated $>4.9\text{ pmol/L}$ (Na ≥ 150) after hypertonic saline = **central DI** ($\approx 97\%$ accuracy).
- ▶ Water deprivation + desmopressin: $>50\%$ rise = **complete central**, $<50\%$ = **nephrogenic**, $<9\%$ = **primary polydipsia**.
- ▶ Posterior pituitary **bright spot absent** in central DI (not fully specific).

- ▶ **DDAVP** = selective **V2 agonist**; oral 100–400 µg, intranasal 10–20 µg, parenteral 1–2 µg; **hyponatremia** is the key adverse effect; use **desmopressin escape**.
- ▶ **Nephrogenic DI**: stop lithium; **thiazide ± amiloride + low-salt diet + NSAID** (nephrotoxic combo); thiazide can cause **lithium toxicity**.
- ▶ **Gestational DI** responds to **DDAVP** (resists placental vasopressinase).

Harrison 22e — Ch 393 “Disorders of the Neurohypophysis” (Christ-Crain & Sherlock), including Tables 393-1, 393-2 and the differential-diagnosis algorithm (Fig. 393-4). SIAD/hyponatremia management is cross-referenced to Ch 56 in the source but is outside this answer’s scope. No coverage gap for the asked topic — investigations and treatment of DI are fully supported by the provided chapter.

Maturity-Onset Diabetes of the Young (MODY)

Asked in: Paper IV Jul 2020 — RGUHS MD General Medicine

Definition / Introduction — MODY is a clinically and genetically heterogeneous group of **monogenic** (single-gene) forms of diabetes characterised by **autosomal-dominant inheritance**, **young age at onset** (typically diagnosed before 30 years, often ≤ 25 years), a **primary β -cell secretory defect** (impaired glucose-induced insulin secretion) rather than insulin resistance, **absence of obesity**, and **absence of islet autoimmunity and ketosis**. It belongs to the “other specific types” category of the ADA classification and accounts for roughly **1–2% of all diabetes**. It is the prototype of **precision (genotype-directed) diabetes medicine** — accurate molecular diagnosis changes treatment, prognosis and family screening.

Historical note & nomenclature

- ▶ The term was coined by **Fajans and Tattersall (1974)** after study of the multigenerational Michigan “**R-W pedigree**” (Fajans, from 1958) and Tattersall’s description of *mild familial diabetes with dominant inheritance*, distinguishing it from classic juvenile-onset (type 1) diabetes.
- ▶ “MODY” historically refers to autosomal-dominant β -cell diabetes; with **>30 causative genes** now known, the older numerical “**MODY-X**” nomenclature (MODY 1–14) is being replaced by **gene-based names** (e.g., *HNF1A*-MODY rather than MODY 3).
- ▶ *Monogenic diabetes* is the umbrella term encompassing both **MODY** and **neonatal diabetes** (onset generally <6 months), plus rarer **syndromic** forms.

When to suspect MODY — clinical clues

MODY is frequently **misclassified as type 1 or type 2 diabetes**; suspect it when atypical features are present.

- ▶ **Atypical for type 1 DM:** absence of pancreatic islet autoantibodies; persistent endogenous insulin production **beyond the honeymoon period**; **measurable C-peptide** (≥ 0.60 ng/mL [≥ 0.2 nmol/L]) in the presence of hyperglycaemia; low insulin requirement; **no ketoacidosis when insulin is withheld**.
- ▶ **Atypical for type 2 DM:** onset **<45 years**; **lack of significant obesity**; absence of acanthosis nigricans; normal triglycerides and/or normal-to-high HDL cholesterol.
- ▶ **Strong multigenerational family history** of diabetes (parent affected; 2–3 generations) with an autosomal-dominant pattern.
- ▶ The **Exeter MODY probability calculator** (uses age at diagnosis, sex, BMI, HbA1c, treatment, family history; valid for diagnosis <35 years) and **type 1 genetic risk scores (T1D-GRS)** help select patients for genetic testing.

Classification of the main MODY subtypes

The four classic genes — GCK, HNF1A, HNF4A, HNF1B — account for the great majority of cases (relative frequencies vary geographically: *HNF1A* predominates in many UK/European registries, while *GCK* predominates in others and in paediatric/incidental cohorts).

Gene (locus) — old name	Protein / defect	Approx. share*	Hallmark clinical features	Precision treatment
GCK (7p) — MODY 2	Glucokinase = β -cell “glucose sensor”; glucose-sensing defect	>70% (of suspected)	Mild, stable, non-progressive fasting hyperglycaemia (≈ 99 –144 mg/dL) present from birth; small OGTT rise (< 90 mg/dL); HbA1c usually $< 7.5\%$; essentially no micro-/macrovascular complications	None — diet only; oral agents/insulin not recommended (contraindicated) ; treat only in pregnancy if fetus unaffected
HNF1A (12q24.2) — MODY 3	Hepatocyte nuclear factor-1 α ; transcription factor $\rightarrow$ progressive β -cell dysfunction	20–30%	Progressive hyperglycaemia; glycosuria at low renal threshold (reduced SGLT2 expression); hepatic adenomas; increased	Low-dose sulfonylurea (markedly sensitive — can cause hypoglycaemia); insulin later as β -cells fail

Gene (locus) — old name	Protein / defect	Approx. share*	Hallmark clinical features	Precision treatment
			cardiovascular mortality	
HNF4A (20q12–13.1) — MODY 1	Hepatocyte nuclear factor-4 α ; transcription factor	~5%	Fetal macrosomia + transient neonatal hyperinsulinaemic hypoglycaemia; progressive hyperglycaemia; low HDL/apoA2	Low-dose sulfonylurea, insulin later
HNF1B (17q12) — MODY 5	Hepatocyte nuclear factor-1 β ; transcription factor	<2%	Renal cysts and diabetes (RCAD) syndrome; pancreatic hypoplasia + exocrine insufficiency; hypomagnesaemia, hyperuricaemia, genital-tract anomalies, abnormal LFTs; 50–60% de novo (17q12 deletions)	Insulin (sulfonylurea-unresponsive)

*Relative incidence among patients suspected to have MODY (Williams Table 37.3).

- **Rarer / disputed subtypes (<1% each):** *IPF1/PDX1* (MODY 4), *NEUROD1* (MODY 6), *INS*, *CEL* (MODY 8), *ABCC8*, *KCNJ11*, *APPL1*; refuted/disputed: *KLF11* (MODY 7), *PAX4* (MODY 9), *BLK* (MODY 11).

Pathophysiology in brief

- All classic MODY genes converge on **defective glucose-stimulated insulin secretion** by the pancreatic β -cell.
- **GCK** raises the glucose threshold for insulin release (a regulatory “reset”), giving lifelong **mild, stable** hyperglycaemia.
- **HNF1A**, **HNF4A**, **HNF1B** are interacting **transcription factors** controlling β -cell development and gene expression; haploinsufficiency causes **progressive** β -cell failure (hence the deteriorating course and eventual insulin need in *HNF1A/HNF4A*).
- *HNF1A* also drives renal **SGLT2** expression — its loss explains glycosuria at a low renal threshold, often **preceding** frank hyperglycaemia.

Diagnostic approach (biomarker-led pathway to genetic testing)

A stepwise strategy avoids unnecessary, costly sequencing:

- ▶ **Endogenous insulin secretion** — serum C-peptide or urinary C-peptide/creatinine ratio (UCPCR).
- ▶ If C-peptide ≥ 0.60 ng/mL (0.2 nmol/L) or UCPCR ≥ 0.2 nmol/mmol $\rightarrow$ measure islet autoantibodies (GAD-65 and IA-2).
- ▶ If autoantibody-negative $\rightarrow$ proceed to **molecular genetic testing** (targeted next-generation sequencing gene panel including GCK, HNF1A, HNF4A, HNF1B $\pm$ others).
- ▶ **GCK-MODY** has a distinctive, near-pathognomonic biochemical signature (mild stable fasting hyperglycaemia, tiny OGTT increment) and can often be recognised clinically before sequencing.
- ▶ Confirming the variant enables **cascade (predictive) genetic screening of first-degree relatives**.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Diagram 1 — Diagnostic algorithm for monogenic diabetes:** boxes labelled “Diabetes” $\rightarrow$ branch on autoantibodies +/- and C-peptide; left arm *autoantibody-positive / low C-peptide* $\rightarrow$ Type 1 DM; *high BMI, acanthosis nigricans, metabolic syndrome* $\rightarrow$ Type 2 DM; right arm *autoantibody-negative, C-peptide ≥ 0.2 nmol/L, family history* $\rightarrow$ MODY testing, splitting to **GCK** (mild fasting hyperglycaemia, HbA1c $< 8\%$, no microvascular complications), **HNF1A** (glycosuria, high HDL), **HNF4A** (low HDL, neonatal hypoglycaemia/macrosomia history), **HNF1B** (renal cysts, hypomagnesaemia, pancreatic/genital anomalies). Add a side box: *diagnosis < 6 months $\rightarrow$ test neonatal-diabetes genes *KCNJ11, ABCC8, INS.**
- ▶ **Diagram 2 — β -cell glucose-stimulated insulin secretion:** label GLUT2 (SLC2A2) glucose entry $\rightarrow$ glucokinase (GCK) $\rightarrow$ glycolysis/Krebs $\rightarrow$ $\uparrow$ ATP $\rightarrow$ closure of K-ATP channel (KCNJ11/ABCC8 subunits) $\rightarrow$ membrane depolarisation $\rightarrow$ opening of voltage-gated Ca^{2+} channel $\rightarrow$ Ca^{2+} influx $\rightarrow$ insulin granule exocytosis; nucleus labelled with transcription factors HNF1A, HNF4A, HNF1B, NEUROD1, PDX1.

Clinical / Diagnostic significance

- ▶ **Treatment is genotype-specific:** GCK-MODY needs **no pharmacotherapy** (and is harmed by it); HNF1A/HNF4A-MODY respond dramatically to **low-dose sulfonylureas** (often allowing patients on insulin to be switched off it); HNF1B-MODY requires **insulin**.
- ▶ **Avoids lifelong mislabelling** — many MODY patients are wrongly on insulin as “type 1,” or chased with intensifying type 2 regimens; a molecular diagnosis can de-escalate therapy.
- ▶ **Prognostic / surveillance value:** HNF1A carries excess **cardiovascular mortality** (warrants statin) and risk of **hepatic adenomas**; HNF1B mandates renal, electrolyte (magnesium), hepatic, urogenital and (in 17q12 deletions) neurodevelopmental surveillance — multidisciplinary care.

- ▶ **Pregnancy** is a special situation: in **GCK-MODY**, management depends on whether the fetus inherited the mutation — if the fetus is **unaffected**, maternal hyperglycaemia drives fetal hyperinsulinism and **macrosomia**, so **insulin** is given (often >1 IU/kg/day) with delivery considered at ~38 weeks; if the fetus is affected, no treatment is needed. *HNF1A/HNF4A* carriers are usually switched from sulfonylurea to **insulin** during pregnancy (glyburide crosses the placenta); *HNF4A* fetuses need monitoring for macrosomia and **neonatal hypoglycaemia**.
- ▶ **GCK-MODY** is a frequent cause of apparent “gestational diabetes” that fails to resolve postpartum (~2% of GDM).

High-yield exam pointers

- ▶ MODY = **autosomal-dominant, young-onset (<25–30 yr), non-obese, autoantibody-negative, ketosis-resistant, C-peptide-positive** diabetes; ~1–2% of all diabetes.
- ▶ **Four classic genes**: GCK, HNF1A, HNF4A, HNF1B — know each gene’s phenotype and treatment.
- ▶ **GCK (MODY 2)** = mild **stable** fasting hyperglycaemia from birth, **no complications, no treatment** (except pregnancy).
- ▶ **HNF1A (MODY 3)** = commonest *symptomatic* MODY in many populations; **glycosuria, sulfonylurea-sensitive**, hepatic adenomas, ↑CV risk.
- ▶ **HNF4A (MODY 1)** = **macrosomia + neonatal hypoglycaemia**, sulfonylurea-responsive.
- ▶ **HNF1B (MODY 5)** = **renal cysts and diabetes (RCAD)**, hypomagnesaemia, pancreatic/genital anomalies, **insulin-requiring**, often **de novo**.
- ▶ Diagnostic gateway: **C-peptide/UCPCR** → **islet autoantibodies** → **gene panel**; use the **Exeter MODY calculator** to triage.
- ▶ It is the **flagship example of precision medicine** in diabetes; molecular diagnosis enables **cascade family screening**.
- ▶ Do not confuse with **neonatal diabetes** (<6 months; *KCNJ11/ABCC8* K-ATP channel mutations → high-dose sulfonylureas; *INS* mutations → insulin) or **MIDD** (m.3243A>G, maternally inherited diabetes + deafness; avoid metformin).

Metabolic Syndrome

Asked in: Paper IV 17 Apr 2026 · Paper I Nov 2021 (2×) — RGUHS MD General Medicine

Definition / Introduction — The **metabolic syndrome** (*syndrome X*, *insulin-resistance syndrome*) is a constellation of inter-related metabolic abnormalities — **central (visceral) obesity**, **atherogenic dyslipidaemia** (high triglycerides, low HDL-cholesterol), **raised blood pressure** and **hyperglycaemia** — that together confer a markedly increased risk of **atherosclerotic cardiovascular disease (ASCVD)** and **type 2 diabetes mellitus**. The unifying pathophysiological substrate is **insulin resistance** driven by an expanded, dysfunctional visceral adipose mass. It is a clustering construct, not a single disease, and is diagnosed by meeting an agreed set of cut-point criteria.

Definitions and diagnostic criteria (evolution)

- The criteria have evolved since the first **WHO definition (1998)**, which required *demonstrable insulin resistance* (type 2 diabetes, impaired glucose tolerance/fasting glucose, or low insulin-mediated glucose uptake) as an obligatory anchor plus additional components.
- The **NCEP:ATP III (2001)** definition popularised a simple, non-glucose-clamp, “any 3 of 5” approach. The **IDF (2005)** definition made *central obesity (ethnicity-specific waist)* mandatory plus 2 others. The **2009 Harmonized joint statement** (IDF, AHA/NHLBI, World Heart Federation, International Atherosclerosis Society, International Association for the Study of Obesity) requires *any 3 of 5* components with **population/ethnicity-specific waist thresholds**.

Component	NCEP:ATP III 2001 (any 3 of 5)	Harmonized / IDF (any 3 of 5; ethnicity-specific waist)
Central obesity (waist)	>102 cm men, >88 cm women	Europid / sub-Saharan African / Eastern & Middle Eastern: ≥ 94 men, ≥ 80 women · South Asian, Chinese, ethnic South & Central American: ≥ 90 men, ≥ 80 women · Japanese: ≥ 85 men, ≥ 90 women
Triglycerides	≥ 150 mg/dL (or on Rx)	>150 mg/dL (or on specific Rx)
HDL cholesterol	<40 mg/dL (men), <50 mg/dL (women), or on Rx	<40 mg/dL (men), <50 mg/dL (women), or on Rx
Blood pressure	≥ 130 systolic or ≥ 85 diastolic (or on Rx)	>130 systolic or >85 diastolic, or prior Dx / specific Rx

Component	NCEP:ATP III 2001 (any 3 of 5)	Harmonized / IDF (any 3 of 5; ethnicity-specific waist)
Fasting glucose	≥100 mg/dL (or on Rx / known T2DM)	≥100 mg/dL (or drug Rx of raised glucose)

- ▶ The AHA/NHLBI (2005) statement is essentially identical (3 of 5), applying Asian waist cut-points of ≥35 in. (men) / ≥32 in. (women) versus ≥40 in. / ≥35 in. for other groups — important because *normal-weight individuals from India, South-East Asia and Central America may be insulin-resistant* with metabolic syndrome at lower waist values.

Epidemiology and risk factors

- ▶ **Prevalence** ~33–35% of US adults (NCEP:ATP III); NHANES 1999–2018 (n = 28,049) showed 33.4%, rising with age from 19.5% (20–39 y) to 48.6% (≥60 y); nearly 50% of those >60 y are affected, with women predominating beyond 60.
- ▶ **Overweight/obesity** (especially central adiposity) is the principal driver; the global obesity epidemic underlies its rising recognition, including in children (~12–30% of obese/overweight children show features).
- ▶ **Sedentary lifestyle / low cardiorespiratory fitness** — >4 h/day of screen time carries a *twofold* increased risk versus <1 h/day.
- ▶ **Genetics** — no single gene; polygenic, with heritability of individual metabolic traits exceeding 50%.
- ▶ **Diabetes / impaired glucose tolerance** — ~75% of patients with type 2 DM or IGT have metabolic syndrome.
- ▶ **Lipodystrophy** — both genetic (*Berardinelli-Seip congenital*, *Dunnigan familial partial*) and acquired (HIV / antiretroviral-related) forms cause severe insulin resistance and the syndrome.

Etiology and pathophysiology

- ▶ **Insulin resistance** is the central, unifying hypothesis. It is heralded by postprandial then fasting **hyperinsulinaemia**, culminating in hyperglycaemia once β-cell compensation fails.
- ▶ **Free fatty acid (FFA) excess** — an expanded adipose mass releases abundant albumin-bound FFAs (lipolysis is the most insulin-sensitive pathway, so resistance amplifies lipolysis). FFAs flood the liver → ↑gluconeogenesis, ↑triglyceride and **VLDL (apoB)** production; in muscle they impair insulin-mediated glucose uptake and cause intramyocellular triglyceride accumulation.
- ▶ **Atherogenic dyslipidaemia** — ↑triglyceride-rich VLDL with elevated **apoC-III** (inhibits lipoprotein lipase, impairs remnant clearance); ↓HDL-cholesterol (cholesteryl-ester depletion via CETP making HDL small, dense, rapidly cleared); predominance of **small dense LDL** (when fasting TG >~180 mg/dL).

- ▶ **Hypertension** — in insulin resistance the vasodilator (nitric-oxide) action of insulin is lost while renal **sodium reabsorption** and **sympathetic** activation are preserved; ↑adipose **angiotensinogen** → **angiotensin II**; perivascular adipose ROS (NADPH oxidase) and **hyperuricaemia** (impaired NO synthase, RAAS stimulation) contribute.
- ▶ **Adipokines and inflammation** — adipose-tissue macrophages oversecrete **TNF-α, IL-6, IL-1, IL-18, resistin**, raising **CRP, fibrinogen and PAI-1** (a *pro-thrombotic state*); **adiponectin** (anti-inflammatory, insulin-sensitising; activates AMP-kinase) is **reduced**. Leptin resistance, mitochondrial/oxidative-stress dysfunction and an altered **gut microbiome** (↑Firmicutes/Bacteroidetes ratio) are additional contributors.

Clinical features and associated conditions

- ▶ Usually **asymptomatic**; examination shows **increased waist circumference and raised blood pressure**; less often **acanthosis nigricans** or lipoatrophy (markers of severe insulin resistance).
- ▶ **Cardiovascular disease** — patients are *twice as likely to die of CVD* and have a *threefold* higher risk of acute MI or stroke; relative risk for new-onset CVD $\approx 1.5\text{--}3\times$. Metabolic syndrome is present in up to **60%** of CHD patients >75 y and ~35% with premature CAD (≤ 45 y). In INTERHEART (26,903 subjects, 52 countries) diabetes (OR 2.72) and hypertension (OR 2.60) were the strongest components.
- ▶ **Type 2 diabetes** — risk increased **three- to fivefold**; in the Framingham Offspring Study the population-attributable risk was **62% (men)** and **47% (women)**, largely explained by rising fasting glucose.
- ▶ **Other associations** — **metabolic-(dysfunction)-associated fatty liver disease (MAFLD/MASLD)** and its progressive form **MASH/NASH** (affects ~10% of non-obese but up to **65%** of metabolic-syndrome patients; a route to cirrhosis and hepatocellular carcinoma); **polycystic ovary syndrome** (insulin resistance in 50–80%); **obstructive sleep apnoea**; hyperuricaemia/gout; microalbuminuria; raised homocysteine, apoB and viscosity.

Diagnosis and investigations

- ▶ Apply **Table criteria** at bedside + laboratory: measure **waist circumference and blood pressure**; **fasting lipid profile and fasting plasma glucose** are essential.
- ▶ Individualise additional tests: **apoB, hsCRP, fibrinogen, uric acid, urine albumin/creatinine ratio, liver function**; a **sleep study** if OSA is suspected; **testosterone, LH, FSH** if PCOS is suspected; assess MAFLD by the **FIB-4 fibrosis score or elastography**.
- ▶ Family history guides cardiovascular and diabetes risk; a **coronary artery calcium score** and the **10-year ASCVD risk estimator** refine primary-prevention decisions.

Management (target each component; weight loss is primary)

- **Lifestyle is first-line.** Weight reduction of **at least 5% (ideally $\geq 10\%$)** improves insulin sensitivity and most components. Caloric restriction is the key element (~ 3500 kcal ≈ 1 lb fat; a ~ 500 -kcal/day deficit ≈ 1 lb/week); diet adherence matters more than macronutrient type, favouring fruit, vegetables, whole grains, lean poultry and fish. **Physical activity** 30 min/day minimum (60–90 min for weight loss) plus behaviour modification for maintenance.

Component	Preferred therapy (after lifestyle)
Obesity	Anti-obesity drugs — semaglutide 2.4 mg ($\sim 14.9\%$ loss/68 wk), tirzepatide (GIP/GLP-1; ~ 15 – 20.9%), liraglutide 3.0 mg ($\sim 6\%$), phentermine/topiramate ($\sim 8\%$ in half), naltrexone/bupropion ($\geq 10\%$ in $\sim 20\%$), orlistat (blocks $\sim 30\%$ fat absorption). Bariatric/metabolic surgery if BMI >40 (or >35 with comorbidity; ≥ 30 with T2DM)
LDL-cholesterol	Statins first-line (lower LDL 15–60%); add ezetimibe (15–20%), bempedoic acid (combo up to 35%); PCSK9 inhibitors (45–60%) if FH or insufficient response
Triglycerides	Fibrates (fenofibrate/gemfibrozil, $\downarrow 30$ – 45%); high-dose EPA omega-3 (REDUCE-IT, JELIS); treat TG >500 mg/dL to prevent pancreatitis
Blood pressure	ACE inhibitor or ARB first choice; add diuretic / CCB / β -blocker / finerenone
Impaired fasting glucose	Lifestyle $\pm$ metformin to prevent progression to T2DM
Insulin resistance	Metformin and pioglitazone (TZD) — a meta-analysis (9 trials, 12,026 participants) showed pioglitazone reduced ASCVD events; GLP-1 RAs also improve insulin sensitivity

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- **Pathophysiology flow diagram (central diagram):** Centre box = *Expanded visceral adipose tissue / Insulin resistance*. Arrows to: **Liver** ($\uparrow$ FFA $\rightarrow$ $\uparrow$ glucose, $\uparrow$ VLDL-TG, $\uparrow$ apoB, $\uparrow$ CRP, $\uparrow$ fibrinogen); **Muscle** ($\downarrow$ insulin-mediated glucose uptake, $\uparrow$ intramuscular triglyceride); **Pancreas** (hyperinsulinaemia $\rightarrow$ β -cell failure $\rightarrow$ hyperglycaemia); **Blood vessel** ($\uparrow$ Na reabsorption, $\uparrow$ SNS, $\uparrow$ angiotensin II $\rightarrow$ hypertension); **Adipokines** ($\uparrow$ TNF- α , $\uparrow$ IL-6, $\uparrow$ PAI-1, $\downarrow$ adiponectin). Output boxes: *small dense LDL, low HDL, pro-thrombotic state, ASCVD, type 2 diabetes*. Labels to include: FFA, VLDL, apoC-III, PAI-1, adiponectin, IL-6, TNF- α , CRP, SNS.

Component	Preferred therapy (after lifestyle)
▶ The “five-pointed star” of diagnostic criteria: a central pentagon labelled <i>Metabolic syndrome</i> (<i>need</i> ≥ 3) with the five arms labelled Central obesity (waist), ↑Triglycerides ≥ 150, ↓HDL (<40 M/<50 F), BP $\geq 130/85$, Fasting glucose ≥ 100.	

Clinical / Diagnostic significance

- ▶ Identifies, beyond LDL-cholesterol, a **high cardiometabolic-risk phenotype** warranting aggressive global risk-factor modification.
- ▶ Fasting glucose within the cluster is the **best predictor of incident type 2 diabetes**; the syndrome flags the need for diabetes screening and prevention.
- ▶ Mandates screening for MAFLD/MASH, OSA and PCOS, each of which both reflects and aggravates insulin resistance.
- ▶ Treatment is **component-directed**: weight loss is the highest-yield single intervention because it improves all five components simultaneously.

High-yield exam pointers

- ▶ Synonyms: **syndrome X** / **insulin-resistance syndrome**; core defect = **insulin resistance** + **visceral adiposity**.
- ▶ **Diagnosis** = any 3 of 5 (NCEP:ATP III / Harmonized); **IDF makes central obesity mandatory**; waist cut-points are **ethnicity-specific** (lower for South Asians: ≥ 90 cm men / ≥ 80 cm women).
- ▶ Five components: **waist**, **TG** ≥ 150 , **HDL** <40 (M)/ <50 (F), **BP** $\geq 130/85$, **FPG** ≥ 100 mg/dL.
- ▶ Confers $\sim 2\times$ CVD mortality, $\sim 3\times$ MI/stroke, $3\text{--}5\times$ type 2 diabetes.
- ▶ Key biochemical signature: **high TG**, **low HDL**, **small dense LDL**, **↑apoB/apoC-III**, **↑CRP/PAI-1/fibrinogen**, **↓adiponectin**.
- ▶ **Acanthosis nigricans** = clinical clue to severe insulin resistance.
- ▶ First-line management = $\geq 5\text{--}10\%$ **weight loss**; antihypertensive of choice = **ACEi/ARB**; insulin sensitisers = **metformin**, **pioglitazone**.
- ▶ Strongly associated with MAFLD/MASH, PCOS, OSA, hyperuricaemia.

Coverage note: Harrison Ch 420 provides full, dedicated coverage of this topic. The detailed WHO 1998 and IDF-2005 obligatory criteria (e.g., microalbuminuria) are summarised from universally accepted standard internal medicine, as Harrison and Williams give only the NCEP:ATP III, Harmonized and AHA/NHLBI cut-point tables verbatim.

Myxedema coma

Asked in: Paper IV May 2022 — RGUHS MD General Medicine

Definition / Introduction — Myxedema coma is the extreme, decompensated, life-threatening end-stage of severe, long-standing **hypothyroidism**, listed in Harrison’s among the rare neurologic complications of thyroid hormone deficiency (alongside reversible cerebellar ataxia, dementia, and psychosis). It is a misnomer because frank coma is often absent; the syndrome is better understood as **decompensated hypothyroidism** characterised by a depressed sensorium, **hypothermia**, and progressive multiorgan slowing, usually unmasked by a precipitating stress in an elderly, undiagnosed or non-adherent hypothyroid patient. It is an **endocrine emergency** with a high mortality, demanding empirical thyroid hormone plus glucocorticoid and intensive supportive care before biochemical confirmation returns.

Predisposing background and precipitating factors

- ▶ **Underlying substrate:** chronic untreated or under-treated hypothyroidism — most commonly **autoimmune (Hashimoto’s) hypothyroidism** (TPO and Tg antibodies positive in >95%), atrophic thyroiditis, post-radioiodine or post-thyroidectomy states, and drug-induced disease (amiodarone, lithium). Onset of hypothyroidism is insidious, so many patients present already decompensated.
- ▶ **Typical patient:** elderly woman in the **winter months**; the mean age at diagnosis of autoimmune hypothyroidism is ~60 years, and prevalence rises with age.
- ▶ **Common precipitants** (these tip compensated hypothyroidism into coma):
 - **Infection / sepsis** — pneumonia, urinary sepsis (most frequent trigger).
 - **Cold exposure** — exploits the already-impaired thermogenesis.
 - **Cardiovascular events** — myocardial infarction, congestive cardiac failure.
 - **Cerebrovascular accident, trauma, surgery, GI bleeding.**

- **CNS-depressant drugs** — sedatives, opioids, anaesthetics, antipsychotics.
- **Abrupt cessation of levothyroxine** (patients feel no immediate difference after missing doses, predisposing to self-discontinuation, per Harrison).
- ▶ **Coexisting adrenal insufficiency** must always be anticipated — autoimmune hypothyroidism associates with **Addison's disease (Schmidt's syndrome)** and **autoimmune polyendocrine syndrome type 2** (Addison's in 40–50%).

Pathophysiology and clinical features

The picture is one of “hypo-everything” — generalised slowing of metabolism with reduced thermogenesis, blunted respiratory drive, and reduced cardiac output, plus tissue **myxedema** (glycosaminoglycan deposition that traps water → non-pitting swelling).

- ▶ **Decreased mental status:** lethargy, obtundation, stupor, frank coma; **seizures** may occur. Memory and concentration are impaired; psychosis (“myxedema madness”) may precede coma.
- ▶ **Hypothermia:** core temperature may fall below 34°C; its degree correlates with prognosis, and a “normal” temperature in a hypothyroid septic patient is a red flag.
- ▶ **Hypoventilation / respiratory failure:** from **diminished ventilatory drive**, impaired respiratory muscle function, pleural effusion, and obstructive sleep apnoea (all named in the chapter) → **CO₂ retention (hypercapnia), hypoxia, and CO₂ narcosis** that deepen the coma.
- ▶ **Cardiovascular:** **bradycardia**, reduced myocardial contractility, reduced stroke volume and cardiac output, increased peripheral resistance with **diastolic hypertension**, and blood diverted from skin → **cool extremities**. **Pericardial effusions occur in up to 30%** (rarely tamponade); cardiomyopathy is rare. Late hypotension and shock supervene.
- ▶ **Renal / metabolic:** **hyponatremia** (impaired free-water excretion / SIADH-like), **hypoglycemia** (especially if concurrent adrenal failure), and free-water retention.
- ▶ **General myxedematous facies:** puffy face with **edematous eyelids**, macroglossia, non-pitting **pretibial edema**, dry coarse skin with carotene-yellow tinge, diffuse alopecia with loss of the outer third of eyebrows, hoarse voice, and **delayed relaxation of tendon reflexes** (hung-up reflexes).
- ▶ **GI:** constipation progressing to ileus / megacolon; ascites from serous cavity effusions.

Laboratory and diagnostic evaluation

- ▶ **Thyroid function:** in primary hypothyroidism, **TSH is markedly elevated** with a **low free T₄**; a normal TSH essentially excludes primary disease. In **secondary (central) hypothyroidism**, TSH may be low, normal, or only slightly raised, so a **low free T₄** is the confirmatory finding — do not be falsely reassured by a non-elevated TSH.
- ▶ **Supportive abnormalities** (per chapter): elevated creatine phosphokinase (CPK), raised cholesterol and triglycerides, and normocytic or macrocytic anemia.

- **Other:** hyponatremia, hypoglycemia, arterial blood gas showing hypoxia + hypercapnia + respiratory acidosis; ECG — sinus bradycardia, low-voltage complexes, prolonged QT, flattened/inverted T waves.
- **Always send a paired cortisol** (and ACTH) before steroids to detect concurrent adrenal insufficiency, and a septic screen (cultures, CXR) for the precipitant.
- **Diagnosis is clinical** — treatment must not await laboratory confirmation.

Management

Myxedema coma is treated in the ICU; therapy is empirical and combines thyroid hormone replacement, stress-dose glucocorticoid, and aggressive supportive care directed at the precipitant.

Component	Action / regimen	Rationale & cautions
Thyroid hormone (T4)	Levothyroxine IV loading 200–400 µg, then maintenance ~1.6 µg/kg/day reduced to ~75% when given IV	Rapidly restores a hormone pool; lower loading dose in the elderly / cardiac disease to avoid precipitating ischaemia or arrhythmia
+/- Liothyronine (T3)	May add IV T3 5–20 µg bolus then 2.5–10 µg every 8 h until stable	Peripheral T4→T3 conversion is impaired in critical illness; T3 acts faster but risks ischaemia — use lower doses in cardiac patients
Glucocorticoid	IV hydrocortisone 50–100 mg every 8 h	Covers coexisting adrenal insufficiency (Schmidt's syndrome / APS-2); give <i>before or with</i> thyroid hormone, as T4 can precipitate adrenal crisis
Ventilation	Airway protection, mechanical ventilation for hypercapnic/hypoxic respiratory failure	Hypoventilation + CO ₂ narcosis are leading causes of death
Rewarming	Passive external rewarming (blankets); avoid vigorous active rewarming	Active surface rewarming causes peripheral vasodilatation → hypotension and circulatory collapse
Hyponatremia	Fluid restriction; hypertonic saline only if severe/symptomatic	Correct slowly to avoid osmotic demyelination
Hypoglycemia	IV dextrose	Common, especially with adrenal failure
Hypotension	Cautious IV fluids; vasopressors often poorly effective until thyroid hormone given	Pressors of limited benefit in hypothyroid myocardium

Component	Action / regimen	Rationale & cautions
Precipitant	Empirical broad-spectrum antibiotics, treat MI/CHF, withdraw sedatives	Infection is the commonest trigger and is often occult (no fever)

- ▶ **General measures:** continuous cardiac monitoring, avoid all CNS depressants, slow careful warming, monitor electrolytes and glucose, and treat the precipitating illness aggressively.
- ▶ **Monitoring response:** clinical (mental status, temperature, respiration, heart rate) and serial TSH/free T4.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Pathophysiology spider diagram of myxedema coma** — central box “Severe long-standing hypothyroidism + Precipitant (infection / cold / sedatives / MI / stopping LT4)” with radiating labelled arms: Hypothermia, Hypoventilation → hypercapnia / hypoxia (CO₂ narcosis), Bradycardia / low cardiac output / pericardial effusion, Hyponatremia, Hypoglycemia, Altered sensorium → coma / seizures, Non-pitting myxedema / puffy facies.
- ▶ **Management flow box** — vertical labels: ICU + airway/ventilation → send cortisol → IV hydrocortisone 50–100 mg q8h → IV levothyroxine load 200–400 µg then 1.6 µg/kg/d → passive rewarming → correct Na⁺ / glucose → empirical antibiotics → treat precipitant.

Clinical / Diagnostic significance

- ▶ Suspect myxedema coma in any **elderly patient with unexplained hypothermia, hyponatremia and depressed consciousness**, especially with a thyroidectomy scar, myxedematous facies, or hung-up reflexes.
- ▶ It is a **clinical diagnosis and a medical emergency** — empirical thyroid hormone + glucocorticoid must begin before TSH/T4 return; delay increases mortality.
- ▶ **Never give thyroid hormone alone** when adrenal reserve is uncertain — it can accelerate cortisol clearance and trigger an Addisonian crisis; hence hydrocortisone first.
- ▶ **Mortality remains high (~20–40%)**; outcome correlates with depth of hypothermia, hypotension, and the severity of the precipitating illness — early recognition is the main determinant of survival.
- ▶ Distinguish from non-thyroidal illness (“sick euthyroid”), sedative overdose, hypothermia of other cause, and CO₂ narcosis from primary lung disease.

High-yield exam pointers

- ▶ Triad to write first: **hypothermia + altered sensorium + precipitating stress** in a known/occult hypothyroid patient.

- ▶ Commonest precipitant = infection (pneumonia/UTI); commonest season = winter; commonest patient = elderly woman.
- ▶ TSH high + free T4 low = primary; free T4 low with non-elevated TSH = central — do not miss it.
- ▶ Classic biochemistry: hyponatremia, hypoglycemia, raised CPK, hypercapnia/hypoxia on ABG; ECG bradycardia + low voltage + prolonged QT.
- ▶ Pericardial effusion in up to 30% of hypothyroid patients (chapter figure).
- ▶ Hydrocortisone before/with levothyroxine — anticipate Schmidt's syndrome (hypothyroidism + Addison's).
- ▶ Passive (not active) rewarming — active rewarming → vasodilatation and shock.
- ▶ High mortality — treat empirically in the ICU; do not wait for thyroid assays.

SOURCE & COVERAGE

Harrison's Principles of Internal Medicine, 22e — Ch 395 “Hypothyroidism” (clinical manifestations Table 395-3; cardiovascular and respiratory features; laboratory evaluation; LT4 dosing; autoimmune/Schmidt's and APS-2 associations; myxedema coma listed among rare neurologic complications).

Coverage note: The provided ch395 text grounds the definition, predisposing causes, clinical features, cardiovascular/respiratory/renal derangements, and laboratory profile, but the file is **truncated and does not contain Harrison's dedicated myxedema-coma management paragraph** (it explicitly names myxedema coma only as a rare neurologic complication, line 259). The specific emergency **management details** — IV levothyroxine loading dose 200–400 µg then ~1.6 µg/kg/d, optional liothyronine 5–20 µg, hydrocortisone 50–100 mg q8h, passive rewarming, ventilatory support, and the ~20–40% mortality figure — are therefore drawn from **universally accepted standard internal medicine** (Harrison's myxedema-coma section / CMDT, flagged here per spec cmdt: true) rather than verbatim from the supplied chapter text. All such figures are standard and accurate; the candidate should treat the management table as textbook-standard rather than quoted from the provided excerpt.

Newer Hypoglycemic agents for management of Type II Diabetes Mellitus

Asked in: Paper IV 17 Apr 2026 — RGUHS MD General Medicine

Definition / Introduction — “Newer” glucose-lowering agents are the classes that have entered type 2 diabetes (T2DM) management after the traditional triad of **metformin**, **sulfonylureas** and **thiazolidinediones** (TZDs), and which target previously untapped pathophysiologic pathways — the

incretin axis and renal glucose handling. The four key groups are the DPP-4 inhibitors, the GLP-1 receptor agonists (GLP-1RAs), the dual GIP/GLP-1 receptor agonist (tirzepatide) and the SGLT-2 inhibitors. Their importance lies less in raw glucose lowering (modest HbA1c reduction of ~0.5–1%) than in their proven **cardiovascular, heart-failure and renal protection**, weight loss, and freedom from hypoglycaemia — which have moved them from “add-on” to **organ-protective first-line agents** in T2DM with comorbidity.

Classification of glucose-lowering agents (mechanistic)

Class	Site/Mechanism	Examples
Biguanide (context)	↓ Hepatic glucose output, ↑ insulin sensitivity	Metformin
Insulin secretagogues (older)	Close ATP-sensitive K ⁺ channel on β-cell	Sulfonylureas; glinides (repaglinide, nateglinide)
TZD (older)	PPAR-γ agonist → ↓ insulin resistance	Pioglitazone
DPP-4 inhibitors (<i>newer</i>)	Block GLP-1/GIP degradation (incretin <i>enhancers</i>)	Sitagliptin, vildagliptin, saxagliptin, linagliptin, alogliptin
GLP-1RAs (<i>newer</i>)	Incretin-mimetic; ↑ glucose-dependent insulin, ↓ glucagon, slows gastric emptying, satiety	Liraglutide, dulaglutide, semaglutide, lixisenatide, exenatide
GIP/GLP-1 dual agonist (<i>newest</i>)	Co-agonism at GIP + GLP-1 receptors	Tirzepatide
SGLT-2 inhibitors (<i>newer</i>)	Block proximal-tubule glucose reabsorption → glycosuria (insulin-independent)	Empagliflozin, dapagliflozin, canagliflozin, ertugliflozin, bexagliflozin
Amylin analogue	Slows gastric emptying, ↓ glucagon	Pramlintide (injectable, with insulin)

Incretin-based therapies: DPP-4 inhibitors, GLP-1RAs and tirzepatide

- **The incretin effect:** oral glucose evokes a larger insulin response than IV glucose because intestinal L-cell GLP-1 (and K-cell GIP) amplify *glucose-dependent* insulin secretion, suppress glucagon, slow gastric emptying and increase satiety. Native GLP-1 is degraded within 1–2 minutes by dipeptidyl peptidase-4 (DPP-4).
- **DPP-4 inhibitors** (incretin *enhancers*) block this enzyme, roughly doubling endogenous GLP-1/GIP. They lower HbA1c by 0.5–0.8%, act mainly on fasting glucose, are **weight-neutral**, oral, and do **not** cause hypoglycaemia alone or with metformin. They are very well tolerated; rare adverse effects include **pancreatitis, severe arthralgia, angioedema and Stevens-Johnson syndrome**. They must **not** be combined with a GLP-1RA (redundant mechanism).

- ▶ **GLP-1RAs** are DPP-4-resistant peptide agonists giving *pharmacologic* GLP-1 levels — far greater incretin action than DPP-4 inhibitors. They produce **HbA1c ↓ 0.5–1.5%**, substantial **weight loss**, and **cardiovascular + renoprotective** benefit. Long-acting once-weekly agents (dulaglutide, extended-release exenatide, semaglutide) are preferred over short-acting twice-daily exenatide/lixisenatide. **Oral semaglutide** (co-formulated with the absorption enhancer **SNAC**) is the first oral GLP-1RA. Liraglutide 3 mg and semaglutide 2.4 mg are separately licensed for **obesity**.
- ▶ **Tirzepatide** — a once-weekly **dual GIP/GLP-1 receptor agonist** — is the most potent agent yet: in head-to-head trial vs semaglutide 1 mg, HbA1c fell **2.3%** (from 8.3% baseline) with **>10% weight loss in 57%** of patients. CMDT quotes HbA1c reductions of **1.9–2.6%** and weight loss of **6–13 kg**.

Agent	Route / frequency	Typical dose (titrated)	HbA1c ↓
Sitagliptin	Oral OD	100 mg (50 if eGFR 30–50; 25 if <30)	0.5–0.8%
Linagliptin	Oral OD	5 mg — <i>no renal adjustment</i> (biliary excretion)	0.5–0.8%
Alogliptin	Oral OD	25 mg (12.5 if eGFR 30–60; 6.25 if <30)	0.5–0.8%
Liraglutide	SC once daily	0.6 → 1.2 → 1.8 mg	0.6–1.5%
Dulaglutide	SC once weekly	0.75 → 1.5 → 4.5 mg	~1.5–1.8%
Semaglutide	SC once weekly	0.25 → 0.5 → 1 → 2 mg	1.5–2.1%
Oral semaglutide	Oral OD, fasting	3 → 7 → 14 mg	—
Tirzepatide	SC once weekly	2.5 → 5 → up to 15 mg	1.9–2.6%

SGLT-2 inhibitors

- ▶ **Mechanism:** SGLT-2 in the proximal convoluted tubule mediates ~90% of filtered glucose reabsorption. Inhibition **lowers the renal threshold for glucose**, producing glycosuria and an **insulin-independent** fall in plasma glucose (so efficacy is *eGFR-dependent* — weaker as CKD advances). Associated **natriuresis** gives a mild diuretic effect and a **3–6 mmHg fall in systolic BP**; caloric loss yields **2–5 kg weight loss**.
- ▶ **Efficacy:** HbA1c ↓ 0.5–1.0%; no intrinsic hypoglycaemia.
- ▶ **Cardiorenal benefit** is the defining feature: reduced **heart-failure hospitalisation** (most consistent effect), reduced MACE/CV mortality in established ASCVD, and **slowed progression of diabetic kidney disease**. Per KDIGO, may be initiated for renoprotection down to **eGFR ~20**

mL/min/1.73 m² and continued until dialysis, even though the *glucose-lowering* effect is lost below eGFR 45.

- **Adverse effects:** genital mycotic infections and UTIs (~8–9%); euglycemic DKA (insulin-deficient states, fasting, surgery, acute illness); volume depletion / transient creatinine rise; necrotizing fasciitis of the perineum (Fournier gangrene); canagliflozin specifically — ↑ amputations (CANVAS, HR ~1.97), ↓ bone mineral density and ↑ fractures; small (3–8%) rise in LDL. Withhold 3 days before major surgery and during acute illness.

Agent	Glycaemic dose	eGFR caution (glycaemic)
Empagliflozin	10 mg OD (max 25)	Avoid <30
Dapagliflozin	10 mg OD (5 mg if liver failure)	Avoid <45 (renoprotection to eGFR 25)
Canagliflozin	100 mg OD (up to 300)	100 mg if eGFR 30–60; avoid <30
Ertugliflozin	5 → 15 mg OD	Avoid <45

Cardiorenal outcome trials (high-yield)

Trial	Drug	Key result
EMPA-REG OUTCOME	Empagliflozin	↓ all-cause mortality 32%, CV death 38%, HF hospitalisation 35%
CANVAS	Canagliflozin	↓ MACE & HF; ↑ amputation (HR 1.97), ↑ fracture
DECLARE-TIMI 58	Dapagliflozin	↓ CV death / HF hospitalisation (incl. primary-prevention cohort)
CREDENCE	Canagliflozin	Renal-outcomes trial — ↓ progression of diabetic nephropathy
LEADER	Liraglutide	↓ MACE 13%, CV death 22%, all-cause mortality 15%, albuminuria 26%
SUSTAIN-6	Semaglutide	↓ MACE 26%; ↓ renal events; retinopathy signal ; no mortality benefit
REWIND	Dulaglutide	↓ MACE and composite microvascular (retinopathy + nephropathy)
SAVOR-TIMI 53 / EXAMINE	Saxagliptin / Alogliptin	↑ heart-failure hospitalisation (DPP-4 class caution)

Trial	Drug	Key result
TECOS / CAROLINA	Sitagliptin / Linagliptin	CV-neutral (CAROLINA: neutral vs glimepiride)

Choice of agent — ADA/EASD-style algorithm (Harrison Fig 416-3)

- ▶ **Metformin + lifestyle** remains the foundation when there is no cardiorenal disease (efficacious, cheap, weight-favourable).
- ▶ **Comorbidity now drives selection, independent of HbA1c:**
 - ASCVD or high CV risk → GLP-1RA or SGLT-2 inhibitor with proven benefit.
 - Heart failure (HFrEF or HFpEF) → SGLT-2 inhibitor.
 - Chronic kidney disease / albuminuria → SGLT-2 inhibitor (GLP-1RA if SGLT-2i not tolerated).
 - Weight loss a priority → GLP-1RA or tirzepatide (greatest effect).
- ▶ These agents may be **combined with metformin or each other** (e.g. metformin + SGLT-2i + GLP-1RA) for additive effect — but GLP-1RA + DPP-4 inhibitor is irrational. Reassess HbA1c every 3 months; add basal insulin if targets unmet.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Diagram 1 — Sites of action of glucose-lowering agents** (label: *intestine/L-cell* → GLP-1, *DPP-4 inhibitor*, *GLP-1RA*, *pancreatic β -cell (insulin) & α -cell (glucagon)*, *liver — hepatic glucose output / metformin*, *muscle & fat — insulin sensitivity / TZD*, *kidney proximal tubule — SGLT-2 inhibitor* → glycosuria).
- ▶ **Diagram 2 — Comorbidity-driven treatment algorithm** (boxes: *T2DM + metformin/lifestyle* → branch to *ASCVD/high risk* → GLP-1RA or SGLT-2i, *Heart failure* → SGLT-2i, *CKD* → SGLT-2i, *Weight loss* → GLP-1RA / tirzepatide).

Clinical / Diagnostic significance

- ▶ **Cardiorenal first:** in T2DM with ASCVD, HF or CKD, start an **SGLT-2 inhibitor and/or GLP-1RA early** regardless of baseline HbA1c — they reduce hard outcomes (CV death, HF hospitalisation, ESKD).
- ▶ **Hypoglycaemia avoidance:** incretin agents and SGLT-2i do not cause hypoglycaemia alone; reduce the dose of a co-prescribed **sulfonylurea or insulin** to prevent it.
- ▶ **Euglycemic DKA:** a “normal glucose” does **not** exclude DKA in a patient on an SGLT-2 inhibitor — check ketones in any unwell SGLT-2i user; hold the drug during fasting, acute illness and perioperatively.
- ▶ **GLP-1RA / tirzepatide safety:** contraindicated with **personal/family history of medullary thyroid carcinoma or MEN-2** (rodent C-cell tumours); avoid in prior **pancreatitis**; warn re

nausea/vomiting and stop if persistent abdominal pain; SUSTAIN-6 flagged worsening **retinopathy** with rapid glucose lowering.

- ▶ **Renal dosing:** linagliptin needs no adjustment (biliary); liraglutide/semaglutide/dulaglutide are safe in renal failure; exenatide is contraindicated below eGFR 30.

High-yield exam pointers

- ▶ “Newer” = DPP-4 inhibitors, GLP-1RAs, GIP/GLP-1 dual agonist (tirzepatide), SGLT-2 inhibitors.
- ▶ DPP-4i = incretin enhancer (weak, weight-neutral, oral); GLP-1RA = incretin mimetic (strong, weight loss, CV/renal benefit).
- ▶ EMPA-REG = first CVOT to show CV/HF benefit of an SGLT-2 inhibitor; LEADER = first for a GLP-1RA.
- ▶ SGLT-2i triad of harm: **genital mycotic infection, euglycemic DKA, Fournier gangrene**; canagliflozin → **amputation + fracture**.
- ▶ **Tirzepatide** (dual GIP/GLP-1) gives the greatest HbA1c ($\approx 2\text{--}2.6\%$) and weight reduction.
- ▶ **Linagliptin** = the DPP-4 inhibitor needing **no renal dose adjustment**.
- ▶ Never combine GLP-1RA with a DPP-4 inhibitor.
- ▶ Metformin: max ~ 2000 mg/day; reduce at eGFR 30–45; **stop if eGFR < 30** (lactic-acidosis risk).
- ▶ Comorbidity, not HbA1c alone, now selects the second agent.

SOURCE & COVERAGE

- ▶ **Harrison’s Principles of Internal Medicine, 22e** — “Diabetes Mellitus: Management and Therapies” (glucose-lowering agent classes, mechanisms, Table of agents, glycaemic-management algorithm Fig 416-3).
- ▶ **Williams Textbook of Endocrinology, 15e** — “Therapeutics of Type 2 Diabetes Mellitus” (incretin physiology, DPP-4 inhibitors, GLP-1RAs, tirzepatide, SGLT-2 inhibitors, and the cardiovascular/renal outcome trials EMPA-REG, CANVAS, DECLARE-TIMI 58, CREDENCE, LEADER, SUSTAIN-6, REWIND, CAROLINA).
- ▶ **CMDT 2026** — “Diabetes Mellitus & Hypoglycemia” (current drug doses, eGFR thresholds, KDIGO renoprotection cut-off, Fournier gangrene, euglycemic DKA, peri-operative discontinuation).

Newer Insulins

Asked in: Paper IV 17 Apr 2026 · Paper II May 2019 (2×) — RGUHS MD General Medicine

Definition / Introduction — “Newer insulins” denotes the **insulin analogues** — insulin molecules whose amino-acid sequence is deliberately altered by recombinant DNA technology to modify absorption kinetics (onset, peak, duration) while preserving full biologic activity. They comprise **rapid-acting** and **ultra-rapid** prandial analogues, **long-acting / ultra-long-acting** basal analogues (including the **once-weekly** insulin), their **concentrated**, **biosimilar**, **premixed** and **fixed-ratio GLP-1RA combination** forms, and **inhaled** insulin. They were developed to mimic physiologic basal–bolus secretion more closely than the older human (regular, NPH) insulins.

Rationale — limitations of conventional human insulins

- ▶ **Regular (soluble) insulin** self-aggregates into hexamers in solution, giving a slow onset (~30–60 min, so it must be injected 20–30 min pre-meal), a delayed peak (2–3 h) and a long tail (6–8 h) that causes **late post-prandial hypoglycaemia**.
- ▶ **NPH (isophane)** has a pronounced peak (4–10 h) and a duration (10–20 h) too short for true 24-h basal cover, mandating twice-daily dosing and producing **nocturnal hypoglycaemia**; its action is variable within and between patients.
- ▶ Goal of analogue design: rapid analogues that match the post-prandial glucose excursion and decay with it, plus **peakless, reproducible, ~24-h (or longer) basal** insulin — together permitting flexible basal–bolus therapy with less hypoglycaemia.

Classification and pharmacokinetics

Category	Members (analogue)	Onset	Peak	Effective duration
Rapid-acting	Lispro, Aspart, Glulisine	<15 min	0.5–1.5 h	3–5 h
Ultra-rapid	Faster aspart (Fiasp), Lispro-aabc (Lyumjev)	~10–11 min faster than parent	—	shorter tail
Inhaled	Technosphere human insulin (Afrezza)	<15 min	~1 h	~3 h
Long-acting	Glargine U-100, Detemir	2–4 h	flat / minimal	20–24 h (detemir 12–24 h)
Ultra-long-acting	Degludec, Glargine U-300	1–9 h	flat	>42 h (degludec); >24 h (U-300)
Once-weekly	Insulin icodec	basal	flat	~1 week

(Standard human insulins for comparison: regular onset 0.5–1 h, peak 2–3 h, duration 6–8 h; NPH onset 2–4 h, peak 6–10 h, duration 12–20 h.)

Rapid-acting and ultra-rapid (prandial) analogues

- ▶ **Mechanism** — single/dual amino-acid changes abolish self-aggregation, so the insulin is absorbed as monomers → **faster onset, lower/earlier peak, shorter duration** than regular insulin. This entrains insulin action to the post-meal glucose rise and, because action decays as glucose falls, **reduces hypoglycaemia**.
- ▶ **Lispro** — proline and lysine at positions **B28/B29 are reversed** (Lys-B28, Pro-B29).
- ▶ **Aspart** — proline at **B28 replaced by aspartic acid**.
- ▶ **Glulisine** — asparagine-B3 → lysine and lysine-B29 → glutamic acid.
- ▶ Injected **just before (<10 min)** a meal; may be given **after** a meal in gastroparesis or unpredictable intake. Preferred over regular insulin for prandial coverage and are the insulins used in CSII pumps.
- ▶ **Ultra-rapid formulations** — *Fiasp* = aspart + **niacinamide (vitamin B3)** (onset ~10 min faster); *Lyumjev* (lispro-aabc) = lispro + **treprostinil + citrate** (local vasodilation + increased vascular permeability; onset ~11 min faster, lower 1–2 h post-prandial excursions). A **biosimilar lispro** (*Admelog*) is available.

Long-acting, ultra-long-acting and once-weekly (basal) analogues

- ▶ **Glargine** — asparagine at A21 replaced by glycine and two arginines added to the C-terminus of the B chain; this raises the isoelectric point so it is soluble at acidic pH but forms **microprecipitates at neutral subcutaneous pH**, releasing slowly → **peakless ~24-h action** with **less nocturnal hypoglycaemia than NPH**. Must **not be mixed** with other insulins (acidic pH). Biosimilars: *Basaglar*, *Semglee*, *Rezvoglar*.
- ▶ **Detemir** — fatty-acid (myristic acid) acylation at Lys-B29 promotes **reversible albumin binding**, prolonging action (12–24 h); being **phased out** of the market.
- ▶ **Degludec** — extension/modification of the B-chain carboxy-terminus causes formation of **soluble multihexamer chains in subcutaneous tissue plus albumin binding** → half-life ~25 h, duration >42 h. Gives glycaemic control similar to glargine but with **less nocturnal and severe hypoglycaemia**, and its long, flat profile allows **flexible (varying) injection timing**. Available U-100 and U-200.
- ▶ **Insulin icodec (once-weekly)** — Lys-B29 conjugated to a C20 fatty diacid (1,20-icosanedioic acid) with three substitutions (**A14E, B16H, B25H**); the diacid gives **strong reversible albumin binding** while the substitutions **attenuate receptor affinity and resist degradation**, yielding a ~1-week duration. Approved in Europe, Canada, Australia, China and Japan.

Concentrated, premixed, biosimilar and combination forms

- ▶ **Concentrated insulins** (smaller injection volume for high requirements / insulin resistance):
 - **U-300 glargine (Toujeo)** — one-third the volume, flatter and longer action, **less hypoglycaemia than U-100 glargine**.

- U-200 degludec, U-200 lispro, and U-500 regular (for severe insulin resistance / total daily dose >200 U; *not bioequivalent* to U-100 — switch with care).
- ▶ **Analogue premixes** — Humalog Mix 75/25 and 50/50 (NPL + lispro), NovoLog Mix 70/30 (aspart protamine/aspart); Ryzodeg 70/30 = degludec/aspart (can be given once or twice daily). Convenient (2 injections) but **not suitable for type 1 DM** as basal and prandial components cannot be titrated independently.
- ▶ **Fixed-ratio basal-insulin + GLP-1RA combinations** — degludec + liraglutide (IDegLira, Xultophy) and glargine + lixisenatide (iGlarLixi, Soliqua) — effective with **less weight gain**.
- ▶ **Biosimilars** lower cost (lispro and glargine biosimilars available).

Inhaled insulin

- ▶ **Technosphere insulin (Afrezza)** — dry-powder **regular human** insulin inhaled pre-meal; rapidly absorbed (peak insulin 12–15 min, baseline by ~3 h), effect comparable to rapid analogues when combined with basal insulin.
- ▶ Supplied as colour-coded 4-, 8-, 12-unit single-use cartridges.
- ▶ **Adverse effects / cautions** — cough (~27%), small early fall in FEV1; **contraindicated in smokers and in asthma/COPD**; perform **spirometry (FEV1)** before and periodically during therapy. A lung-cancer signal was noted (all in ever-smokers); the earlier inhaled insulin Exubera was withdrawn.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Pharmacokinetic (action-profile) graph** — x-axis *Time (h)* 0–42, y-axis *Plasma insulin / glucose-lowering effect*; overlay labelled curves: **Rapid** (aspart/lispro/glulisine) sharp early peak; **Regular** broader peak; **NPH** intermediate dome; **Glargine U-100 / Detemir** flat ~24 h; **Degludec / Glargine U-300** flat >24–42 h; **Inhaled** narrow early spike. Label *onset*, *peak*, *duration* on the rapid and NPH curves.
- ▶ **Insulin molecule schematic** — A-chain and B-chain with labelled modification sites: B28/B29 reversal (lispro), B28 Asp (aspart), A21 Gly + B-chain di-arginine (glargine), B29 fatty-acid acylation (detemir/degludec/icodec).

Clinical / Diagnostic significance

- ▶ **Basal-bolus (MDI) regimen** — basal glargine/degludec once daily + rapid analogue (lispro/aspart/glulisine) at each meal; total **0.4–1.0 U/kg/day**, ~30–50% as basal. Prandial dose set by an **insulin-to-carbohydrate ratio** (commonly 1 U / 10–15 g) plus a **correction factor** ($\approx 1500 \div \text{total daily dose for mg/dL drop per unit}$).
- ▶ **Hypoglycaemia reduction** — flat, reproducible basal analogues markedly lower **nocturnal/severe hypoglycaemia** versus NPH; rapid analogues lower late post-prandial hypoglycaemia.

- ▶ **Flexibility** — degludec and U-300 glargine allow varied daily injection times; note degludec's long washout (~42 h) when a patient fasts for procedures or is switched to another basal insulin.
- ▶ **Special situations** — concentrated insulins for severe insulin resistance; ultra-rapid/inhaled insulin for unpredictable intake or needle-averse patients; fixed-ratio GLP-1RA combos when weight gain is a concern; biosimilars to reduce cost.
- ▶ Delivered by **pens (including Bluetooth “smart” pens)**, **vial/syringe**, or **CSII pumps / automated insulin-delivery (hybrid closed-loop) systems** using rapid analogues.

High-yield exam pointers

- ▶ Rapid analogues (lispro/aspart/glulisine): inject **<10–15 min pre-meal**; onset <15 min, duration 3–5 h; **do not self-aggregate**.
- ▶ **Glargine** = A21 Asn→Gly + 2 Arg on B-chain → microprecipitates; **peakless ~24 h**; never mix.
- ▶ **Degludec** = multihexamer + albumin binding; half-life ~25 h, duration **>42 h**; flexible timing.
- ▶ **Icodec** = once-weekly basal (C20 diacid → albumin binding; A14E/B16H/B25H substitutions).
- ▶ **Fiasp** = aspart + niacinamide; **Lyumjev** = lispro + treprostinil + citrate (ultra-rapid).
- ▶ **U-300 glargine / U-200 degludec / U-200 lispro / U-500 regular** = concentrated; U-500 for resistance >200 U/day.
- ▶ **Fixed-ratio combos**: IDegLira (Xultophy), iGlarLixi (Soliqua).
- ▶ **Inhaled (Afrezza)**: 4/8/12-U cartridges; cough ~27%, falls FEV₁; **contraindicated in smokers/asthma/COPD**; spirometry first.
- ▶ Only **regular and aspart** insulin may be given IV.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Diabetes Mellitus: Management and Therapies” (insulin preparations, mechanisms of lispro/glargine/degludec, Table 416-5, basal-bolus regimens).
- ▶ **Williams Textbook of Endocrinology, 15e** — “Type 1 Diabetes Mellitus” (insulin types and action profiles, Table 35.6; ultra-rapid analogues; concentrated insulins; MDI/CSII dosing).
- ▶ **CMDT 2026** — “Diabetes Mellitus & Hypoglycemia” (analogue characteristics, ultra-rapid Fiasp/Lyumjev, glargine/degludec/**icodec** details, concentrated and premixed insulins, inhaled Technosphere insulin and its cautions).

Coverage note: The corpus richly covers all analogue classes including once-weekly icodec; insulin **detemir**'s specific fatty-acid (myristoyl) acylation mechanism is stated here as universally accepted standard pharmacology (the corpus notes detemir is being phased out but does not detail its structure).

Osteoporosis

Asked in: Paper IV Nov 2022 — RGUHS MD General Medicine

Definition / Introduction — Osteoporosis is a condition characterised by a **reduction in the strength of bone leading to skeletal fragility and an increased risk of fractures**. Although bone mineral density (BMD) is used to define it, bone strength also depends on **bone quality** — microarchitecture, remodelling rate, mineralisation and the accumulation of microdamage. It is operationally defined by the WHO as a BMD that is ≥ 2.5 standard deviations below the young-adult mean (T-score ≤ -2.5). It is the commonest metabolic bone disease, affecting >10 million individuals in the United States, predominantly **postmenopausal women**, though **30% of fragility fractures occur in men**. The clinically important fractures are **vertebral, hip and wrist (Colles') fractures**.

Densitometric classification (WHO) and key definitions

- ▶ T-score compares an individual's BMD with the mean of a **young-adult (age 30), sex- and race-matched** population (1 T-score unit = 1 SD); the **Z-score** compares with an **age- and sex-matched** reference population.

Category	T-score (lumbar spine / femoral neck / total hip)
Normal	> -1.0
Low bone density / osteopenia	-1.0 to -2.5
Osteoporosis	≤ -2.5
Severe (established) osteoporosis	≤ -2.5 with a fragility fracture

- ▶ **Fragility (low-trauma) fracture** = fracture following a fall from standing height or less; in adults aged >50, any fracture **except those of fingers, toes, face and skull** is regarded as fragility. Any fracture in a **woman >50 or a man >60** should trigger investigation for osteoporosis.
- ▶ Because **>50% of fractures occur in individuals with osteopenia** (T-score -1.0 to -2.5), emphasis has shifted to **absolute fracture risk** (e.g., FRAX) rather than BMD threshold alone.

Pathophysiology — bone remodelling

- ▶ In adults the principal skeletal process is **remodelling** (not modelling), performed by the **basic multicellular unit (BMU)**: osteoclasts (monocyte-macrophage lineage) resorb a cavity, then osteoblasts (mesenchymal lineage) lay down osteoid that mineralises; **osteocytes** are terminally differentiated osteoblasts that orchestrate the process.
- ▶ **Peak bone mass** is achieved by early adulthood and is largely **genetically determined** (heritability 50–80%); after age 30–45 years **resorption exceeds formation**, producing slow bone loss, exaggerated in women by oestrogen deficiency.

- ▶ **RANK–RANKL–OPG axis:** RANKL (a TNF-family cytokine from osteoblasts, osteocytes, T cells) binds **RANK** on osteoclast precursors → osteoclast formation, activation and survival. **Osteoprotegerin (OPG)** is a decoy receptor that neutralises RANKL. The balance of these three determines bone resorption.
- ▶ **Wnt–sclerostin pathway:** Wnt signalling (stimulated by mechanical loading and PTH) promotes osteoblastic bone formation and lowers RANKL; **sclerostin**, an osteocyte protein, inhibits Wnt and bone formation. Both RANKL and Wnt pathways are major drug targets.
- ▶ **Oestrogen deficiency** (chiefly menopause, mean age 51 y) drives loss by **increasing RANKL and decreasing OPG**, increasing remodelling activation frequency and prolonging osteoclast (while shortening osteoblast) lifespan. **Trabecular bone** (80% of surface area) is affected first — hence **vertebral fractures are the earliest consequence**.
- ▶ **Calcium/vitamin D:** inadequate intake → **secondary hyperparathyroidism** → increased remodelling and bone loss. **LRP5** activating mutations cause high bone mass; inactivating mutations cause osteoporosis–pseudoglioma syndrome.

Aetiology — primary and secondary causes

- ▶ **Primary:** postmenopausal (type I, oestrogen-related, trabecular/vertebral) and age-related/senile (type II); idiopathic (including in men and pre-menopausal women).
- ▶ **Secondary** — suggested by very low Z-scores, fractures in younger patients, or atypical features.

Group	Risk factors / causes
Non-modifiable	Personal history of adult fracture, family history of hip fracture, advanced age, female sex, white race, dementia
Modifiable	Current smoking, oestrogen deficiency, early menopause (<45 y) / oophorectomy , prolonged amenorrhoea (>1 y), low calcium/vitamin D intake, alcoholism, impaired vision, recurrent falls, inadequate physical activity, low BMI
Endocrine	Cushing's syndrome, hyperparathyroidism , thyrotoxicosis, diabetes mellitus (type 1 and 2) , acromegaly, adrenal insufficiency, hypogonadism (Turner's, Klinefelter's, anorexia nervosa, hyperprolactinaemia)
GI / nutritional	Malabsorption, coeliac disease , gastrectomy, primary biliary cirrhosis, malnutrition
Marrow / malignancy	Multiple myeloma , lymphoma/leukaemia, mastocytosis, thalassaemia
Inherited / other	Osteogenesis imperfecta, Marfan's, Ehlers–Danlos, homocystinuria, hypophosphatasia; rheumatoid

Group	Risk factors / causes
	arthritis, ankylosing spondylitis, immobilisation, COPD, multiple sclerosis
Drugs (Table 423-3)	Glucocorticoids (commonest medication-induced; risk if ≥ 5 mg prednisone/day for >3 months), aromatase inhibitors, androgen-deprivation therapy , GnRH agonists, excess thyroxine, anticonvulsants, SSRIs, proton-pump inhibitors, thiazolidinediones, heparin, lithium, cyclosporine, cytotoxics

Clinical features

- ▶ Osteoporosis itself is **asymptomatic until fracture** (“silent disease”).
- ▶ **Vertebral fractures**: ~70% are clinically silent; present with acute back pain (only ~30% are symptomatic), progressive **height loss** (>4 cm), **dorsal kyphosis**, restrictive lung disease (thoracic) or abdominal distension/early satiety (lumbar). Chronic pain is largely myofasciogenic, not bony.
- ▶ **Hip fracture**: almost always needs surgery; carries **20–25% mortality in the first year** and ~30% of survivors require long-term care.
- ▶ **Wrist (Colles’) fractures** rise after menopause; a first fracture markedly increases further-fracture risk, especially in the next **12–24 months** (“**imminent fracture risk**”).

Diagnosis and investigations

- ▶ **DXA (dual-energy x-ray absorptiometry)** of lumbar spine and hip is the **standard** for BMD; the **total hip** best predicts hip-fracture risk. Serial scans should use the same machine. (QCT, HR-pQCT, peripheral QCT and ultrasound are alternatives; **trabecular bone score [TBS]** adds microarchitectural information to spinal DXA.)
- ▶ **Indications for BMD testing**: all women ≥ 65 and men ≥ 70 ; younger post-menopausal women / men 50–69 with risk factors; any adult with a fracture at/after age 50; adults on a high-risk drug (e.g., glucocorticoids) or disease.
- ▶ **FRAX®**: integrates age, sex, BMI, prior fracture, parental hip fracture, smoking, alcohol, glucocorticoids, rheumatoid arthritis and secondary causes ($\pm$ femoral-neck BMD) to give the **10-year probability of major osteoporotic (hip, clinical spine, wrist, humerus) and of hip fracture**. US intervention threshold: **10-year major osteoporotic risk $\geq 20\%$ and/or hip risk $\geq 3\%$** .
- ▶ **Vertebral fracture assessment (VFA)/lateral spine imaging** detects silent vertebral fractures.
- ▶ **Laboratory screen for secondary causes**: CBC, serum & 24-h urine calcium, renal and liver function, serum 25(OH)D, TSH, PTH (if hypercalcaemic), **serum/urine electrophoresis and free light chains** (myeloma), **testosterone in men**, 24-h urinary free cortisol/overnight

dexamethasone (Cushing's), tissue transglutaminase IgA (coeliac), tryptase/urinary histamine (mastocytosis).

- ▶ **Biochemical bone-turnover markers** — formation: bone-specific alkaline phosphatase, osteocalcin, P1NP (preferred); resorption: urine/serum NTX, **serum CTX** (preferred, fasting 9 a.m.). Chiefly used to **monitor treatment response** (change earlier than BMD); a meaningful change is $\geq 30\text{--}40\%$.

Management

Non-pharmacological / universal measures

- ▶ Adequate **calcium** (RDA 1000–1200 mg/day; dietary preferred; supplement doses ≤ 600 mg) and **vitamin D** (target 25(OH)D > 30 ng/mL; 800–2000 IU/day, up to 4000 IU/day safe). Calcium + vitamin D reduces fractures mainly in the **deficient, institutionalised elderly**.
- ▶ **Weight-bearing and progressive resistance exercise** (small 3–4% BMD gains); **balance training/tai chi** reduces falls by $\sim 25\%$.
- ▶ **Risk-factor reduction**: smoking cessation, limit alcohol, treat impaired vision, minimise sedating drugs, **home/fall-proofing**, hip protectors in nursing-home residents.

Pharmacological agents — antiresorptive (slow resorption) versus anabolic (build bone). Anabolics are first-line in **very-high-risk/imminent-risk** patients; the ideal sequence is **anabolic followed by an antiresorptive**.

Agent	Class / mechanism	Dose & route	Fracture reduction
Alendronate	N-bisphosphonate (inhibits farnesyl-PP synthase $\rightarrow$ osteoclast apoptosis)	70 mg PO weekly	Vertebral $\sim 50\%$, hip up to 50%
Risedronate	N-bisphosphonate	35 mg PO weekly	Vertebral 40–50%, hip 40%
Ibandronate	N-bisphosphonate	150 mg PO monthly / 3 mg IV q3-monthly	Vertebral $\sim 40\%$, no overall non-vertebral benefit
Zoledronic acid	N-bisphosphonate	5 mg IV annually (30-min infusion)	Vertebral 70%, hip 40%, non-vertebral 25%
Denosumab	Human anti-RANKL monoclonal antibody	60 mg SC every 6 months	Vertebral 68%, hip 40%, non-vertebral 20%
Raloxifene	SERM (oestrogen agonist on bone)	60 mg PO daily	Vertebral 30–50%; also $\downarrow$ ER+ breast cancer

Agent	Class / mechanism	Dose & route	Fracture reduction
Teriparatide	PTH(1–34), anabolic (Wnt/osteoblast)	20 µg SC daily	Vertebral 65%, non-vertebral 53%
Abaloparatide	PTHrP analogue, anabolic	SC daily	Vertebral 86%, non-vertebral 43% (ACTIVE)
Romosozumab	Anti-sclerostin antibody (↑formation, ↓resorption)	210 mg SC monthly ×12	Vertebral 73% (FRAME)
Calcitonin	Hormone (osteoclast inhibition)	200 IU/day intranasal	Weak; analgesic in acute vertebral fracture

- **Oestrogen/hormone therapy** reduces hip & spine fracture (WHI: –34%) but raises MI, stroke, VTE and breast cancer; **not recommended for disease prevention** — reserved for menopausal symptoms.
- **Key adverse effects/precautions:** oral bisphosphonates cause **oesophagitis** (take fasting with a full glass of water, remain upright ≥30 min) and are **contraindicated if eGFR <30–35 mL/min**; class effects include **medication-related osteonecrosis of the jaw (MRONJ)** and **atypical femoral (subtrochanteric) fractures** (lateral thigh/groin pain warning), hypocalcaemia, and an **acute-phase reaction** with IV zoledronate. **Denosumab** has a **rebound increase in bone turnover with multiple vertebral fractures on discontinuation** — never give a drug holiday; bridge with a bisphosphonate. **Teriparatide** carried a (rodent) osteosarcoma signal. **Romosozumab** carries a **cardiovascular warning** — **avoid after recent MI/stroke** (ARCH trial).
- **Glucocorticoid-induced osteoporosis (GCIOP):** commonest cause of drug-induced osteoporosis; use lowest steroid dose, ensure calcium/vitamin D, and treat with bisphosphonates (alendronate, risedronate, zoledronate), denosumab or teriparatide.
- **Monitoring:** repeat DXA ~every 2 years; a significant change must exceed ~3% at **spine**, ~6% at **hip**; turnover markers detect response earlier (~3 months). “**Drug holidays**” apply to bisphosphonates only (long skeletal half-life) — avoided with denosumab and anabolic agents.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- **RANK–RANKL–OPG and Wnt–sclerostin remodelling unit:** label *osteoblast/osteocyte*, *RANKL*, *RANK* (on preosteoclast), *osteoprotegerin (OPG, decoy)*, *multinucleated osteoclast resorbing bone*, *Wnt signal → bone formation*, *sclerostin (inhibits Wnt)*; mark drug targets — *denosumab → RANKL*, *romosozumab → sclerostin*, *bisphosphonates → osteoclast*.
- **T-score normal distribution curve:** label *young-adult mean (T = 0)*, *normal (> –1.0)*, *osteopenia (–1.0 to –2.5)*, *osteoporosis (≤ –2.5)*, with a marker at **T = –2.5**.

Clinical / Diagnostic significance

- ▶ Osteoporosis is a **silent disease diagnosed only after fracture or screening** — hence proactive DXA + FRAX in at-risk groups.
- ▶ A **first fragility fracture predicts imminent further fractures**; **fracture liaison services** improve secondary-fracture prevention (~20% fall in hip-fracture rate in the Kaiser system).
- ▶ Distinguish from **osteomalacia** (defective mineralisation, low/normal calcium and phosphate, raised ALP, looser zones) and **multiple myeloma** (punched-out lytic lesions, paraproteinaemia).
- ▶ Always exclude **secondary causes** before labelling primary osteoporosis, especially in men, premenopausal women and unexpectedly low Z-scores.

High-yield exam pointers

- ▶ WHO T-score ≤ -2.5 = **osteoporosis**; -1.0 to -2.5 = **osteopenia**; T = young-adult reference, Z = age-matched.
- ▶ **>50% of fractures occur in osteopenic patients** → use **absolute risk (FRAX)**; US thresholds $\geq 20\%$ major / $\geq 3\%$ hip.
- ▶ RANKL–RANK–OPG and Wnt–sclerostin are the central pathways and the basis for **denosumab** and **romosozumab**.
- ▶ **Zoledronic acid** (annual IV) gives the largest bisphosphonate fracture reduction (vertebral 70%, hip 40%).
- ▶ **Denosumab** — never stop abruptly (rebound vertebral fractures); bridge with bisphosphonate.
- ▶ **Romosozumab** — anabolic + antiresorptive but **cardiovascular boxed warning**.
- ▶ **Anabolic-first then antiresorptive** in very-high/imminent-risk patients.
- ▶ **Glucocorticoids** = commonest drug cause (risk ≥ 5 mg prednisone/day > 3 months).
- ▶ Oral bisphosphonate rules: **fasting, full glass of water, upright ≥ 30 min; avoid if eGFR < 30** ; watch for **MRONJ** and **atypical femoral fracture**.
- ▶ Hip fracture carries **20–25% one-year mortality**.

SOURCE & COVERAGE

Harrison 22e — Ch 423 “Osteoporosis” (P.R. Ebeling). Standard definitions (normal/osteopenia/osteoporosis T-score bands, “severe/established osteoporosis”, type I/II classification) and the osteomalacia/myeloma differential are universally accepted internal-medicine teaching used to round out the answer; all drug doses, fracture-reduction figures, trial names and thresholds are taken verbatim from the chapter. No coverage gap.

Pituitary hormones

Asked in: Paper I May 2022 — RGUHS MD General Medicine

Definition / Introduction — The pituitary gland (~600 mg, lying within the sella turcica ventral to the diaphragma sella) is the “master gland” that, with the hypothalamus, orchestrates most endocrine function. It has two embryologically and functionally distinct lobes: the **anterior pituitary (adenohypophysis)**, derived from *Rathke’s pouch*, which secretes **six major hormones** — prolactin (PRL), growth hormone (GH), adrenocorticotrophic hormone (ACTH), luteinizing hormone (LH), follicle-stimulating hormone (FSH) and thyroid-stimulating hormone (TSH); and the **posterior pituitary (neurohypophysis)**, a neural extension storing **arginine vasopressin (AVP/ADH)** and **oxytocin**. All are secreted in a pulsatile manner under hypothalamic and feedback control.

Anatomy, development and regulatory principles

- ▶ **Vascular supply:** superior and inferior hypophyseal arteries. The **hypothalamic-pituitary portal plexus** carries hypothalamic releasing/inhibiting peptides to the anterior lobe in high concentration *without systemic dilution*, so anterior cells receive discrete hypothalamic pulses.
- ▶ The **posterior lobe** is supplied by the inferior hypophyseal arteries and is *directly innervated* by hypothalamic neurons via the supraopticohypophyseal and tuberohypophyseal tracts — hence AVP/oxytocin output is sensitive to stalk or hypothalamic damage.
- ▶ **Development from Rathke’s pouch** is governed by lineage-specific transcription factors: *Prop-1* and *Pit-1* (GH, PRL, TSH lineages), *SF-1* and *DAX-1* (gonadotropes), and *T-Pit* (corticotropes/POMC). Their mutations cause selective or combined pituitary hormone deficiency.
- ▶ **Three regulatory layers:** (1) hypothalamic releasing/inhibiting factors via the portal system; (2) **negative feedback** by peripheral target-gland hormones (e.g., cortisol on ACTH, T3/T4 on TSH); (3) **hormonal rhythms** — most pituitary hormones are entrained to sleep/circadian cycle (e.g., ACTH–cortisol peak ~6 a.m., nadir ~midnight; GH and PRL peak in non-REM/early sleep).

Anterior pituitary hormones — summary

Hormone	Cell (% of anterior cells)	Chemical nature	Hypothalamic stimulator	Inhibitor	Target	Principal action
PRL	Lactotrope (~20%)	Polypeptide, 198 aa	TRH, VIP, estrogen	Dopamine (tonic, D2 receptor)	Breast	Lactation; suppresses GnRH/gonadotropins
GH	Somatotrope (up to 50%)	Polypeptide, 191 aa (22 kDa)	GHRH, ghrelin	Somatostatin (SRIF), IGF-1	Liver, bone, tissues	IGF-1 generation, linear growth, insulin antagonism, lipolysis

Hormone	Cell (% of anterior cells)	Chemical nature	Hypothalamic stimulator	Inhibitor	Target	Principal action
ACTH	Corticotrope (~20%)	Polypeptide, 39 aa (from POMC, 266 aa)	CRH, AVP, cytokines (IL-6)	Glucocorticoids	Adrenal cortex	Cortisol/adrenal steroidogenesis
LH	Gonadotrope (~10%)	Glycoprotein ($\alpha + \beta$)	GnRH	Sex steroids (feedback)	Ovary/testis	Ovulation, corpus luteum; Leydig cell testosterone
FSH	Gonadotrope (~10%)	Glycoprotein ($\alpha + \beta$)	GnRH, activin	Inhibin	Ovary/testis	Folliculogenesis, ovarian estrogen; spermatogenesis
TSH	Thyrotrope (~5%)	Glycoprotein ($\alpha + \beta$)	TRH	T3/T4, dopamine, somatostatin, glucocorticoids	Thyroid	T4 synthesis and secretion

The glycoprotein hormones (LH, FSH, TSH; also hCG) share a common α subunit; biologic specificity resides in the hormone-specific β subunit.

Individual anterior hormones — key mechanisms

- **Prolactin:** 198 aa, weakly homologous to GH and human placental lactogen; half-life ~50 min. Uniquely, its predominant hypothalamic control is **inhibitory** (tonic dopamine via **D2 receptors**) — so stalk section (trauma, compressive lesions) *raises* PRL. The PRL receptor is a **type I cytokine receptor** signalling through JAK/STAT. PRL induces and maintains lactation and **suppresses reproductive function** by inhibiting hypothalamic GnRH and pituitary gonadotropins → hypogonadism (this underlies amenorrhoea-galactorrhoea and male hypogonadism in hyperprolactinaemia). PRL rises ~10-fold in pregnancy.
- **Growth hormone / IGF-1:** Most abundant anterior hormone. Stimulated by **GHRH** (44-aa peptide) and **ghrelin**; inhibited by **somatostatin (SRIF)** and by IGF-1 feedback. Of the five somatostatin receptor subtypes (SST1–SST5), **SST2 and SST5** suppress GH (and TSH). GH receptor belongs to the cytokine/haematopoietic family (JAK/STAT). GH causes protein synthesis/nitrogen retention, **insulin antagonism** (impaired glucose tolerance), lipolysis, and Na⁺/K⁺/water retention; much of its growth action is mediated by **IGF-1** (chiefly hepatic, carried by IGFBP3). *Pegvisomant*, a GH-receptor antagonist, treats acromegaly.
- **ACTH:** A 39-aa peptide cleaved from the **proopiomelanocortin (POMC, 266 aa)** precursor, which also yields β -lipotropin, β -endorphin, met-enkephalin, α -MSH and CLIP. POMC is

stimulated by **CRH** (41-aa, paraventricular nucleus), AVP and cytokines, and suppressed by glucocorticoids. ACTH acts via the **melanocortin-2 receptor** (GPCR) to drive adrenal cortisol synthesis; it shows a marked circadian rhythm and mediates the neuroendocrine stress response.

- ▶ **Gonadotropins (LH, FSH):** Controlled by **GnRH** (10-aa peptide) released in **pulses every 60–120 min**, itself regulated by **kisspeptin** (KISS1 gene). *Pulsatile* GnRH is essential; *continuous* exposure desensitises gonadotropes — the basis for long-acting **GnRH agonists** in precocious puberty and prostate cancer. **Inhibin** selectively suppresses FSH while **activin** stimulates it. Estrogen is normally inhibitory, but the rising preovulatory estrogen exerts **positive feedback** to trigger the mid-cycle LH surge.
- ▶ **TSH:** Stimulated by **TRH** (a hypothalamic tripeptide, pyroglutamyl-histidyl-prolinamide) and suppressed by thyroid hormone (the predominant negative regulator), dopamine, somatostatin and glucocorticoids. Long half-life and low pulse amplitude mean a single TSH level reliably reflects status. It acts on a thyroid follicular-cell GPCR.

Posterior pituitary (neurohypophysis) hormones

- ▶ The neurohypophysis is the distal axons of **magnocellular neurons** whose cell bodies lie in the **paraventricular and supraoptic nuclei**.
- ▶ **Arginine vasopressin (AVP/ADH):** a **nonapeptide** (six-member disulfide ring + tripeptide tail) synthesised as a precursor yielding AVP, **neurophysin II** and **copeptin** (single gene, chromosome 20). Secretion is governed mainly by **osmoreceptors** in the anteromedial hypothalamus; the osmotic set point is **~275 mosmol/L** (plasma Na⁺ ~135 meq/L), with a 2–4% rise giving maximal antidiuresis. AVP is also released by a fall in BP or volume loss **>10–20%** (baroregulated), and potently by nausea/emesis. **Action:** via renal **V2 receptors** → cAMP → insertion of **aquaporin-2 (AQP2)** channels into principal-cell apical membrane → water reabsorption (urine osmolarity up to **1200 mOsmol/L** at AVP 1–3 pg/mL). **V1a/V1b** receptors mediate vasoconstriction, hepatic glycogenolysis and ACTH potentiation. Half-life 10–30 min; *desmopressin (DDAVP)* resists vasopressinase and acts longer.
- ▶ **Oxytocin:** also a nonapeptide, differing from AVP at **positions 3 and 8**; little antidiuretic effect. It stimulates **milk letdown** (suckling reflex) and uterine smooth-muscle contraction in labour, and centrally regulates socioemotional behaviour (bonding, empathy).
- ▶ **Thirst** is regulated by a hypothalamic osmostat set **~3% higher** than the AVP osmostat, ensuring fluid intake before plasma tonicity exceeds the antidiuretic defence.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Hypothalamic-pituitary axes (Fig. 390-1):** Hypothalamus (label releasing factors: *CRH, GnRH, TRH, GHRH, somatostatin/SRIF, dopamine*) → portal vessels → anterior pituitary (label cells: *corticotrope-ACTH, gonadotrope-LH/FSH, thyrotrope-TSH, somatotrope-GH, lactotrope-PRL*) → target glands (*adrenal-cortisol, gonads-sex steroids/inhibin, thyroid-*

T4/T3, liver-IGF-1, breast); draw **negative-feedback arrows** from target hormones back to hypothalamus/pituitary.

- ▶ **Posterior pituitary / AVP pathway** (Fig. 393-1/2): Label *supraoptic + paraventricular nuclei* → *magnocellular axons* → *posterior pituitary* → *AVP release*; and renal collecting-duct cell with labels *V2 receptor*, *Gs-cAMP*, *AQP2 (apical)*, *AQP3/AQP4 (basolateral)*, *water reabsorption*.

Clinical / Diagnostic significance

- ▶ **Hormone-excess syndromes from adenomas**: prolactinoma (amenorrhoea-galactorrhoea, hypogonadism), GH excess (gigantism/acromegaly; treat with somatostatin analogues, pegvisomant), ACTH excess (Cushing disease), TSH-secreting adenoma (central hyperthyroidism with inappropriately normal/high TSH).
- ▶ **Hypopituitarism** may be inherited (Pit-1/Prop-1 mutations) or acquired (tumour, surgery, irradiation, apoplexy, Sheehan syndrome); mass effect adds headache and **bitemporal hemianopia** (optic chiasm).
- ▶ **Stalk compression** raises PRL (loss of dopamine inhibition) — a useful localising clue.
- ▶ **Pulsatility matters**: pulsatile GnRH stimulates but continuous GnRH suppresses gonadotropins (therapeutic GnRH agonists).
- ▶ **Posterior pituitary disorders**: **AVP deficiency** (central DI) vs **AVP resistance** (nephrogenic DI) cause hypotonic polyuria (>40–50 mL/kg/24 h); differentiate with serum Na⁺, the desmopressin test and **copeptin** (baseline >21.4 pmol/L = AVP resistance; stimulated >4.9 pmol/L at Na⁺ ≥150 mmol/L diagnoses AVP deficiency, ~96.5% accuracy). The **pituitary “bright spot”** on T1 MRI marks AVP-containing vesicles and may be lost in AVP deficiency. Excess/inappropriate AVP causes **SIAD/hyponatraemia**.

High-yield exam pointers

- ▶ Six anterior hormones: **PRL, GH, ACTH, LH, FSH, TSH**; posterior stores **AVP and oxytocin** (made in hypothalamus, not the posterior lobe).
- ▶ Cell proportions: **GH ~50%**, **PRL ~20%**, **ACTH ~20%**, **LH/FSH ~10%**, **TSH ~5%**.
- ▶ **Prolactin is the only anterior hormone under tonic inhibitory (dopaminergic D2) control** → stalk section causes hyperprolactinaemia.
- ▶ Glycoprotein hormones (LH, FSH, TSH, hCG) share a **common α subunit**; β subunit confers specificity.
- ▶ ACTH derives from **POMC** (also yields α-MSH, β-endorphin, β-lipotropin); receptor = **melanocortin-2**.
- ▶ GH actions are largely mediated by **IGF-1**; GH itself is **diabetogenic** (insulin antagonist).

- ▶ GnRH pulses every **60–120 min**; kisspeptin is the upstream gatekeeper; continuous GnRH desensitises.
- ▶ AVP is a **nonapeptide** acting via **V2 receptors–AQP2**; osmotic set point **~275 mosmol/L**; copeptin is its stable surrogate.
- ▶ **Inhibin** ↓FSH, **activin** ↑FSH; rising estrogen gives positive feedback → LH surge.

SOURCE & COVERAGE

Harrison's Principles of Internal Medicine, 22e — Ch 390 "Physiology of Anterior Pituitary Hormones" (anterior lobe, synthesis/secretion/action of PRL, GH, ACTH, LH/FSH, TSH; anatomy, development, regulation) and Ch 393 "Disorders of the Neurohypophysis" (AVP and oxytocin physiology, osmoregulation, DI/copeptin). Coverage note: the topic is fully supported by the two provided chapters; specific adenoma-syndrome management details (e.g., bromocriptine/cabergoline doses) are clinical add-ons drawn from standard internal medicine and are summarised, not source-detailed.

Regulation of Energy Balance in Human Adult

Asked in: Paper I Sep 2025 — RGUHS MD General Medicine

Definition / Introduction — *Energy balance* is the state in which **energy intake** (calories from food) equals **total energy expenditure** (TEE), so that body energy stores (chiefly adipose triglyceride) and body weight remain stable over long periods. It is not a matter of conscious choice alone but a tightly **homeostatically regulated** process: the amount of stored energy is defended by fundamental physiologic mechanisms essential to survival. The **hypothalamus** is the master integrator, receiving adiposity signals (leptin, insulin) and gut signals (ghrelin, GLP-1, PYY, CCK, etc.) and translating them, via the **leptin–melanocortin pathway**, into adjustments of hunger, satiety and energy expenditure. Chronic imbalance (intake > expenditure) of as little as **~7 kcal/day** sustained over years produces obesity.

The energy balance equation and components of energy expenditure

- ▶ **Fundamental equation:** Change in energy stores = Energy intake – Total energy expenditure. Positive balance → fat storage (as triacylglycerol, which yields >2× the energy/gram of carbohydrate and needs no accompanying water); negative balance → mobilisation of free fatty acids and glycerol.
- ▶ **Macronutrient fuel value:** carbohydrate **4 kcal/g**, protein **4 kcal/g**, fat **9 kcal/g**, alcohol **7 kcal/g** (alcohol is a fuel but not a nutrient).
- ▶ **Total energy expenditure (TEE)** has three quantitatively important parts plus a minor one:

Component	Approx. share of TEE	Nature / regulation
Resting energy expenditure (REE / BMR)	~70%	Energy for basal cellular and organ function; chiefly regulated by thyroid hormone (thyrotoxicosis ↑ REE → weight loss)
Physical activity (exercise + NEAT)	~20%	Voluntary exercise + non-exercise activity thermogenesis (posture, fidgeting); most variable component
Thermic effect of food (TEF / specific dynamic action)	~10%	Energy of chewing, digestion, absorption and post-prandial sympathetic activation
Cold-induced (shivering) thermogenesis	minor	Thermoregulatory

- ▶ **Estimating requirements (Harrison/DRI):** the Estimated Energy Requirement (EER) = REE × physical activity level (PAL). In weight-stable adults, REE = 900 + 10m (males) and REE = 700 + 7m (females), where *m* = mass in kg. PAL multipliers: 1.4 (inactive), 1.6 (low active), 1.75 (active), 2.05 (very active). Average intake ≈ 2600 kcal/d (US men), 1800 kcal/d (US women).

The hypothalamus — the integrating centre

- ▶ The hypothalamus is **partially outside the blood–brain barrier**, allowing it to sample circulating hormones and combine them with neural, sensory and cognitive inputs.
- ▶ **First-order (primary) neurons** lie in the **arcuate nucleus** and fall into two antagonistic, leptin-responsive populations:

Neuronal population (arcuate n.)	Peptides released	Effect on appetite	Response to leptin
POMC neurons (anorexigenic)	Pro-opiomelanocortin → α-/β-MSH	↓ Food intake, ↑ energy expenditure	Stimulated by leptin
NPY/AGRP neurons (orexigenic)	NPY, AGRP, inhibitory GABA	↑ Food intake	Inhibited by leptin

- ▶ α-/β-MSH act on the **melanocortin-4 receptor (MC4R)** on **second-order neurons** in the **paraventricular nucleus (PVN)** → reduced intake and ↑ sympathetically-driven energy expenditure. AGRP is an endogenous antagonist that actively *switches off* melanocortin receptors. γ-MSH (**MC3 receptor**) influences linear growth and nutrient partitioning (lean vs fat).
- ▶ **Downstream effectors:** BDNF (ventromedial nucleus) and its receptor TrkB, and SIM1 (acts downstream of MC4R) — disruption causes hyperphagia and severe obesity.

- ▶ Lateral hypothalamus harbours orexigenic peptides **melanin-concentrating hormone (MCH)** and **orexin** (orexin loss → narcolepsy). The **endocannabinoid system** (CB1 receptors; ligands **anandamide** and **2-arachidonoylglycerol**) also promotes feeding.

Peripheral signals: adiposity (long-term) and gut (short-term)

- ▶ **Adiposity (long-term tonic) signals** report the *size of energy stores*: **leptin** (from adipocytes) and **insulin** (β -cells) rise with fat mass and act centrally to suppress intake.
- ▶ **Gut (short-term episodic) signals** report *the meal*: ghrelin drives hunger before meals; the post-prandial incretin/satiety peptides terminate the meal, often acting via **vagal afferents** → **brainstem** → **hypothalamus**.

Hormone	Source	Action on energy balance
Leptin	Adipocytes	Anorexigenic ; rises with fat stores; stimulates POMC, inhibits NPY/AGRP; falls <i>faster than fat</i> during caloric restriction
Insulin	Pancreatic β -cells	Central anorexigenic adiposity signal
Ghrelin	Stomach	Orexigenic ; rises in the unfed state/pre-meal, falls after eating — the only known circulating appetite <i>stimulant</i>
CCK	Duodenal I cells	Satiety via vagal CCK-A receptors → brainstem
GLP-1	L cells, small intestine	Satiety + incretin (glucose-dependent insulin release)
GIP	K cells, duodenum/proximal jejunum	Incretin; modulates adipocyte metabolism
PYY (PYY3-36)	L cells, large intestine	Satiety via Y2 receptor (NPY2R)
Oxyntomodulin	L cells, large intestine	Satiety
Amylin	Pancreatic β -cells (co-secreted with insulin)	Slows gastric emptying, hindbrain-mediated satiety, restores leptin sensitivity
GDF15	Many tissues under stress	Anorexia via brainstem GFRAL receptor

- ▶ Diets richer in **protein and fat** induce earlier satiation, partly because the appetite-suppressing gut hormones rise more in response to protein than to carbohydrate.

Set-point, adaptive thermogenesis and leptin resistance

- ▶ **Set-point / homeostatic defence:** classic 1940s rodent experiments showed animals *defend* a fixed body-fat level — after forced over- or under-feeding they return to baseline. In humans, body weight is similarly defended: weight loss triggers a *fall* in energy expenditure and a powerful *rise* in hunger that drive regain.
- ▶ **Adaptive (metabolic) thermogenesis:** hypocaloric feeding reduces energy expenditure by ~8 kcal/kg lean body mass in obese and ~6 kcal/kg in normal-weight individuals (a 15–20% daily fall) — beyond what the loss of body mass alone explains. This makes the dieter transiently more “energy-efficient” and promotes weight regain. (REE rebounds once weight stabilises.)
- ▶ **Asymmetry of leptin action explains “why leptin doesn’t prevent obesity”:** a *fall* in leptin below the habitual level is a **strong** stimulus to eat, whereas *raises* above normal have a **weak** suppressive effect — and at high levels extra leptin has little effect (**leptin resistance**). Evolution wired the system to defend against starvation, not against surfeit. Even “leptin-resistant” obese people retain *some* leptin action — otherwise they would be as hyperphagic as a congenitally leptin-deficient child.
- ▶ **Genes vs environment:** twin/adoption studies confirm a strong genetic basis for adiposity; the predisposition is exerted **mainly through the brain’s control of food intake** (predisposed individuals eat more and are less readily satiated), not through a measurably lower metabolic rate (severe hypothyroidism is the main “low-REE” exception). The recent epidemic, however, reflects an **obesogenic environment** (cheap, energy-dense, ubiquitous palatable food + mechanisation + thermoneutral living) acting on susceptible genotypes.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Diagram 1 — Hypothalamic leptin–melanocortin circuit (sagittal/box scheme).** Labels: *Adipose tissue* → *Leptin*; *Arcuate nucleus*; *POMC neuron (LEPR)*; *NPY/AGRP/GABA neuron (LEPR)*; α/β -*MSH*; *AGRP (antagonist)*; *MC4R neuron in Paraventricular nucleus*; *BDNF (ventromedial nucleus)*; *SIM1*; arrows to “↓ Food intake, ↑ Energy expenditure.” Show leptin stimulating POMC and inhibiting NPY/AGRP.
- ▶ **Diagram 2 — Energy-balance / peripheral signals scheme.** Central box “Hypothalamus” with Brainstem relay; arrows in from Adipose (leptin), Pancreas (insulin, amylin), Stomach (ghrelin — orexigenic), Small intestine (GLP-1, GIP, CCK), Large intestine (PYY, oxyntomodulin), and vagus nerve. Adjacent pie chart of TEE: REE 70% / Physical activity 20% / TEF 10%.

Clinical / Diagnostic significance

- ▶ **Monogenic obesity (treatable forms):** *Congenital leptin deficiency* → severe early-onset obesity + hyperphagia, hypogonadotrophic hypogonadism — **treatable with recombinant leptin**; *leptin-receptor deficiency* is leptin-unresponsive. **MC4R mutations** are the **commonest monogenic obesity** (5–6% of severe early-onset obesity; ~1 in 300 of the population). **POMC deficiency** →

obesity + ACTH deficiency (adrenal crisis, cholestatic jaundice) + **red hair/pale skin**. PCSK1 deficiency → obesity + neonatal enteropathy + post-prandial hypoglycaemia.

- ▶ **Pharmacological exploitation of the pathway:** **setmelanotide** (MC4R agonist) is licensed for **leptin-receptor, POMC and PCSK1 deficiency** and trialled in hypothalamic (e.g. craniopharyngioma) obesity. The modern incretin-based anti-obesity drugs (GLP-1 RA e.g. **semaglutide**; dual GIP/GLP-1 e.g. **tirzepatide**; amylin analogues) act on these same satiety pathways; bariatric surgery works largely by **altering the gut-hormone milieu**, not merely by restriction/malabsorption.
- ▶ **Secondary causes to screen:** **hypothyroidism** (check TSH ± free T4 — ↓ REE), **Cushing's syndrome** (centripetal fat, striae, myopathy), **insulinoma**, and **hypothalamic damage** (craniopharyngioma, head injury) causing acquired hyperphagic obesity.
- ▶ **Bedside assessment:** BMI (WHO: overweight 25–29.9, obese ≥30 kg/m²; lower Asian cut-offs), **waist-to-hip ratio** (>0.9 women, >1.0 men) and waist circumference as surrogates of visceral fat and metabolic risk.

High-yield exam pointers

- ▶ TEE = REE (70%) + **physical activity/NEAT** (20%) + **thermic effect of food** (10%); REE is governed mainly by **thyroid hormone**.
- ▶ EER = REE × PAL; REE = 900 + 10m (M) / 700 + 7m (F); PAL 1.4 → 2.05. Macronutrient kcal/g: CHO 4, protein 4, fat 9, alcohol 7.
- ▶ **Arcuate nucleus** = first-order integrator: **POMC/CART** (anorexigenic) vs **NPY/AGRP/GABA** (orexigenic); leptin stimulates POMC, inhibits NPY/AGRP.
- ▶ The effector arm is the **leptin → POMC → α-MSH → MC4R (PVN)** axis; AGRP antagonises MC4R; BDNF/TrkB and SIM1 act downstream.
- ▶ **Ghrelin** = the only orexigenic gut hormone (rises pre-meal); **GLP-1, PYY, CCK, GIP, oxyntomodulin, amylin** = satiety/incretin signals.
- ▶ **Leptin** is a “fat-store” (adiposity) signal that defends *against starvation* more than against obesity → **leptin resistance** explains why high leptin fails to curb obesity.
- ▶ **Adaptive thermogenesis:** dieting lowers energy expenditure (~15–20%), driving weight regain — the metabolic basis of the **set-point**.
- ▶ A sustained surplus of just ~7 **kcal/day** can cause obesity over years; predisposition is mediated chiefly through **appetite (food intake)**, not low metabolic rate.

Role of Glucagon Like Peptide 1 (GLP 1) in the pathogenesis and management of Type II diabetes mellitus

Asked in: Paper I Nov 2022 — RGUHS MD General Medicine

Definition / Introduction — *Glucagon-like peptide 1 (GLP-1)* is an **incretin hormone**: an intestinally derived peptide that, together with *glucose-dependent insulintropic peptide (GIP)*, binds specific beta-cell receptors to **amplify glucose-stimulated insulin secretion and suppress inappropriate glucagon secretion**. Its action is *glucose-dependent* (operative only when blood glucose is above the fasting level), so it does not, by itself, cause hypoglycaemia. A relative deficiency of incretin action contributes to the impaired insulin secretion of type 2 DM, and harnessing the GLP-1 pathway — with **GLP-1 receptor agonists (GLP-1RAs)**, the dual GIP/GLP-1 agonist **tirzepatide**, and **DPP-4 inhibitors** — is now central to its management, with proven cardiorenal benefit.

Physiology of GLP-1 and the incretin axis

- ▶ **Source:** GLP-1 is classically released from **neuroendocrine L-cells of the gastrointestinal tract** after food ingestion; GIP is released from intestinal K-cells. Recent preclinical data suggest **intra-islet production of GLP-1 from pancreatic alpha cells** may also regulate insulin secretion.
- ▶ **Beta-cell action:** GLP-1 and GIP bind specific receptors on the beta cell and stimulate insulin secretion **through cyclic AMP production** — but *only when blood glucose is above the fasting level* (glucose-dependent insulintropic effect).
- ▶ **Alpha-cell action:** incretin hormones also **suppress glucagon production and secretion**.
- ▶ **Incretin effect:** this enteroinsular amplification (the augmented insulin response to enterally absorbed glucose) accounts for a large share of meal-stimulated insulin output. “Incretins”

thereby *amplify glucose-stimulated insulin secretion and suppress inappropriate glucagon secretion*.

- ▶ **Inactivation:** native GLP-1 and GIP are rapidly degraded by the enzyme **dipeptidyl peptidase IV (DPP-4)**, which is widely expressed on the surface of endothelial cells and some lymphocytes and degrades a wide range of peptides (i.e., it is *not incretin-specific*). This short half-life is the rationale for both DPP-4-resistant analogues and DPP-4 inhibitors.
- ▶ **Extrapankreatic actions:** the **GLP-1 receptor is expressed in several tissues, including the brain**; pharmacologically GLP-1RAs **slow gastric emptying** and promote **satiety and weight loss**.

Role of GLP-1 / incretins in the pathogenesis of type 2 DM

- ▶ Type 2 DM arises from the interaction of **insulin resistance, impaired (and progressively failing) insulin secretion, and increased hepatic glucose production**. Incretin biology intersects each of these.
- ▶ **Beta-cell secretory defect:** in early type 2 DM the secretory defect selectively involves **glucose-stimulated insulin secretion, with a greatly reduced first secretory phase**; overall beta-cell function is reduced by *as much as 50%* at onset and the defect is **progressive**. Because GLP-1/GIP normally augment glucose-stimulated insulin release, blunting of the **incretin axis** removes an important amplifier of meal-time insulin secretion.
- ▶ **Glucagon dysregulation:** a *decline in insulin secretion and/or increased glucagon secretion* drives hyperglycaemia. Loss of the incretin-mediated **suppression of glucagon** contributes to inappropriate post-prandial and fasting glucagon excess.
- ▶ **Hepatic glucose overproduction:** failure of hyperinsulinaemia to suppress gluconeogenesis produces fasting hyperglycaemia; glucagon excess aggravates this — both are partly counter-regulated by intact incretin signalling.
- ▶ **Islet milieu:** chronic hyperglycaemia (“glucose toxicity”), free-fatty-acid “lipotoxicity”, islet inflammation and **islet amyloid (amylin) deposition** further impair beta-cell function, compounding the deficient incretin response.
- ▶ *Coverage note:* Harrison establishes that incretins amplify glucose-stimulated insulin secretion and suppress glucagon, and that type 2 DM has a progressive secretory defect; that the **incretin effect is quantitatively diminished in established type 2 DM** is universally accepted physiology but is not separately quantified in these chapters (see Source).

GLP-1-based therapeutic agents (classification & key data)

GLP-1RAs are modified to **resist enzymatic inactivation by DPP-4**, giving sustained receptor activation. They are approved for type 2 DM **and obesity**; *higher doses of liraglutide and semaglutide than those used for glucose lowering are effective for weight loss in obesity*.

Class	Examples (per Harrison)	HbA1c reduction	Salient features
GLP-1 receptor agonists	Dulaglutide, exenatide (sustained-release), liraglutide, lixisenatide, semaglutide (oral formulation available)	0.5–1.0%	↑ glucose-stimulated insulin, ↓ glucagon, slow gastric emptying, satiety; weight loss; ↓ CV events, modest renoprotection; <i>no hypoglycaemia unless combined with a secretagogue/insulin</i>
Dual GIP + GLP-1 receptor agonist	Tirzepatide	1.8–2.4%	Once-weekly SC; dual agonism at GIPR and GLP-1R; <i>greater weight loss than a GLP-1RA alone</i>
DPP-4 inhibitors (enhance endogenous incretins)	Alogliptin, linagliptin, saxagliptin, sitagliptin, vildagliptin	0.5–0.8%	Inhibit degradation of native GLP-1/GIP → enhance the incretin effect ; oral; <i>no hypoglycaemia or weight gain</i> ; preferential post-prandial effect; reduce dose in renal impairment

- ▶ **Long-acting GLP-1RAs** (per Harrison: sustained-release exenatide, dulaglutide, lixisenatide, semaglutide) are **administered weekly** and are the most commonly used; **daily oral semaglutide** uses a formulation enabling gastric absorption that avoids proteolytic degradation in the small intestine.
- ▶ **GLP-1 action achieved is greater with GLP-1RAs than with DPP-4 inhibitors** — explaining the superior glucose lowering, weight loss and cardiovascular outcomes of the injectable/oral agonists.
- ▶ It is **not known** whether GLP-1RAs enhance beta-cell survival or proliferation, and it is unclear whether they alter the natural history of type 2 DM.

Place in management of type 2 DM

- ▶ **Glucose-dependent, low-hypoglycaemia control:** GLP-1RAs lower fasting and post-prandial glucose without intrinsic hypoglycaemia risk, an advantage over sulfonylureas/insulin.
- ▶ **Cardiorenal indication:** because GLP-1RAs (and SGLT-2 inhibitors) **reduce cardiovascular events and slow progression of renal disease**, a GLP-1RA or an SGLT-2 inhibitor should be **used in most individuals with type 2 DM**, with choice dictated by whether ASCVD, heart failure or CKD is present or whether **weight loss is a major goal**. Liraglutide, semaglutide and

dulaglutide each reduced CVD events in trials; dulaglutide also reduced composite microvascular (retinopathy/nephropathy) outcomes; semaglutide was associated with an *increased rate of retinopathy-related complications*.

- ▶ **Combination therapy:** useful regimens include **metformin + GLP-1RA** and **long-acting insulin + GLP-1RA**; fixed-dose long-acting-insulin/GLP-1RA combinations (**degludec + liraglutide**, **glargine + lixisenatide**) are effective and cause *less weight gain*. Adding a GLP-1RA to insulin **limits weight gain and reduces the insulin dose needed**. (The NIH-funded GRADE comparative-effectiveness study evaluated add-on agents to metformin, including **liraglutide** and basal insulin.)
- ▶ **Obesity / prediabetes:** GLP-1RAs and tirzepatide are weight-lowering and, given their greater weight loss, are transforming pharmacologic prevention of type 2 DM in prediabetes; intensive lifestyle measures remain foundational.
- ▶ **Practical use:** start at a **low dose and up-titrate** to minimise initial side effects (nausea being limiting); GLP-1RAs may **alter absorption of other oral drugs** because they slow gastric emptying.

Adverse effects, cautions and contraindications

- ▶ **Common:** nausea, vomiting and GI intolerance (dose-limiting; mitigated by slow titration).
- ▶ **Pancreatitis:** evidence of a **possibly increased risk of acute pancreatitis** with GLP-1RAs (less so DPP-4 inhibitors); avoid in pancreatic disease or risk factors — **heavy alcohol use, severely elevated triglycerides, hypercalcaemia**.
- ▶ **Thyroid:** FDA **black-box warning** for increased **thyroid C-cell tumours in rodents**; *contraindicated in medullary carcinoma of the thyroid or multiple endocrine neoplasia (MEN)*.
- ▶ **Other cautions:** renal disease; co-administration with agents that also slow GI motility; previous ileus; possible worsening of retinopathy. DPP-4 inhibitors: allergy/rash, hypersensitivity (anaphylaxis, angioedema, **Stevens-Johnson syndrome**), severe joint pain — reduce dose in renal insufficiency.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Diagram 1 — The incretin axis and drug targets (flow diagram).** Labels: *Ingested nutrients* → *Intestinal L-cell* → *GLP-1* and *K-cell* → *GIP* → arrow to **Pancreatic beta cell** (↑ glucose-dependent insulin, via cAMP); arrow to **Pancreatic alpha cell** (↓ glucagon); arrow to **Stomach** (delayed gastric emptying); arrow to **Brain/hypothalamus** (↑ satiety, ↓ appetite) → net ↓ post-prandial glucose + weight loss. Mark DPP-4 (rapid inactivation of GLP-1/GIP), and the two drug actions: GLP-1RA (DPP-4-resistant agonist) and DPP-4 inhibitor (blocks inactivation).

- ▶ **Diagram 2 — Pathogenic triad of type 2 DM.** Central box *Hyperglycaemia* fed by three labelled arrows: (1) **Insulin resistance** (muscle, liver, adipose), (2) **Progressive beta-cell secretory defect — loss of first-phase insulin**, (3) **Increased hepatic glucose production / glucagon excess**, with a fourth contributing arrow **Reduced incretin (GLP-1/GIP) action**.

Clinical / Diagnostic significance

- ▶ **Outcome-driven prescribing:** GLP-1RAs are a preferred add-on (or partner to SGLT-2 inhibitors) when established ASCVD, high CV risk, CKD, or obesity coexist with type 2 DM.
- ▶ **Weight and metabolic dysfunction:** in type 2 DM with metabolic-dysfunction-associated steatotic liver disease/steatohepatitis, a GLP-1RA or GIP/GLP-1 RA ($\pm$ pioglitazone) should be considered.
- ▶ **Safety screening:** take a personal/family history of medullary thyroid carcinoma/MEN and pancreatitis risk before initiation; counsel on GI side effects and slow titration; review timing of orally absorbed drugs given delayed gastric emptying.
- ▶ **Hypoglycaemia logic:** glucose-dependence means hypoglycaemia occurs essentially only when combined with a sulfonylurea or insulin — pre-emptively reduce those agents.

High-yield exam pointers

- ▶ GLP-1 = incretin from intestinal L-cells; acts via cAMP, is glucose-dependent, and suppresses glucagon — hence low intrinsic hypoglycaemia risk.
- ▶ DPP-4 rapidly inactivates GLP-1/GIP $\rightarrow$ GLP-1RAs are engineered to resist DPP-4; DPP-4 inhibitors block this degradation.
- ▶ Four cardinal GLP-1RA actions: $\uparrow$ insulin, $\downarrow$ glucagon, $\downarrow$ gastric emptying, $\uparrow$ satiety/weight loss.
- ▶ HbA1c lowering: GLP-1RA 0.5–1.0%, DPP-4i 0.5–0.8%, tirzepatide 1.8–2.4%.
- ▶ Tirzepatide = once-weekly dual GIP/GLP-1 agonist $\rightarrow$ greater weight loss than a GLP-1RA alone.
- ▶ Weekly long-acting GLP-1RAs + oral semaglutide; GLP-1 action is greater with GLP-1RAs than DPP-4 inhibitors.
- ▶ Cardiorenal benefit (liraglutide, semaglutide, dulaglutide) $\rightarrow$ a GLP-1RA or SGLT-2 inhibitor in most type 2 DM.
- ▶ Key safety flags: acute pancreatitis caution, medullary thyroid carcinoma/MEN contraindication (rodent C-cell tumours, black-box), nausea/vomiting, semaglutide–retinopathy signal.

SOURCE & COVERAGE

Harrison's Principles of Internal Medicine, 22e (2025) — Ch 416 “Diabetes Mellitus: Management and Therapies” (GLP-1RAs, tirzepatide, DPP-4 inhibitors, Table 416-6, combination/cardiorenal strategy) and Ch 415 “Diabetes Mellitus: Diagnosis, Classification, and Pathophysiology” (incretin physiology — GLP-1/GIP, cAMP, glucose-dependence, glucagon suppression, L-cell/alpha-cell source; type 2 DM secretory defect). *Coverage note:* the chapters describe incretin amplification of insulin secretion and the progressive beta-cell defect of type 2 DM but do not separately quantify the magnitude of the *incretin effect* or explicitly state that it is *reduced* in type 2 DM — that statement and the broad “ominous octet” framing are standard textbook physiology included here for completeness, not verbatim from these two chapters.

Sick Euthyroid Syndrome (Nonthyroidal Illness Syndrome)

Asked in: Paper IV Jul 2020 — RGUHS MD General Medicine

Definition / Introduction — *Sick euthyroid syndrome (SES)*, also termed *nonthyroidal illness syndrome (NTIS)* or *euthyroid sick syndrome*, refers to the constellation of abnormal circulating thyroid-function tests that arise in acutely or severely ill patients **in the absence of intrinsic hypothalamic–pituitary–thyroid (HPT) axis disease**. The hallmark is a fall in serum triiodothyronine (T3) with a reciprocal rise in reverse T3 (rT3), and in the most severely ill, a fall in thyroxine (T4) and thyrotropin (TSH). It is largely an **adaptive** response to systemic illness, fasting and inflammation rather than a true thyroid disorder, and it normalises with recovery. Its great clinical importance lies in the diagnostic confusion it creates and in the temptation to inappropriately treat it.

Pathophysiology

- ▶ **Triggers:** any acute, severe systemic illness — sepsis, trauma, burns, myocardial infarction, surgery, starvation/caloric deprivation, bone-marrow transplantation, critical illness in the ICU. The principal mediators are **pro-inflammatory cytokines, especially interleukin-6 (IL-6)** (also IL-12 and IL-18, implicated in the TSH changes).
- ▶ **Altered peripheral deiodination (the central mechanism):**
 - **Type 1 deiodinase (D1)** activity is *reduced* → impaired outer-ring (5') deiodination of T4 to active T3.
 - **Type 3 deiodinase (D3)** activity is *increased* (activated in muscle and liver, especially with hypoperfusion) → increased inner-ring (5) conversion of T4 to the inactive **reverse T3 (rT3)**; D3 is the most important source of rT3 in SES.
 - **Net effect: low T3, raised rT3, and a fall in the T3:rT3 ratio.**

- ▶ **Reverse-T3 kinetics:** rT3 is normally cleared by D1 (5'-deiodination). Because D1 is impaired, *decreased clearance* of rT3 — rather than increased production — is the major basis for the elevated rT3. T4 is also alternately metabolised to the inactive **T3 sulfate**.
- ▶ **Adaptive teleology:** the same low-T3 pattern can be induced in normal individuals by **fasting**; the fall in T3 is thought to limit catabolism and conserve energy/protein in the starved or ill patient.
- ▶ **Central (hypothalamic–pituitary) suppression — prolonged illness:** with sustained critical illness, **hypothalamic TRH gene expression falls**, pulsatile TSH secretion is lost, and TSH and T4 decline. Endogenous dopamine and hypercortisolaemia contribute; an altered feedback set-point via local type 2 deiodinase may also be involved.
- ▶ **Iatrogenic contributors** that further suppress the axis: dopamine, high-dose glucocorticoids, somatostatin, amiodarone, and iodine-containing contrast/wound dressings.

Biphasic model (acute vs prolonged critical illness)

Feature	Acute phase (hours–days)	Prolonged phase (weeks)
Dominant mechanism	Altered peripheral metabolism (↓D1, ↑D3)	Added central suppression (↓TRH, ↓pulsatile TSH)
T3	↓	↓↓ (further fall)
rT3	↑	Normalising / high-normal
T4	Brief rise → normal	↓
TSH	Brief rise → normal	Low / inappropriately normal
Interpretation	Adaptive (energy conservation)	Possibly maladaptive in part

Spectrum of biochemical patterns

- ▶ **Low T3 syndrome (most common):** ↓ total and unbound T3, with **normal T4 and TSH**; rT3 increased. Reflects impaired peripheral T4→T3 conversion.
- ▶ **Low T4 syndrome (very sick patients):** dramatic fall in both **total T4 and T3** — carries a **poor prognosis** (mortality rises as T4 falls). Driven by accelerated metabolism (muscle/liver D3 with hypoperfusion) and reduced TBG binding. Note: routine **free-T4 immunoassays are subject to artefact** when binding proteins are low and tend to *underestimate* the true free T4.
- ▶ **TSH fluctuations:** subnormal TSH (0.01–0.1 mIU/L) is seen in ~10% (especially with dopamine or glucocorticoids); raised TSH (>20 mIU/L) is seen in ~5%, characteristically during the **recovery phase**. A truly *undetectable* TSH (<0.01 mIU/L) makes **intrinsic thyroid disease (thyrotoxicosis)** more likely and warrants endocrine evaluation.
- ▶ **Recovery phase:** a rise in TSH (sometimes transiently >20 mIU/L) **precedes** normalisation of T3 and can mimic primary hypothyroidism if tested in isolation.

Disease-specific patterns (distinctive variants)

- ▶ **Acute liver disease:** initial rise in *total* (not unbound) T3 and T4 from TBG release; levels become subnormal as liver failure progresses.
- ▶ **Acute psychiatric illness:** transient rise in total and unbound T4 (usually with normal T3) in 5–30%; TSH may be low, normal or high.
- ▶ **HIV/AIDS:** T3 and T4 *rise* in early HIV (even with weight loss); T3 falls with progression to AIDS, but TSH usually stays normal.
- ▶ **Renal disease:** low T3 but with **normal rather than increased rT3** (an unusual feature) due to increased hepatic uptake of rT3.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Diagram 1 — HPT axis in SES (acute vs prolonged):** Draw a vertical axis. Boxes top-to-bottom: *Hypothalamus (TRH) → Anterior pituitary (TSH) → Thyroid (mainly T4) → Peripheral tissues*. In peripheral tissues show two arrows from T4: one via **D1/D2 (5'-deiodination) → T3 (active)** and one via **D3 (5-deiodination) → rT3 (inactive)**. Label: *Acute phase — D1↓, D3↑, T3↓, rT3↑, T3:rT3↓, TSH and T4 normal/brief rise. Prolonged phase — TRH↓ → TSH↓ → T4↓, T3↓↓. Mark trigger arrow: Cytokines (IL-6), fasting, hypoperfusion.*
- ▶ **Diagram 2 — Deiodinase pathway:** Central T4 molecule; arrow labelled **D1/D2 (outer-ring 5')** to T3; arrow labelled **D3 (inner-ring 5)** to rT3; both T3 and rT3 converging by further deiodination to **T2 (diiodothyronine)**. Annotate D1↓ and D3↑ in SES.

Clinical / Diagnostic significance

- ▶ **Avoid routine thyroid testing in acutely ill patients** unless a thyroid disorder is strongly suspected — abnormal values are common, transient and misleading.
- ▶ **Distinguishing SES from true central hypothyroidism** is the key diagnostic challenge (both show low T4/T3 with non-elevated TSH):
 - **rT3 is high (or normal) in SES but low in true hypothyroidism** — the most useful discriminator.
 - Supportive: absence of thyroid history/antibodies, the clinical context and time-course of the acute illness, and review of drugs (dopamine, glucocorticoids, amiodarone, phenytoin) affecting hormone levels or binding.
 - A low/normal TSH does **not** exclude pre-existing primary hypothyroidism in the critically ill; conversely, an **elevated T3 is highly unusual** in critical illness and should raise suspicion of thyrotoxicosis/thyroid storm.
- ▶ **Confirmation is often presumptive** — only resolution of the abnormal tests with clinical recovery clearly establishes the diagnosis; **repeat thyroid function after recovery**.

- ▶ **Management** — treat the underlying illness, not the labs:
 - **Thyroid hormone replacement (T4 and/or T3) is generally NOT recommended.** Interventional trials of hormone supplementation in the acute phase have shown **no outcome benefit**; experimentally, lowering T4 appears deleterious while a low T3:rT3 ratio seems beneficial/adaptive. CMDT explicitly states levothyroxine is **not indicated** for euthyroid sick syndrome.
 - Monitor thyroid function through recovery; give thyroid hormone only where there is genuine historic/clinical evidence of hypothyroidism.
 - In patients with **pre-existing hypothyroidism**, continue usual levothyroxine; if switching to IV, reduce the dose by ~25% (oral bioavailability ~75%).
- ▶ **Prognostic marker:** the magnitude of T3/T4 fall (the **low T4 syndrome**) correlates with illness severity and mortality; a persistently low T3:rT3 ratio after recovery has been linked to poorer functional recovery (weaker handgrip, shorter 6-minute walk).

High-yield exam pointers

- ▶ Most common pattern = **low T3 syndrome** (↓T3, normal T4/TSH, ↑rT3).
- ▶ Mechanism = ↓ **type 1 deiodinase** + ↑ **type 3 deiodinase**, driven by IL-6; rT3 rises mainly from **reduced clearance**, not overproduction.
- ▶ **rT3 = high in SES, low in true hypothyroidism** — the single best differentiator.
- ▶ **Low T4 syndrome = poor prognosis** (marker of severity / mortality).
- ▶ **TSH >20 mIU/L during recovery** can mimic primary hypothyroidism; **TSH <0.01 mIU/L** suggests true thyrotoxicosis.
- ▶ The low-T3 state is **adaptive** — also reproduced by **fasting**.
- ▶ **Do NOT give thyroid hormone**; treat the underlying illness and recheck TFTs after recovery (no proven benefit of replacement; CMDT — levothyroxine not indicated).
- ▶ Aggravating drugs: **dopamine, glucocorticoids, somatostatin, amiodarone, iodinated contrast**.
- ▶ Renal failure variant = low T3 with **normal rT3**; acute liver disease = early rise then fall in total T3/T4.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Hyperthyroidism and Other Causes of Thyrotoxicosis” (Sick Euthyroid Syndrome / Nonthyroidal Illness section) and “Thyroid Gland Physiology and Testing” (deiodinases, rT3, laboratory interpretation).
- ▶ **Williams Textbook of Endocrinology, 15e** — “Endocrine Disorders of Critical Illness” (acute vs prolonged thyroid-axis alterations, TRH suppression, treatment evidence and recovery).

- **CMDT 2026** — “Disorders of the Pituitary, Thyroid, & Adrenal Glands” (euthyroid sick syndrome — diagnosis and that levothyroxine is not indicated).

Thyroid Functions Tests

Asked in: Paper II Nov 2022 — RGUHS MD General Medicine

Definition / Introduction — Thyroid function tests (TFTs) are the biochemical, immunological and radioisotopic investigations used to assess the **hypothalamic–pituitary–thyroid (HPT) axis**, to confirm and grade thyroid dysfunction, and to establish its aetiology. Because thyroid hormone secretion is governed by a classic **negative-feedback loop**, serum **TSH** is the single most useful physiologic marker of thyroid hormone action and the first-line screening test; it is interpreted alongside free hormone levels, autoantibodies, thyroglobulin and radioiodine studies. Rational testing follows a “**TSH-first**” strategy, since with rare exceptions a normal TSH excludes a primary thyroid abnormality.

Physiologic basis & the testing strategy

- The thyroid secretes **T4** and **T3**; T4 is secreted in ~**15-fold excess** over T3 and acts as a prohormone, being converted peripherally to the more potent T3 by **deiodinases** (Type I — liver/kidney/thyroid; Type II — pituitary/brain/brown fat; Type III — inactivates T4/T3 and is the chief source of **reverse T3**).
- **TRH** from the hypothalamus stimulates pituitary **TSH**; T4/T3 feed back (mainly via **TRβ2**) to suppress TRH and TSH. Reduced hormone raises TSH; high hormone rapidly suppresses TSH.
- TSH has a long plasma **half-life** (~**50 min**) and only modest pulsatility/diurnal variation (peak at night), so a **single random measurement** is adequate.
- Because TSH changes dynamically and *logarithmically* in response to small T4/T3 shifts, the logical approach is to **first determine whether TSH is suppressed, normal or elevated**, then confirm with circulating (preferably free) hormone levels.

Serum TSH — the primary screening test

- Measured by highly sensitive, specific **immunometric (immunoradiometric)** assays that easily separate normal from suppressed values. Modern “third-generation” assays detect TSH down to **≤0.004 mIU/L**; assays sensitive to **≤0.01 mIU/L** suffice for practice.
- **Low TSH** → primary hyperthyroidism/thyrotoxicosis; **High TSH** → primary hypothyroidism. A suppressed TSH **<0.01 mIU/L** usually indicates thyrotoxicosis.
- The sensitive TSH assay has rendered the **TRH stimulation test obsolete** — failure of TSH to rise after an IV bolus of **200–400 µg TRH** carries the same meaning as a suppressed basal TSH.

- **Caveat — central (secondary) disease:** in hypothalamic–pituitary disease, TSH is *inappropriately* low-to-high-normal for a low T4; TSH must therefore **not** be used as an isolated test when pituitary/hypothalamic disease is suspected. Rare causes of an *inappropriately normal/high* TSH *with high hormones* are TSH-secreting pituitary adenoma, resistance to thyroid hormone (RTH) and assay artefact.

Pattern	TSH	Free T4	Free T3	Interpretation
Primary hyperthyroidism	Low (<0.01)	High	High/normal	Graves', toxic nodule/MNG
T3 toxicosis	Low	Normal	High	2–5% of thyrotoxicosis
Subclinical hyperthyroidism	Low	Normal	Normal	Risk of AF, bone loss
Primary hypothyroidism	High	Low	Low/normal	Hashimoto's, post-ablation
Subclinical hypothyroidism	High	Normal	Normal	Antibody-positive at risk
Central hypothyroidism	Low/normal (inappropriate)	Low	Low	Pituitary/hypothalamic
Inappropriate TSH secretion	Normal/High	High	High	TSH-oma or RTH

Measurement of thyroid hormones — total vs free

- Automated immunoassays measure serum **total T4 and total T3**, but ~99.98% of T4 and 99.7% of T3 are **protein-bound**, so total levels track binding-protein changes. The biologically active fraction is the **free (unbound) hormone**, which is preferred.
- **Direct free-hormone methods:** (1) competition of unbound hormone with radiolabelled T4/analogue for a solid-phase antibody, and (2) physical separation by **equilibrium dialysis** or **ultracentrifugation** (reference standard, but technically demanding/expensive).
- **Indirect method (now less used):** the **Free T4/T3 index** = total hormone × **thyroid hormone binding ratio (THBR)**, where THBR is derived from the **T3-resin uptake** test (resin uptake rises when binding sites are reduced, e.g. TBG deficiency, and falls in the opposite situation). The index “corrects” anomalous total values caused by binding variation.
- **Free T4** usually suffices to confirm thyrotoxicosis, but because 2–5% **have isolated T3 toxicosis**, measure **free T3** when TSH is suppressed but free T4 is normal.

Binding proteins, drugs & analytic interferences

- Carrier proteins: TBG (low concentration 1–2 mg/dL but high affinity, carries ~80% of bound hormone), **albumin** (~3.5 g/dL, binds up to 10% of T4, 30% of T3) and **transthyretin/TTR** (formerly TBPA, ~10% of T4).

- ▶ These confound *total* (not free) hormone, so free-hormone assays are preferable when binding is altered.

Factor	Effect on binding	Total T4/T3	Free T4/T3	Thyroid status
Estrogen (pregnancy, OCP, HRT, tamoxifen/SERM), inflammatory liver disease	↑ TBG	↑	Normal	Euthyroid
Androgens, nephrotic syndrome	↓ TBG	↓	Normal	Euthyroid
X-linked TBG deficiency	↓↓ TBG	Very low	Normal	Euthyroid (do not treat)
FDH (albumin R218H), familial TTR excess	↑ affinity	↑	Normal	Euthyroid (normal TSH)

- ▶ **Drugs** displacing hormone or perturbing binding/conversion: salicylates, salsalate, NSAIDs, phenytoin, carbamazepine; **propranolol**, **amiodarone**, **ipodate**, **glucocorticoids**, **PTU** also impair T4→T3 conversion.
- ▶ **Biotin interference (high-yield)**: biotin supplements/multivitamins containing $\geq 1000 \mu\text{g}$ taken < 18 h before sampling interfere with biotinylated antibodies and streptavidin capture, giving **falsely low TSH and falsely high T4/T3** (mimicking Graves'). Advise stopping biotin ≥ 2 days before testing.

Tests to determine the aetiology — antibodies & thyroglobulin

- ▶ **Anti-TPO antibodies** are the key marker of autoimmune thyroid disease: present in *almost all* autoimmune (Hashimoto's) hypothyroidism and up to **80% of Graves' disease**, usually at high titre. Since anti-Tg antibodies alone are less common, measuring **TPO antibodies alone is reasonable**. About **5–15% of euthyroid women and up to 2% of euthyroid men** are antibody-positive and are at increased risk of future dysfunction.
- ▶ **TSH-receptor antibodies (TRAb / TSI)**: stimulating antibodies of **Graves' disease**, usually measured by tracer-displacement **TRAb** assays. Uses: confirm Graves' aetiology, predict **remission** after antithyroid-drug withdrawal (higher if TRAb disappears), and predict **fetal/neonatal thyrotoxicosis** when maternal TRAb/TSI is $> 3 \times$ the **upper limit of normal** in the last trimester.
- ▶ **Serum thyroglobulin (Tg)**: raised in all thyrotoxicoses *except thyrotoxicosis factitia* (helps distinguish factitious from endogenous disease) and markedly raised in **thyroiditis**. Its principal

role is **follow-up of differentiated thyroid cancer** — after total thyroidectomy + radioablation, Tg should be **<0.2 ng/mL** (in absence of anti-Tg antibodies); measurable Tg signals residual/recurrent disease. Always interpret with **anti-Tg antibodies**, which interfere with the assay.

Radioiodine uptake & thyroid scintigraphy

- ▶ The gland selectively traps/organifies iodine isotopes (^{123}I , ^{125}I , ^{131}I) and traps $^{99\text{m}}\text{Tc}$ -pertechnetate (imaged but not organified; fractional **uptake quantitation only for iodine isotopes**).
- ▶ 24-h RAIU is 10–25% in iodine-replete normals, rising to 70–90% in Graves'.

Disorder	RAIU	Scan appearance
Graves' disease	High (70–90%)	Diffuse, homogeneous ↑ uptake, enlarged
Toxic adenoma	Focal high	“Hot” nodule; rest of gland suppressed
Toxic multinodular goiter	Patchy	Multiple hot + suppressed/cold areas
Subacute/viral/postpartum thyroiditis	Very low	Patchy/absent (follicular damage)
Thyrotoxicosis factitia	Very low	Exogenous hormone suppresses TSH
Iodine contamination (contrast)	Reduced	Low uptake despite ↑ hormone

- ▶ Scintigraphy is **not routine** for thyroid nodules but is indicated when TSH is **subnormal** to identify autonomously functioning (“hot”) nodules — these are almost never malignant, so FNA is **not required**.

Thyroid testing in special situations

- ▶ **Pregnancy:** use **trimester-specific reference ranges**. hCG weakly stimulates the TSH-R → first-trimester TSH falls; estrogen raises TBG so **total T4/T3 are ~1.5× higher** throughout pregnancy, while free T4 falls toward/below the non-pregnant range by the third trimester.
- ▶ **Non-thyroidal illness (sick-euthyroid syndrome):** any severe illness can derange TSH and lower T3 (↑Type III deiodinase, ↑reverse T3); avoid testing in acute illness unless thyroid disease is strongly suspected.
- ▶ **End-organ tests** (basal metabolic rate, ankle-reflex relaxation time, serum cholesterol) are insensitive and not used clinically.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **HPT feedback axis:** boxes for *Hypothalamus (TRH) → Anterior pituitary (TSH) → Thyroid (T4, T3) → Peripheral tissues*; draw **negative-feedback arrows** from T4/T3 back to pituitary and hypothalamus. Label *TSH-R, negative feedback*, and the deiodinase step *T4 → T3*.
- ▶ **TSH-first testing algorithm:** top box *Measure serum TSH* branching to **Low TSH → free T4 (±free T3) → thyrotoxicosis / T3 toxicosis**, **Normal TSH → euthyroid**, **High TSH → free T4 → primary hypothyroidism**; side-branch *discordant pattern → suspect central disease / RTH / assay (biotin) artefact*. Label *anti-TPO, TRAb, RAIU/scan*.

Clinical / Diagnostic significance

- ▶ TSH is the screening and monitoring test for primary thyroid disease and for titrating levothyroxine and antithyroid therapy.
- ▶ **Free T4 + TSH** together classify overt vs **subclinical** dysfunction and identify central disease (discordant TSH–T4).
- ▶ **Anti-TPO** confirms autoimmune aetiology and stratifies risk of progression; **TRAb** confirms Graves', predicts relapse and neonatal thyrotoxicosis.
- ▶ **RAIU/scan** differentiates high-uptake thyrotoxicosis (Graves', toxic nodule/MNG) from low-uptake states (thyroiditis, factitia, iodine load) — directing therapy.
- ▶ **Thyroglobulin** is the tumour marker for differentiated thyroid cancer surveillance.
- ▶ Recognising **binding-protein and biotin artefacts** prevents misdiagnosis and inappropriate treatment.

High-yield exam pointers

- ▶ **Test TSH first** — a normal TSH (with rare exceptions) excludes primary thyroid disease.
- ▶ Sensitive TSH assay detects ≤ 0.004 mIU/L; it made the **TRH stimulation test obsolete**.
- ▶ Always measure **free** hormones; total T4/T3 are misleading because **~99.98% T4 / 99.7% T3 are protein-bound** (TBG carries ~80%).
- ▶ **T3 toxicosis (2–5%)** — measure **free T3** when TSH is low but free T4 normal.
- ▶ **Biotin ≥ 1000 μg → falsely low TSH, high T4/T3; stop biotin 2 days before testing.**
- ▶ **Anti-TPO** in ~all autoimmune hypothyroidism and up to **80% of Graves'**; **TRAb = Graves' marker** and predicts **neonatal thyrotoxicosis ($>3\times$ ULN)**.
- ▶ Post-thyroidectomy/ablation **Tg <0.2 ng/mL**; rising Tg = recurrence (interpret with anti-Tg antibodies).
- ▶ **24-h RAIU:** normal 10–25%, Graves' 70–90%; **low uptake = thyroiditis / factitia / iodine load**.
- ▶ Central hypothyroidism = **low free T4 with inappropriately non-elevated TSH** — never rely on TSH alone in pituitary disease.

SOURCE & COVERAGE

Harrison's Principles of Internal Medicine, 22e (2025) — Ch 394 “Thyroid Gland Physiology and Testing” (Jameson, Weetman, Mandel), with cross-references to Ch 395 (hypothyroidism), Ch 396 (thyrotoxicosis) and Ch 397 (nodules) as cited in the chapter. Coverage note: the TSH/free-T4/free-T3 interpretation grid and the deiodinase/sick-euthyroid summary are standard textbook syntheses consistent with the chapter; quantitative limits (RAIU 10–25%/70–90%, Tg <0.2 ng/mL, biotin ≥1000 µg, TRAb >3× ULN, TRH 200–400 µg) are verbatim from Ch 394.

Thyroid Hormones: Physiology

Asked in: Paper I May 2022 — RGUHS MD General Medicine

Definition / Introduction — The thyroid gland produces two related iodothyronine hormones, **thyroxine (T4)** and **triiodothyronine (T3)**, derived by iodination and coupling of tyrosyl residues on the precursor protein **thyroglobulin (Tg)**. Acting via nuclear **thyroid hormone receptors (TR) α and β**, they are critical for cell differentiation and organogenesis during development and for maintaining **thermogenic and metabolic homeostasis** in the adult. T4 is essentially a *prohormone* that is converted in peripheral tissues to the more potent T3, the principal active hormone. Output is governed by a classic negative-feedback endocrine loop — the **hypothalamic–pituitary–thyroid (HPT) axis**.

Functional anatomy and the synthetic unit

- ▶ The gland (*Greek thyreos*, shield + *eidos*, form) has two lobes joined by an isthmus, lies anterior to the trachea between the cricoid cartilage and suprasternal notch, weighs **12–20 g**, and is highly vascular.
- ▶ It develops from the floor of the primitive pharynx in the **3rd week of gestation** and descends along the **thyroglossal duct** — explaining ectopic *lingual thyroid* and thyroglossal duct cysts. Hormone synthesis begins at **~11 weeks**.
- ▶ Development is orchestrated by transcription factors **TTF1, TTF2, NKX2-1, FOXE1 and PAX8**, which induce thyroid-specific proteins: **Tg, thyroid peroxidase (TPO), the sodium–iodide symporter (NIS) and the TSH receptor (TSH-R)**.
- ▶ The functional unit is the **follicle** — follicular cells surrounding colloid (rich in Tg). Cells are *polarized*: the **basolateral** membrane faces blood (bears NIS, TSH-R), the **apical** membrane faces the lumen (bears TPO, pendrin).
- ▶ Neural-crest–derived **parafollicular C cells** (from the ultimobranial body) secrete **calcitonin** (minimal role in human calcium homeostasis) and are the origin of medullary thyroid cancer.

Hypothalamic–Pituitary–Thyroid (HPT) axis and its regulation

- ▶ Hypothalamic TRH is the major positive regulator of TSH synthesis/secretion by anterior-pituitary thyrotropes; TSH then stimulates all steps of thyroid hormone production. Peak TSH occurs ~15 min after TRH.
- ▶ TSH is a 31-kDa glycoprotein with α and β subunits; the α subunit is shared with LH, FSH and hCG, whereas the β subunit is unique to TSH and confers specificity.
- ▶ T4 and T3 exert **negative feedback** predominantly through the TR β 2 isoform in the hypothalamus and pituitary, inhibiting both TRH and TSH. High hormone levels rapidly suppress TSH gene expression; low levels increase basal TSH and enhance TRH responsiveness — establishing the axis “set point.”
- ▶ Dopamine, glucocorticoids and somatostatin suppress TSH (significant only at pharmacologic doses).
- ▶ TSH is secreted in a **pulsatile** fashion with a **diurnal rhythm** (highest at night) but has a long plasma half-life (~50 min), so a *single TSH measurement* reliably reflects circulating levels.
- ▶ TSH acts via the TSH-R, a seven-transmembrane G-protein-coupled receptor linked to G α → adenylyl cyclase → cyclic AMP; it also activates phospholipase C (phosphatidylinositol turnover).

Biosynthesis of thyroid hormones (sequential steps)

- ▶ **Iodide trapping** — NIS on the basolateral membrane actively concentrates iodide; in the iodine-replete state the gland takes up 10–25% of a tracer dose over 24 h, rising to 70–90% in Graves’ disease. NIS is up-regulated by low iodine/TSH and suppressed by high iodine. (Pendrin on the apical membrane effluxes iodide into the lumen; its mutation causes Pendred syndrome — defective organification, goiter, sensorineural deafness.)
- ▶ **Organification** — at the apical surface, TPO with H₂O₂ (generated by DUOX/DUOXA) oxidises iodide and adds it to tyrosyl residues of Tg, forming **monoiodotyrosine (MIT)** and **diiodotyrosine (DIT)**.
- ▶ **Coupling** — TPO catalyses ether-linkage coupling of iodotyrosines: DIT + DIT → T₄; MIT + DIT → T₃, stored within Tg in colloid.
- ▶ **Storage and release** — TSH triggers reuptake (endocytosis) of Tg into the follicular cell, lysosomal proteolysis, and secretion of T₄ and T₃. Uncoupled MIT/DIT are deiodinated by **iodotyrosine deiodinase**, recycling iodide.
- ▶ **Autoregulation** — excess iodide transiently inhibits its own organification, the **Wolff–Chaikoff effect**; a normal gland “escapes” this within days.
- ▶ **Iodine requirement**: RDA 220 μ g/day (pregnancy) and 290 μ g/day (lactation); the ATA advises prenatal supplements containing 150 μ g/day; urinary iodine >100 μ g/L indicates sufficiency.

Transport, binding proteins and peripheral metabolism

- T4 is secreted in ~15-fold excess over T3. Both circulate almost entirely **protein-bound** — ~99.98% of T4 and ~99.7% of T3 — to **thyroxine-binding globulin (TBG)**, **transthyretin (TTR)** / **thyroxine-binding prealbumin**) and **albumin**. Only the small **unbound (free)** fraction is biologically active; homeostasis defends free-hormone levels.

Binding protein	Plasma level / affinity	Share of bound hormone
TBG	Low conc. (1–2 mg/dL), high affinity (T4 > T3)	carries ~80%
Albumin	High conc. (~3.5 g/dL), low affinity	binds up to 10% T4, 30% T3
Transthyretin (TTR)	Intermediate	~10% of T4, little T3
Property (Table 394-1)	T4	T3
Total serum concentration	8 µg/dL	0.14 µg/dL
Fraction unbound (free)	0.02%	0.3%
Production rate (incl. peripheral conversion)	90 µg/d	32 µg/d
Fraction arising directly from thyroid	100%	~20% (rest = peripheral conversion)
Serum half-life	~7 days	~1 day
Relative metabolic potency	0.3	1

- **Deiodinases** convert/inactivate hormone in the periphery and determine local T3 availability:

Enzyme	Reaction / site	Physiologic role
Type I (D1)	5'-deiodination; thyroid, liver, kidney; low T4 affinity	major source of circulating T3
Type II (D2)	5'-deiodination; pituitary, brain, brown fat, thyroid; high T4 affinity	local intracellular T3; induced in hypothyroidism; important during levothyroxine (T4) replacement
Type III (D3)	5-(inner-ring) deiodination; placenta, muscle/liver in illness	inactivates T4 & T3; chief source of reverse T3 (rT3); up in sick-euthyroid syndrome; large hemangiomas → consumptive hypothyroidism

- **Drugs/states impairing T4 → T3 conversion** (raising rT3): **propylthiouracil, propranolol, amiodarone, glucocorticoids**, iodinated contrast (ipodate, iopanoic acid), fasting, acute illness/trauma — the basis of the **sick-euthyroid (low-T3) syndrome**.

Mechanism of action

- ▶ Thyroid hormones enter cells by passive diffusion and via specific transporters — **MCT8, MCT10 and OATP1C1**; *MCT8* mutations cause X-linked psychomotor retardation (low T₄, high T₃, high TSH).
- ▶ They act mainly through **nuclear receptors TR α and TR β** (tissue distribution: **TR α** — brain, kidney, gonads, **muscle, heart**; **TR β** — pituitary, liver; **TR β 2** — hypothalamus/pituitary feedback).
- ▶ **T₃ binds TR with 10–15× greater affinity than T₄**, explaining its greater potency; receptors are occupied mainly by T₃.
- ▶ TR forms heterodimers with the **retinoid X receptor (RXR)** and binds **thyroid response elements (TREs)** in target-gene promoters. *Without hormone*, TR binds **co-repressors** that silence transcription; *T₃ binding* dissociates co-repressors and recruits **co-activators**, altering transcription (stimulating e.g. myosin heavy chain α , or repressing e.g. TSH β -subunit).
- ▶ **Non-genomic actions** also occur via mitochondrial enzymes and **integrin receptors** on blood vessels and heart.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **HPT axis feedback loop:** Hypothalamus → **TRH (+)** → Anterior pituitary → **TSH (+)** → Thyroid → **T₄ / T₃** → negative feedback (–) arrows back to pituitary (via **TR β 2**) and hypothalamus. Label modulators: dopamine/glucocorticoids/somatostatin (–), peripheral **deiodinase (T₄→T₃)**.
- ▶ **Follicular cell synthesis schematic:** Label **bloodstream**, **basolateral membrane (NIS, TSH-R)**, **apical membrane (TPO, pendrin)**, **colloid/lumen with Tg**, steps — **iodide trapping (NIS) → organification (TPO + H₂O₂) → MIT/DIT → coupling → T₄/T₃**; cAMP second messenger from TSH-R.

Clinical / Diagnostic significance

- ▶ **TSH is the single best first-line test** of thyroid status: high in primary hypothyroidism, low in thyrotoxicosis; modern assays detect ≤ 0.01 mIU/L. An abnormal TSH is confirmed with **free T₄ ($\pm$ free T₃)**.
- ▶ **TSH is unreliable** in central (secondary) hypothyroidism, recent treatment of thyrotoxicosis, severe non-thyroidal illness and TSH-secreting adenoma — here measure **free T₄** directly.
- ▶ Altered binding proteins (estrogen/pregnancy raise **TBG**; androgens/nephrotic syndrome lower it; **FDH, RTH**) change **total** but not **free** hormone — measure free fractions to avoid misdiagnosis.

- ▶ **Pregnancy physiology:** hCG weakly stimulates TSH-R (first-trimester TSH dip $\pm$ gestational thyrotoxicosis/hyperemesis); estrogen raises TBG (total T4/T3 $\sim 1.5\times$); placental D3 increases hormone turnover; levothyroxine needs rise by up to 45%.
- ▶ Etiologic tests: **anti-TPO/anti-Tg antibodies** (autoimmune disease), **TRAb/TSI** (Graves'), serum **Tg** (thyroid-cancer follow-up), and **radioiodine uptake/scan** (high homogeneous in Graves', focal "hot" toxic adenoma, low in thyroiditis/factitia).

High-yield exam pointers

- ▶ DIT + DIT $\rightarrow$ T4; MIT + DIT $\rightarrow$ T3; coupling and organification are both TPO-catalysed.
- ▶ NIS = basolateral (iodide in); pendrin = apical (iodide to lumen) — Pendred syndrome = goiter + deafness.
- ▶ T4 half-life ~ 7 days, T3 ~ 1 day; T4:T3 secretion $\sim 15:1$; $>99\%$ protein-bound; only free hormone is active.
- ▶ D1 (liver/kidney) $\rightarrow$ circulating T3; D2 (pituitary/brain/brown fat) $\rightarrow$ local T3; D3 $\rightarrow$ inactivation + rT3.
- ▶ TR β 2 mediates pituitary feedback; RTH is usually a dominant-negative TR β mutation (high T4/T3 with non-suppressed TSH).
- ▶ Wolff–Chaikoff effect = iodide excess transiently blocks organification; TSH-R = Gsa/cAMP GPCR.
- ▶ Drugs blocking T4 $\rightarrow$ T3: PTU, propranolol, amiodarone, glucocorticoids, iodinated contrast — recall in sick-euthyroid syndrome.
- ▶ TSH α -subunit is shared (LH/FSH/hCG); β -subunit is hormone-specific.

SOURCE & COVERAGE

Harrison's Principles of Internal Medicine, 22e (2025) — Ch 394 "Thyroid Gland Physiology and Testing" (Jameson, Weetman, Mandel). Fully covers the ask. *Coverage note:* T3 serum half-life is stated here as the standard textbook value (~ 1 day) as the source Table 394-1 OCR value is ambiguous; MCT8-mutation eponym (Allan–Herndon–Dudley syndrome) is standard medicine and not named verbatim in the provided text.

Vitamin D in Health and Disease

Asked in: Paper I Dec 2023 — RGUHS MD General Medicine

Definition / Introduction — Vitamin D is a fat-soluble *secosteroid* that functions as a **hormone precursor** rather than a true vitamin, since in the proper biologic setting it can be synthesised endogenously in skin. Its active metabolite, **1,25-dihydroxyvitamin D** [1,25(OH) $_2$ D, **calcitriol**], is the

major steroid hormone regulating mineral-ion homeostasis, acting through the nuclear **vitamin D receptor (VDR)** to maintain serum calcium and phosphate and to mineralise the skeleton. Deficiency produces **rickets** in children and **osteomalacia** in adults, while the wide tissue distribution of the VDR underlies proposed (largely unproven) non-skeletal roles.

SOURCE & COVERAGE

- ▶ **Two forms, equal activity:** Vitamin D₂ (**ergocalciferol**) from plant sources; vitamin D₃ (**cholecalciferol**) from animal sources and cutaneous synthesis. Both are activated equally by human vitamin D hydroxylases.
- ▶ **Cutaneous synthesis (major source):** UV-B radiation (290–320 nm) cleaves 7-dehydrocholesterol in skin to vitamin D₃. Reduced by **melanin, high-SPF sunblock, ageing, and limited sun exposure**, increasing reliance on diet (fortified cereals/dairy, fish oils, egg yolks).
- ▶ **Transport:** Vitamin D circulates bound to **vitamin D-binding protein (DBP)**, an α -globulin made in the liver.
- ▶ **First hydroxylation (liver):** A hepatic cytochrome P450 oxidase performs 25-hydroxylation $\rightarrow$ **25-hydroxyvitamin D [25(OH)D]**, the major circulating and storage form. This step is *not tightly regulated*. Half-life $\sim$ 2–3 weeks; $\sim$ 88% bound to DBP, $\sim$ 0.03% free.
- ▶ **Second hydroxylation (kidney) — the rate-limiting, regulated step:** The 25(OH)D-1 α -hydroxylase (CYP27B1) in proximal convoluted tubule cells produces active 1,25(OH)₂D.
 - *Inducers:* PTH and hypophosphatemia. *Repressors:* calcium, FGF23, and 1,25(OH)₂D itself.
- ▶ **Extra-renal 1 α -hydroxylase:** Present in keratinocytes, placental trophoblast, and macrophages of granulomas and lymphomas — induced by IFN- γ and TNF- α , unregulated by calcium $\rightarrow$ cause of **PTH-independent hypercalcemia** (e.g., sarcoidosis).
- ▶ **Inactivation:** 24-hydroxylase (CYP24A1) adds a hydroxyl group; induced by 1,25(OH)₂D (negative feedback) and FGF23. *CYP24A1 loss-of-function* causes infantile hypercalcemia, hypercalciuria, nephrocalcinosis and nephrolithiasis.

Mechanism of Action and Physiological Roles

- ▶ **VDR:** Member of the nuclear-receptor superfamily; binds DNA as a **heterodimer with the retinoid X receptor (RXR)** at vitamin D response elements, recruiting coactivators to regulate transcription. Affinity for 1,25(OH)₂D is **$\sim$ 1000-fold** higher than for other metabolites.
- ▶ **Intestine (the dominant action):** Induces **calbindin-9K** and the calcium channels **TRPV5 and TRPV6**, increasing the efficiency of **active calcium absorption**. (Phosphate is absorbed efficiently even without vitamin D.)

- ▶ **Bone:** In osteoblasts upregulates **osteocalcin** and **osteopontin** and represses type I collagen; with PTH induces **RANK ligand**, driving osteoclast differentiation and **bone resorption**; induces FGF23 in osteocytes (phosphate regulation).
- ▶ **Parathyroid:** Antiproliferative on parathyroid cells and **suppresses transcription of the PTH gene** — the rationale for vitamin D analogue therapy in renal hyperparathyroidism.
- ▶ **Non-classical:** Antiproliferative effects on keratinocytes, breast and prostate cancer cells; roles proposed in muscle, immune function and inflammation. Alopecia of VDR mutation is *ligand-independent*.

Vitamin D Deficiency: Causes and Pathophysiology

Mechanistically, deficiency arises from defective production, intake, loss, activation, or resistance (Table 421-6):

Mechanism	Representative causes
Impaired cutaneous production	Ageing, dark skin, sunblock, northern latitude, institutionalisation
Dietary absence / malabsorption	Poor intake; short-gut syndrome, gastric bypass , fat malabsorption
Accelerated loss / inactivation	Barbiturates, phenytoin, rifampin (P450 induction); impaired enterohepatic circulation (terminal ileal disease); nephrotic syndrome (urinary DBP loss); CYP3A4 gain-of-function
Impaired 25-hydroxylation	Severe liver disease, isoniazid , 25-hydroxylase mutation
Impaired 1 α -hydroxylation	Hypoparathyroidism , ketoconazole, CYP27B1 mutation, FGF23 excess / oncogenic osteomalacia , X-linked hypophosphatemia, chronic kidney disease
Target-organ resistance	VDR mutation , phenytoin
Other	Obesity

- ▶ **Pathophysiologic cascade:** ↓ intestinal calcium absorption → ↓ serum (ionised) calcium → **secondary hyperparathyroidism** → ↑ bone turnover (raised **alkaline phosphatase**), ↓ urinary calcium and **phosphaturia** → **hypophosphatemia**, which worsens the mineralisation defect.
- ▶ **Rickets (children, before epiphyseal fusion):** Growth retardation with **expansion of the hypertrophic chondrocyte zone** of the growth plate (impaired apoptosis of late hypertrophic chondrocytes); clinically rachitic rosary, bowed legs, frontal bossing.
- ▶ **Osteomalacia (adults):** Defective mineralisation of bone matrix → biomechanically inferior bone, **bowing of weight-bearing limbs and fractures**.

- ▶ **Proximal myopathy:** Striking feature in severe deficiency; resolves rapidly with treatment.
- ▶ Severe acute hypocalcemia is uncommon unless precipitated by concurrent **hypomagnesemia** or potent bisphosphonates.

Inherited Rickets — VDDR Type I vs Type II

Feature	Pseudovitamin D–deficiency rickets (VDDR I)	Hereditary vitamin D–resistant rickets (VDDR II)
Defect	Mutation in renal 1 α -hydroxylase (CYP27B1)	VDR mutation (hormone resistance)
Inheritance	Autosomal recessive	Autosomal recessive
Serum 1,25(OH) ₂ D	Low (despite normal 25(OH)D)	Markedly elevated
PTH	Elevated	Elevated
Alopecia	Absent	Often present (ligand-independent VDR role in hair follicle)
Treatment	Calcitriol / 1,25(OH) ₂ D (bypasses block)	High-dose calcium $\pm$ phosphate, often IV infusions

Assessment, Treatment, Prevention and Toxicity

- ▶ **Best test:** Serum 25(OH)D (reflects stores). Levels <37 nmol/L (<15 ng/mL) associate with rising PTH and lower bone density.
- ▶ **Sufficiency (National Academy of Medicine):** >50 nmol/L (>20 ng/mL); some experts advocate >30 ng/mL for non-skeletal endpoints (to convert ng/mL $\rightarrow$ nmol/L, $\times 2.496$).
- ▶ **RDA:** 600 IU/d (15 μ g/d) for most adults; 800 IU/d (20 μ g/d) for those >70 years.
- ▶ **Treatment of deficiency:** 50,000 IU vitamin D weekly for 6–8 weeks, then maintenance 800 IU/d (20 μ g/d) from food and supplements once levels normalise. D₂ and D₃ have similar long-term effect.
- ▶ **Glucocorticoid-induced osteoporosis prevention:** Calcium 1000–1200 mg/d + vitamin D 600–800 IU/d with weight-bearing exercise.
- ▶ **Toxicity:** Tolerable **upper limit** 4000 IU/d; true intoxication is rare and usually from excessive supplements or faulty fortification $\rightarrow$ **hypercalcemia** (high 1,25(OH)₂D and very high 25(OH)D displacing 1,25(OH)₂D from DBP). Manage by stopping vitamin D/calcium and treating hypercalcemia.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Vitamin D activation cascade (Fig 421-4/421-5):** Boxes/arrows — *Skin:* 7-dehydrocholesterol $\rightarrow$ (UV-B) $\rightarrow$ Vitamin D₃; *Diet:* D₂/D₃; $\rightarrow$ *Liver:* 25-hydroxylase $\rightarrow$

25(OH)D (major circulating form); → Kidney: 1 α -hydroxylase (CYP27B1) → 1,25(OH)₂D.
Label regulators on the renal step — + PTH, + low PO₄ / – Ca²⁺, – FGF23, – 1,25(OH)₂D
— and the 24-hydroxylase (CYP24A1) → inactivation branch. Show targets: Intestine
(↑Ca absorption), Bone, Parathyroid (– PTH).

- ▶ **Deficiency feedback loop:** ↓Vitamin D → ↓intestinal Ca → ↓serum Ca → ↑PTH (secondary hyperPTH) → ↑bone resorption + phosphaturia → ↓PO₄ → impaired mineralisation (rickets/osteomalacia).

Clinical / Diagnostic significance

- ▶ **Diagnostic panel of deficiency:** ↓ or low-normal calcium, low phosphate, high alkaline phosphatase, high PTH, low 25(OH)D; radiographs show osteopenia/Looser zones/rachitic changes.
- ▶ **Vitamin D analogues** suppress PTH gene transcription — used in **secondary hyperparathyroidism** of CKD.
- ▶ **Granulomatous/lymphoma hypercalcemia** (extra-renal 1 α -hydroxylase) responds to glucocorticoids, ketoconazole or chloroquine.
- ▶ Calcium + vitamin D supplementation reduces **hip fractures** in deficient elderly/nursing-home residents; deficiency is associated with increased overall and cardiovascular mortality.
- ▶ **Evidence caveat (high-yield):** Recent placebo-controlled trials show **no therapeutic benefit** of vitamin D for prevention of cancer, cardiovascular disease, type 2 diabetes, depression, tuberculosis or respiratory infection — supplementation is justified mainly for **bone health/correction of deficiency**, not as a population-wide disease-prevention strategy.

High-yield exam pointers

- ▶ Active hormone = 1,25(OH)₂D (calcitriol); storage/best-test form = 25(OH)D.
- ▶ Rate-limiting, regulated step = renal 1 α -hydroxylase (CYP27B1): ↑ by PTH/low phosphate, ↓ by Ca/FGF23/1,25(OH)₂D.
- ▶ VDR acts as **VDR–RXR heterodimer**; chief action is **intestinal calcium absorption** (calbindin, TRPV5/6).
- ▶ **Deficiency biochemistry:** ↓Ca, ↓PO₄, ↑ALP, ↑PTH, ↓25(OH)D.
- ▶ **Rickets** = growth-plate (hypertrophic-zone) expansion; **osteomalacia** = defective matrix mineralisation; **proximal myopathy** reversible.
- ▶ **VDDR I** = enzyme defect → low 1,25(OH)₂D, give calcitriol; **VDDR II** = receptor defect → high 1,25(OH)₂D + **alopecia**, resistant.
- ▶ Sufficiency >20 ng/mL; RDA 600 IU/d (800 if >70 y); treat with 50,000 IU/week ×6–8 wk; upper limit 4000 IU/d.

- **Sarcoidosis/lymphoma** → $1,25(\text{OH})_2\text{D}$ -mediated hypercalcemia, steroid-responsive.

SOURCE & COVERAGE

Harrison 22e — Ch 421 “Bone and Mineral Metabolism in Health and Disease” (vitamin D synthesis, metabolism, VDR action, deficiency, rickets/osteomalacia, VDDR I/II, diagnosis) + Ch 344 “Vitamin and Trace Mineral Deficiency and Excess” (dietary sources, reference ranges, RDA/treatment dosing, toxicity, non-skeletal-disease evidence). *Coverage note:* All classifications, doses, enzyme/gene names and cut-offs above are drawn from these two chapters; standard deficiency-panel correlations (Looser zones, frontal bossing) are universally accepted textbook medicine added for completeness.

Vitamin D physiology

Asked in: Paper I May 2022 — RGUHS MD General Medicine

Definition / Introduction — *Vitamin D* is best regarded as a **prohormone**, not a true vitamin: in the proper biologic setting it can be synthesised endogenously in skin, and its active metabolite **1,25-dihydroxyvitamin D** [$1,25(\text{OH})_2\text{D}$, **calcitriol**] is the major **steroid hormone** regulating mineral-ion (calcium and phosphate) homeostasis. The native vitamin is biologically inert and must undergo **two sequential hydroxylations** — 25-hydroxylation in the liver and tightly regulated 1α -hydroxylation in the kidney — to become active. It acts through a nuclear **vitamin D receptor (VDR)** to optimise intestinal calcium and phosphate absorption, support skeletal mineralisation, and complete the parathyroid–calcium feedback loop.

SOURCE & COVERAGE

- **Cutaneous synthesis (major source):** ultraviolet (UV-B) radiation of skin causes photochemical cleavage of **7-dehydrocholesterol** → **vitamin D₃**. This is the dominant physiological source.
- Cutaneous production is **reduced** by melanin (dark skin), high-SPF sunblocks (which block UV-B skin penetration), reduced solar exposure, and ageing — driving increased reliance on dietary vitamin D.
- **Dietary sources:** fortified cereals and dairy products, fish oils, egg yolks.
 - **Vitamin D₂ (ergocalciferol)** — from plant sources.
 - **Vitamin D₃ (cholecalciferol)** — from animal sources.
 - Both forms have **equivalent biologic activity** and are activated equally well by human vitamin D hydroxylases.

Synthesis and two-step metabolic activation

Whether absorbed from the gut or synthesised in skin, vitamin D enters the circulation bound to **vitamin D-binding protein (DBP)**, an α -globulin made in the liver, then undergoes ordered activation:

Step	Site / enzyme	Product	Regulation
25-hydroxylation	Liver — cytochrome P450 oxidase (mitochondria + microsomes)	25-hydroxyvitamin D [25(OH)D]	Not tightly regulated; reflects substrate supply
1 α -hydroxylation	Kidney — CYP27B1 (25-OH-D-1 α -hydroxylase) in proximal convoluted tubule	1,25(OH) ₂ D (calcitriol) — the active hormone	Tightly regulated
24-hydroxylation (inactivation)	Most tissues — CYP24A1 (24-hydroxylase)	24,25(OH) ₂ D / 1,24,25(OH) ₃ D (inactive)	Induced by 1,25(OH) ₂ D and FGF23

- ▶ 25(OH)D is the **major circulating and storage form**: ~88% bound to DBP, ~0.03% free, the remainder bound to albumin; half-life ~2–3 weeks. Hence it is the **best index of vitamin D status**.
- ▶ DBP affinity is lower for the D₂ metabolites, so 25(OH)D₂ has a shorter half-life than 25(OH)D₃; half-life also shortens when DBP is lost (e.g., **nephrotic syndrome**).

Regulation of the active hormone (hormonal control loop)

- ▶ CYP27B1 (1 α -hydroxylase) is the key control point:
 - Induced ($\uparrow$ 1,25(OH)₂D) by: PTH and hypophosphatemia.
 - Repressed ($\downarrow$ 1,25(OH)₂D) by: calcium, FGF23, and the product 1,25(OH)₂D itself (negative feedback).
- ▶ **Integrated calcium loop**: a fall in serum calcium below ~2.2 mmol/L (8.8 mg/dL) stimulates PTH secretion $\rightarrow$ mobilises bone calcium and stimulates renal 1,25(OH)₂D synthesis $\rightarrow$ 1,25(OH)₂D enhances **intestinal calcium absorption** and, with PTH, restores serum calcium; 1,25(OH)₂D in turn **suppresses PTH gene transcription** (closing the loop).
- ▶ **Auto-limitation**: 1,25(OH)₂D is the major inducer of its own catabolising enzyme CYP24A1, promoting its own inactivation and limiting biologic effect.
- ▶ **Extrarenal 1 α -hydroxylase** is expressed in keratinocytes, the placental trophoblast, and **macrophages of granulomas and lymphomas**, where it is induced by IFN- γ and TNF- α and is NOT regulated by calcium or 1,25(OH)₂D — explaining the **hypercalcemia of sarcoidosis/granulomatous disease and lymphoma** (responsive to glucocorticoids, ketoconazole, chloroquine in sarcoid).

Mechanism of action — VDR and target-organ effects

1,25(OH)₂D binds the **vitamin D receptor (VDR)**, a member of the nuclear-receptor superfamily (related to thyroid hormone, retinoid, and PPAR receptors). The VDR heterodimerises with the **retinoid X receptor (RXR)**, binds vitamin D response elements, and recruits coactivators to modulate target-gene transcription. The VDR's affinity for 1,25(OH)₂D is **~1000-fold (three orders of magnitude)** higher than for other metabolites.

Target tissue	Action of 1,25(OH) ₂ D
Intestine	Induces calbindin-9K and calcium channels TRPV6 (gut) / TRPV5 (renal); increases efficiency of active calcium absorption and stimulates phosphate absorption (Na ⁺ /PO ₄ cotransporters, e.g., Npt2b)
Bone (osteoblast)	Upregulates osteocalcin , osteopontin ; represses type I collagen ; with PTH induces RANK ligand → osteoclast differentiation and bone resorption
Osteocyte	Induces FGF23 → regulates phosphate homeostasis
Parathyroid	Antiproliferative ; suppresses PTH gene transcription
Skin / other	Antiproliferative on keratinocytes, breast and prostate cancer cells; VDR mutation → alopecia (a ligand-independent effect, not seen in simple deficiency); regulates the bone–tendon attachment (enthesis)

- ▶ Active (transcellular, 1,25(OH)₂D-dependent) calcium transport occurs mainly in **duodenum/proximal jejunum** and normally accounts for **20–70%** of dietary calcium absorption; passive paracellular absorption (~5%) is vitamin D-independent.

Vitamin D deficiency — causes and consequences

Biochemical cascade: deficiency → impaired intestinal calcium absorption → **hypocalcemia** → **secondary hyperparathyroidism** → increased bone turnover (↑**alkaline phosphatase**), **phosphaturia** → **hypophosphatemia** → impaired skeletal **mineralisation**.

- ▶ **Children (before epiphyseal fusion): rickets** — expansion of the growth-plate **hypertrophic chondrocyte zone** (of the reserve, proliferating, hypertrophic zones).
- ▶ **Adults: osteomalacia** — defective mineralisation of bone matrix; plus **proximal myopathy**, osteopenia/low BMD; associated with **increased overall (incl. cardiovascular) mortality**.

Mechanism	Examples (Table 421-6)
Vitamin D deficiency	Impaired cutaneous production; dietary absence; malabsorption (short-gut, gastric bypass)
Accelerated loss / catabolism	Hepatic P450 inducers — barbiturates , phenytoin , rifampin ; impaired enterohepatic circulation

Mechanism	Examples (Table 421-6)
	(terminal ileal disease); nephrotic syndrome; CYP3A4 mutation
Impaired 25-hydroxylation	Liver disease, isoniazid; 25-hydroxylase mutation
Impaired 1 α -hydroxylation	Hypoparathyroidism; ketoconazole; CYP27B1 (1 α -hydroxylase) mutation; FGF23 excess; oncogenic osteomalacia; chronic kidney disease
Target-organ resistance	VDR mutation; obesity

- ▶ **Pseudovitamin D–deficiency rickets (vitamin D–dependent rickets type I):** autosomal-recessive 1 α -hydroxylase (CYP27B1) mutation — low 1,25(OH) $_2$ D, normal/high 25(OH)D, high PTH; responds to calcitriol.
- ▶ **Hereditary vitamin D–resistant rickets (type II):** VDR mutation with end-organ resistance — markedly elevated 1,25(OH) $_2$ D, often alopecia; needs calcium $\pm$ phosphate infusions to bypass the defect.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Vitamin D synthesis and activation cascade (vertical flow):** Skin: 7-dehydrocholesterol $\rightarrow$ (UV-B) $\rightarrow$ Vitamin D $_3$ and Diet: D $_2$ /D $_3$ $\rightarrow$ DBP-bound transport $\rightarrow$ Liver: 25-hydroxylase $\rightarrow$ 25(OH)D $\rightarrow$ Kidney (PCT): 1 α -hydroxylase/CYP27B1 $\rightarrow$ 1,25(OH) $_2$ D $\rightarrow$ target organs. Side label: 24-hydroxylase/CYP24A1 $\rightarrow$ inactive 24,25(OH) $_2$ D.
- ▶ **Hormonal control loop (Harrison Fig. 421-5):** central box Blood calcium; arrows to Parathyroid glands (PTH), Kidney (1,25(OH) $_2$ D), Bone, Intestine. Labels: $\downarrow$ Ca $^{2+}$ $\rightarrow$ $\uparrow$ PTH; PTH + $\downarrow$ PO $_4$ $\rightarrow$ $\uparrow$ 1 α -hydroxylase; 1,25(OH) $_2$ D $\rightarrow$ $\uparrow$ gut Ca $^{2+}$ /PO $_4$ absorption; Ca $^{2+}$, FGF23, 1,25(OH) $_2$ D $\rightarrow$ $\downarrow$ 1 α -hydroxylase; 1,25(OH) $_2$ D $\rightarrow$ $\downarrow$ PTH gene (negative feedback).

Clinical / Diagnostic significance

- ▶ **Best screening test:** serum 25(OH)D (reflects stores). <37 nmol/L (<15 ng/mL) associates with rising PTH and lower bone density; National Academy of Medicine defines sufficiency as >50 nmol/L (>20 ng/mL) (higher may be needed in the elderly/obese).
- ▶ Do **not** use serum 1,25(OH) $_2$ D to assess deficiency — it may be normal or high (driven by secondary hyperparathyroidism) despite depleted stores.
- ▶ **Deficiency biochemistry:** $\downarrow$ Ca, $\downarrow$ PO $_4$, $\uparrow$ PTH, $\uparrow$ alkaline phosphatase, low 25(OH)D.
- ▶ **At-risk groups:** elderly/nursing-home residents (skin synthesis and gut absorption both decline with age), malabsorption/short-gut/bariatric surgery, terminal ileal disease, nephrotic syndrome, chronic liver/kidney disease, obesity, enzyme-inducing drugs.
- ▶ **Management principles (from chapter):** calcium + vitamin D supplementation reduces hip-fracture incidence in deficient elderly; in CKD/hypoparathyroidism use calcitriol/active

analogues to bypass the 1α -hydroxylation block; type II resistant rickets needs calcium/phosphate infusions.

- ▶ **Hypercalcemia of granulomatous disease/lymphoma** is driven by unregulated extrarenal 1α -hydroxylase — treat with glucocorticoids ($\pm$ ketoconazole/chloroquine).
- ▶ **CYP24A1 loss-of-function** mutation $\rightarrow$ impaired inactivation $\rightarrow$ **infantile hypercalcemia**, later hypercalciuria, nephrocalcinosis, nephrolithiasis.

High-yield exam pointers

- ▶ Vitamin D is a **prohormone**; $1,25(\text{OH})_2\text{D}$ (**calcitriol**) is the active steroid hormone.
- ▶ Activation = liver 25-hydroxylase (**not regulated**) then renal CYP27B1/ 1α -hydroxylase (**tightly regulated**).
- ▶ **1α -hydroxylase**: $\uparrow$ by PTH + hypophosphatemia; $\downarrow$ by calcium, FGF23, $1,25(\text{OH})_2\text{D}$.
- ▶ $25(\text{OH})\text{D}$ = best status marker (half-life 2–3 weeks, $\sim 88\%$ DBP-bound); sufficiency >20 ng/mL.
- ▶ Action via **VDR–RXR heterodimer**; affinity for $1,25(\text{OH})_2\text{D}$ **1000 $\times$ higher** than other metabolites.
- ▶ Gut: induces **calbindin-9K** + TRPV6 $\rightarrow$ calcium absorption (duodenum/jejunum, 20–70%).
- ▶ Deficiency $\rightarrow$ $\downarrow$ Ca, **secondary hyperPTH**, $\downarrow\text{PO}_4$, $\uparrow$ ALP $\rightarrow$ **rickets (children)/osteomalacia (adults)** + proximal myopathy.
- ▶ **CYP24A1 (24-hydroxylase)** inactivates vitamin D; mutation $\rightarrow$ infantile hypercalcemia.
- ▶ **Type I rickets** = CYP27B1 mutation (treat calcitriol); **Type II** = VDR mutation + alopecia (very high $1,25(\text{OH})_2\text{D}$).

SOURCE & COVERAGE

Harrison 22e — Ch 421 “Bone and Mineral Metabolism in Health and Disease” (Vitamin D: synthesis/metabolism, actions, deficiency; Figs 421-4 and 421-5; Tables 421-6). **Coverage note:** the chapter names the dietary forms as “vitamin D_2/D_3 ” but does not use the terms *ergocalciferol/cholecalciferol*; these (and *calcitriol* for $1,25(\text{OH})_2\text{D}$) are added as universally accepted standard nomenclature. Harrison Ch 421 does not specify numeric vitamin D RDA/IU or repletion **dosing regimens**, so quantitative treatment doses are deliberately omitted; only the chapter’s qualitative management points are stated.

Environment & poisonings

◆ ◆ ◆

Carbon Monoxide Poisoning

Asked in: Paper IV Jun 2024 — RGUHS MD General Medicine

Definition / Introduction — Carbon monoxide (CO) is a colourless, odourless, non-irritant gas produced by incomplete combustion of carbon-containing fuels. It is a prototype “**asphyxiant**” (systemic chemical hypoxia) poison that binds haemoglobin with ~200–250 times the affinity of oxygen, forming **carboxyhaemoglobin (COHb)**, thereby reducing oxygen-carrying capacity, impairing oxygen delivery and disrupting cellular oxidative metabolism. It is one of the leading causes of poisoning death worldwide — in the United States alone it accounts for >50,000 emergency-department visits and ~2000 deaths per year — and is frequently lethal before the patient reaches hospital.

SOURCE & COVERAGE

- ▶ **Common sources:** automobile exhaust, smoke inhalation in house/structural fires, improperly vented or defective domestic gas heaters/geysers, generators and industrial appliances, and degradation of some anaesthetic gases by CO₂ adsorbents.
- ▶ **Intent:** about half of non-lethal exposures are deliberate (self-harm); the **motor vehicle is the commonest source of intentional poisoning**. Accidental poisoning clusters in **cold weather** when faulty heating systems are used in poorly ventilated rooms.
- ▶ It is the **third leading cause of death from poisoning** overall, but is under-represented in hospital statistics because victims are often found dead and referred directly to medical examiners.
- ▶ The **fetus and newborn are especially susceptible** because fetal haemoglobin has a high affinity for CO.

Pathophysiology — mechanisms of toxicity

CO produces injury by several overlapping mechanisms, not by hypoxaemia alone:

Mechanism	Consequence
Binds Hb → carboxyhaemoglobin (affinity ~200–250× O ₂)	Reduced oxygen-carrying capacity → anaemic-type (histotoxic) hypoxia
COHb shifts the oxy-Hb dissociation curve to the LEFT	O ₂ unloaded only at very low tissue tensions → worsened tissue hypoxia
Binds myoglobin	Impaired O ₂ storage/use in cardiac and skeletal muscle
Binds cytochrome a/a3 (cytochrome c oxidase)	Blockade of mitochondrial electron transport / oxidative metabolism → lactic acidosis
Lipid peroxidation in brain, leukocyte adherence to endothelium, oxidative stress	Delayed neuronal injury and neuropsychiatric sequelae

- ▶ The **brain and heart** are the most sensitive target organs (high blood flow, high O₂ demand, poor tolerance of hypoxia).

- ▶ CO is also a low-affinity **anaesthetic agent** and an endogenous gaseous neurotransmitter linked to nitric oxide metabolism.

Clinical features (correlate with COHb saturation)

COHb saturation	Typical clinical features
10–20%	Headache, dizziness, nausea, abdominal pain, lethargy, poor concentration
20–40% (higher)	Confusion, impaired short-term memory, dyspnoea on exertion, syncope, visual disturbance, irritability
>50–60%	Hypotension, seizures, coma , cardiac ischaemia/arrhythmia, sudden collapse, death

- ▶ Symptoms are **non-specific and “flu-like”**, so the diagnosis is easily missed; suspect CO in any patient with severe headache or acutely altered mental status, **especially during cold weather** or when multiple household members are simultaneously ill.
- ▶ *Classic “cherry-red” skin* is the traditionally described sign but is **unreliable and usually a late/post-mortem finding**; importantly, CO does NOT produce true cyanosis — carboxyhaemoglobinaemia is listed as a cause of skin discolouration that is *not true cyanosis*.
- ▶ Other features: myocardial ischaemia (even in young patients), rhabdomyolysis, non-cardiogenic pulmonary oedema, and (with concurrent fire exposure) **co-existent cyanide poisoning and thermal airway injury**.

Diagnosis and investigations

- ▶ **Diagnosis rests on direct measurement of arterial or venous COHb saturation by CO-oximetry.** A normal smoker may have 5–10%; non-smokers <2–3%.
- ▶ **Pitfalls:** routine **pulse oximetry (SpO₂) is falsely normal/elevated** — it cannot distinguish COHb from oxyhaemoglobin; **arterial blood gas PaO₂ is also falsely normal** because dissolved O₂ is unaffected. Calculated O₂ saturation is normal but measured (co-oximetry) saturation is low — a *discordant* picture characteristic of asphyxiants. Specialised pulse CO-oximeters can estimate COHb with variable accuracy.
- ▶ **Admission COHb level confirms exposure but does NOT reliably reflect severity or prognosis,** and falls rapidly once high-flow oxygen is started.
- ▶ Supporting tests: ABG showing **elevated anion-gap (lactic) metabolic acidosis**; ECG and troponin for myocardial ischaemia; serum lactate; CK for rhabdomyolysis; and in selected cases neuroimaging (CT/MRI may show **basal ganglia / globus pallidus changes** — a standard radiological association).

Management

A. Emergency and supportive measures

- ▶ Remove the patient from the source of exposure immediately.
- ▶ Secure airway, assist ventilation; treat coma, seizures and hypotension along standard poisoning lines.
- ▶ If smoke inhalation/fire is involved, anticipate and treat **concurrent cyanide poisoning** (IV hydroxocobalamin ± sodium nitrite/sodium thiosulfate) and thermal airway injury.

B. Specific treatment — OXYGEN is the antidote

- ▶ The elimination half-life of COHb is ~4–5 h (~5.5 h) **breathing room air**, falling to ~60–90 min (~71 min) on 100% oxygen at 1 ATA, and to ~20 min (~21 min) on oxygen at 2.0 ATA.
- ▶ Give 100% oxygen by tight-fitting high-flow non-rebreather reservoir mask or via endotracheal tube; continue until the patient is asymptomatic and COHb is near-normal.

C. Hyperbaric oxygen (HBO) therapy

- ▶ HBO delivers 100% O₂ at supra-atmospheric pressure, dramatically shortening COHb half-life and (more importantly) is thought to reduce **delayed neuropsychiatric sequelae** via mechanisms beyond reversal of hypoxia — displacing CO from cytochromes, upregulating antioxidant defences, reducing leukocyte adherence and lipid peroxidation.
- ▶ CO poisoning is a **recognised primary indication** for HBO (Undersea & Hyperbaric Medical Society list), including poisoning **complicated by cyanide**.
- ▶ **Commonly recommended indications for HBO** (criteria differ between sources — RCTs disagree on benefit):

Source	Indications / risk markers for HBO referral
CMDT 2026	History of loss of consciousness; COHb >25%; metabolic acidosis; age >50 years; cerebellar findings on examination
Harrison (Hyperbaric & Diving Medicine)	Moderate–severe poisoning; age >35 years; metabolic acidosis on ABG; lengthy exposure (>24 h); history of unconsciousness; pregnancy is also a widely accepted indication

- ▶ **Evidence:** the most rigorous RCT (Weaver et al.) showed cognitive sequelae at 6 weeks in 25% with HBO vs 46% with normobaric oxygen ($p = .007$, NNT = 5) and a persisting benefit at 12 months (18% vs 32%, NNT = 7). A Cochrane review found insufficient pooled evidence, so HBO use remains individualised and time-sensitive (ideally first sessions within 24 h).

Delayed neuropsychiatric syndrome and prognosis

- ▶ Survivors of severe poisoning may develop **persistent or delayed neuropsychiatric deficits** — characteristically after an interval of *days to weeks* of apparent recovery.

- ▶ Reported features: cognitive impairment/dementia, short-term memory loss, **parkinsonism and other movement disorders**, peripheral neuropathy, hearing loss, vestibular dysfunction, personality change and psychosis.
- ▶ **Risk factors for poor outcome:** age >35 years, exposure >24 h, metabolic acidosis, and loss of consciousness.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Oxygen–haemoglobin dissociation curve:** plot S_{aO_2} (y-axis) vs P_{o_2} (x-axis); show the normal sigmoid curve and a left-shifted curve in CO poisoning. Label: *normal curve, left shift due to COHb, P_{50} reduced, O₂ unloaded only at low tissue P_{o_2} → tissue hypoxia.*
- ▶ **Pathophysiology flow diagram:** *Inhaled CO → binds Hb (200–250× O₂ affinity) → ↓ O₂-carrying capacity + LEFT shift of ODC; binds myoglobin; inhibits cytochrome c oxidase → impaired oxidative phosphorylation → lactic acidosis + brain/heart hypoxia → coma, seizures, delayed neuropsychiatric sequelae.*

Clinical / Diagnostic significance

- ▶ Never rely on SpO_2 or PaO_2 to exclude CO poisoning — both are falsely reassuring; demand a CO-oximetry COHb level.
- ▶ Consider CO in clusters of simultaneously ill household members, in winter, and in all fire/smoke-inhalation victims (screen for cyanide too).
- ▶ An unexplained **high-anion-gap lactic acidosis** with normal PaO_2 should trigger consideration of asphyxiant poisoning (CO, cyanide, H₂S).
- ▶ Pregnant patients warrant lower thresholds for 100% O₂ and HBO because of fetal vulnerability.
- ▶ Counsel survivors and arrange neuropsychological follow-up given the risk of the delayed syndrome.

High-yield exam pointers

- ▶ CO affinity for Hb = ~200–250× that of O₂; forms **carboxyhaemoglobin** and shifts the oxy-Hb curve to the LEFT.
- ▶ Diagnosis = **CO-oximetry**; **pulse oximetry & PaO_2 are falsely normal**; admission COHb does not predict severity/prognosis.
- ▶ COHb half-life: ~5 h (air) → ~71 min (100% O₂, 1 ATA) → ~21 min (O₂ at 2 ATA).
- ▶ **Antidote = oxygen**; 100% O₂ by non-rebreather is first-line; HBO for severe/high-risk cases.
- ▶ HBO indications (CMDT): LOC, **COHb >25%**, metabolic acidosis, **age >50**, cerebellar signs; (Harrison risk markers): age >35, acidosis, prolonged exposure, LOC, pregnancy.
- ▶ Toxicity is multi-mechanistic: Hb + **myoglobin** + **cytochrome c oxidase** binding → lactic acidosis; brain and heart are most vulnerable.

- ▶ CO does not cause true cyanosis; “cherry-red” skin is classic but unreliable/late.
- ▶ Beware concurrent cyanide toxicity and airway burns in fire victims.
- ▶ Delayed neuropsychiatric syndrome (parkinsonism, cognitive/memory deficits) can appear days–weeks after recovery; basal ganglia (globus pallidus) lesions on imaging.

SOURCE & COVERAGE

- ▶ **Harrison’s Principles of Internal Medicine, 22e** — “Poisoning and Drug Overdose” (asphyxiant toxic syndromes, oxygen/antidotal therapy); “Hyperbaric and Diving Medicine” (dedicated Carbon Monoxide Poisoning section — epidemiology, mechanisms, COHb half-lives, HBO indications and Weaver RCT data); “Hypoxia and Cyanosis” (CO intoxication, left-shift of dissociation curve, carboxyhaemoglobinaemia is not true cyanosis).
- ▶ **CMDT 2026** — “Poisoning” (Carbon Monoxide: clinical findings by COHb level, diagnosis by CO-oximetry, HBO indication criteria) and “Pulmonary Disorders — Smoke Inhalation” (combined CO/cyanide injury).
- ▶ *Coverage note:* The corpus does not present a formal staging or a discrete table of cherry-red-skin/retinal signs for CO; the “cherry-red skin” and basal-ganglia/parkinsonism associations included are universally accepted standard internal medicine and are stated with appropriate caveats. HBO benefit is genuinely debated across the cited sources, reflected faithfully above.

Clinical features and management of organophosphorus poisoning

Asked in: Paper IV May 2019 — RGUHS MD General Medicine

Definition / Introduction — Organophosphorus (OP) compounds are anticholinesterase insecticides (e.g. diazinon, malathion, parathion, chlorpyrifos, acephate) and chemical-warfare nerve agents (tabun, sarin, soman, VX) that **irreversibly inhibit acetylcholinesterase**, causing accumulation of acetylcholine at muscarinic, nicotinic and central synapses — a *cholinergic crisis*. OP poisoning, usually deliberate self-poisoning, is a leading cause of pesticide death in the developing world; **>150,000 pesticide poisoning deaths occur worldwide each year**, with insecticides accounting for the majority. Death is from bronchorrhoea, respiratory-muscle paralysis and CNS depression; management hinges on aggressive resuscitation, atropine and an oxime.

Toxicokinetics & Mechanism (Pathophysiology)

- ▶ **Absorption** is by all routes — inhalational (fastest onset), transdermal, transconjunctival, mucous-membrane and gastrointestinal; most OPs are lipophilic and formulated in aromatic-hydrocarbon solvents (e.g. xylene), aiding skin penetration.
- ▶ **Two cholinesterases are inhibited:** *true (RBC) acetylcholinesterase* — found in erythrocyte membranes, nervous tissue and skeletal muscle; and *plasma cholinesterase (pseudocholinesterase / butyrylcholinesterase)* — found in serum, liver, pancreas, heart and brain.
- ▶ OP **phosphorylates** the enzyme's active site, blocking acetylcholine hydrolysis → ACh accumulates at: CNS synapses, autonomic ganglia, post-ganglionic *muscarinic* parasympathetic and sympathetic (sweat-gland) endings, and *nicotinic* neuromuscular junctions.
- ▶ ***Aging** = *permanent, irreversible covalent binding of the OP to cholinesterase after loss of an alkyl group; once aged, the enzyme is destroyed and recovery requires resynthesis over weeks. Time-to-aging is highly agent-dependent (minutes for soman to >24 h). Oximes work only before aging** — hence the urgency.

Clinical Features — the four syndromes

Most patients are symptomatic within **8 hours** and nearly all within **24 hours**. The hallmark acute toxidrome combines muscarinic, nicotinic and CNS effects:

Receptor / system	Manifestations	Mnemonic
Muscarinic	Salivation, Lacrimation, Urination, Defaecation, GI cramps, Emesis; Miosis; Bradycardia, Bronchorrhoea, Bronchospasm (“Killer Bs”)	SLUDGE / DUMBELS
Nicotinic	Muscle fasciculations, cramps, weakness (incl. diaphragm) → paralysis; mydriasis, pallor, tachycardia, hypertension (sympathetic ganglia/adrenal)	“days of the week” – MTWtHF
CNS	Anxiety, restlessness, emotional lability, tremor, headache, dizziness, confusion, delirium, hallucinations, seizures, coma	—

- ▶ **Mixed autonomic picture:** parasympathetic effects usually predominate, but nicotinic stimulation of sympathetic ganglia/adrenal medulla can produce *early* tachycardia, hypertension, pallor and mydriasis — so a normal/raised pulse does **not** exclude OP poisoning.
- ▶ **Severe poisoning** classically presents with **altered mental status, pinpoint pupils, profuse sweating and difficulty breathing**; a *garlic-like / hydrocarbon odour* on breath or clothing is a useful clue.

- ▶ *Other features*: abdominal pain (rarely pancreatitis), aspiration/lipoid pneumonia from hydrocarbon solvent, pulmonary oedema, early myocardial ischaemia; ECG may show QT prolongation, ST/T changes, AV block, torsades, VT/VF.

The four recognised clinical syndromes

- ▶ **Acute cholinergic crisis** — the muscarinic/nicotinic/CNS toxidrome above; onset minutes (inhalation/large ingestion) to hours.
- ▶ **Intermediate syndrome** — 1–5 days after exposure (up to ~40% of ingestions); weakness of **neck flexors, cranial-nerve-innervated muscles, proximal limbs and respiratory muscles** (may need ventilation). *Cholinergic features are absent*; EMG aids diagnosis; usually resolves within 7 days. **Not** caused by nerve agents.
- ▶ **Organophosphate-induced delayed neuropathy (OPIDN)** — cognitive dysfunction, impaired memory, mood change, autonomic dysfunction, distal **peripheral neuropathy** and extrapyramidal signs (related to neuropathy-target-esterase inhibition).
- ▶ **Chronic toxicity** — in chronically exposed agricultural workers; a symmetrical **sensorimotor axonopathy** beginning as leg cramps progressing to weakness/paralysis, *mimicking Guillain-Barré syndrome*.

Diagnosis / Investigations

- ▶ **Clinical** — diagnosis rests on the history and a suggestive cholinergic toxidrome; **never delay antidote** awaiting laboratory confirmation.
- ▶ **Cholinesterase assays** (confirmatory markers):
 - *Plasma butyrylcholinesterase* — easier, more available, falls first; may drop ~50% in asymptomatic exposure; normalises in **28–42 days** (if no oxime given).
 - *RBC acetylcholinesterase* — better reflects synaptic inhibition; falls to **10–20% of normal in moderate** and **<10% in severe** poisoning; full recovery may take up to **120 days** (needs RBC turnover).
 - As a rule, plasma + RBC cholinesterase activity is **<50% of normal** in significant intoxication.
 - *Caveats*: BuChE is low in genetic variants, liver disease, malnutrition, pregnancy; standardisation between labs is poor.
- ▶ **Ancillary** — pancreatic enzymes, glucose (hypo/hyper), leucocytosis, deranged LFTs; CXR (pulmonary oedema/aspiration); ECG; EMG quantifies NMJ block (intermediate syndrome).

Management

Principles — *protect rescuers, decontaminate, resuscitate (ABC), give atropine + oxime, support ventilation*. Manage in an ICU for significant poisoning.

- ▶ **Staff & decontamination**: wear **nitrile/neoprene** gloves, gown, mask/face-shield (latex is inadequate); remove and bag all clothing as hazardous waste; wash

skin/hair/nails/conjunctivae/skin-folds with copious **soap (mild detergent) and water**; contain runoff. *Dilute hypochlorite (household bleach 1:10)* breaks down OP/nerve agent on equipment. Avoid skin abrasion.

- **Airway & breathing:** 100% O₂ via non-rebreather; gentle suction of secretions; **endotracheal intubation and ventilation** for coma, seizures, respiratory failure, severe bronchospasm/bronchorrhoea. **Avoid succinylcholine** (metabolised by plasma BuChE → prolonged paralysis) — use a *non-depolarising* blocker; avoid ester anaesthetics and β -blockers.
- **GI decontamination:** gastric lavage has **no proven benefit** (may consider within 1 h of a large ingestion *after* the airway is secured, never delaying antidote); single/multiple-dose activated charcoal is of unproven benefit; haemodialysis/haemoperfusion are of no proven value.

Specific antidotes

Antidote	Action	Regimen (adult)
Atropine	Competitive antagonist at muscarinic receptors — reverses bronchorrhoea, bronchospasm, secretions, bradycardia, cramps; does <i>not</i> affect nicotinic weakness	Bolus 1.2–3.0 mg IV (child 0.05 mg/kg); double the dose every 5 min until <i>atropinised</i> : clear chest, HR >80/min, SBP >80 mmHg. Then infusion at 10–20%/h of the total atropinising dose (~0.4–4 mg/h). Massive ingestions may need hundreds of mg.
Pralidoxime (2-PAM)	Oxime — reactivates cholinesterase by displacing OP from the active site; reverses nicotinic weakness/paralysis <i>if given before aging</i>	30 mg/kg IV over 5–10 min loading (WHO), then infusion 8 mg/kg/h for 24–48 h . (<i>CMDT alternative: 1–2 g IV load, then 200–500 mg/h.</i>) Continue while signs of ACh excess persist.
Benzodiazepines	Control seizures / agitation	IV diazepam/lorazepam; atropine may abort early cholinergic seizures.

- **Atropine end-points:** titrate to *adequate atropinisation* (above); **pupillary dilatation and tachycardia are NOT end-points** and tachycardia is *not* a contraindication (it may be hypoxia/bronchospasm-driven, reversible by atropine). Watch for atropine toxicity: absent bowel sounds, hyperthermia, delirium, urinary retention. **Glycopyrrolate** (no CNS penetration) is an alternative for peripheral muscarinic control.
- **Pralidoxime caveats:** give as **early as possible** (before aging); still worth giving even **24–48 h** after exposure; **not** for asymptomatic patients or single-agent **carbamate** poisoning (carbamylated enzyme reactivates spontaneously and 2-PAM may worsen carbaryl toxicity). Use it if the agent is unknown or a mixed OP–carbamate exposure.

- ▶ **Adjuncts of uncertain benefit (not routine):** magnesium sulphate, calcium-channel blockers, clonidine, sodium bicarbonate.
- ▶ **Disposition:** minor exposure → decontaminate + observe 6–8 h. Significant poisoning → ICU; most respond to oxime with rising cholinesterase within 48 h; with early treatment and no hypoxic brain injury, symptomatic recovery by ~10 days. Lipid-soluble agents (fenthion, dimethoate) cause prolonged/recurrent toxicity needing continued atropine/oxime over weeks. End-point of oxime therapy = no recurrence of signs on withholding it.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Cholinergic synapse / mechanism schematic:** pre-synaptic neuron releasing acetylcholine into the synaptic cleft → post-synaptic **muscarinic** and **nicotinic receptors**; **acetylcholinesterase** in the cleft with a red “X” showing **OP-induced inhibition** (phosphorylation → aging); arrow to **ACh accumulation**. Side boxes: *Muscarinic effects* (SLUDGE / DUMBELS, Killer Bs), *Nicotinic effects* (fasciculations, weakness, tachycardia, HTN), *CNS effects* (seizures, coma). Label antidote actions: **Atropine** → **blocks muscarinic receptor**; **Pralidoxime** → **reactivates acetylcholinesterase**.
- ▶ **Time-course bar:** *Acute crisis* (0–24 h) → *Intermediate syndrome* (1–5 days) → *OPIDN* (delayed, weeks).

Clinical / Diagnostic significance

- ▶ The triad **miosis + sweating/secretions + diarrhoea (with a garlic odour)** in a collapsed patient should prompt empirical atropine even before assay results.
- ▶ **Inadequate atropinisation** (persistent bronchorrhoea/hypoxia) is a common, fatal pitfall — titrate hard against chest auscultation, not pupils.
- ▶ Recognising the **intermediate syndrome** prevents fatal *unmonitored* respiratory failure 1–5 days after apparent recovery — keep monitoring even after the cholinergic crisis settles.
- ▶ **Carbamates** (reversible, do not age) need atropine but generally not pralidoxime, and recover within ~24 h — distinguishing them changes management.
- ▶ Serial RBC AChE/plasma BuChE help confirm diagnosis and gauge recovery, but treatment must never wait for them.

High-yield exam pointers

- ▶ OP **irreversibly** inhibits acetylcholinesterase; carbamates do so **reversibly** (no aging) → carbamate course is shorter and milder.
- ▶ ***Aging** = *irreversible OP–enzyme binding* → *oxime ineffective*; *soman ages in minutes**, leaving almost no oxime window.
- ▶ **SLUDGE/DUMBELS** = muscarinic; **fasciculations + weakness + tachycardia/HTN** = nicotinic; **seizures/coma** = CNS.

- ▶ **Atropinisation end-points:** clear chest, HR >80, SBP >80 — *not* pupils; tachycardia is **not** a contraindication to atropine.
- ▶ **Pralidoxime** reverses *nicotinic* weakness and must be given **early, before aging**; atropine does *not* reverse muscle weakness.
- ▶ **Avoid succinylcholine** (prolonged paralysis via BuChE inhibition); use non-depolarising relaxants.
- ▶ **Four syndromes:** acute crisis → **intermediate syndrome** (1–5 d, proximal/respiratory/neck-flexor weakness, **no cholinergic signs**) → OPIDN (delayed neuropathy) → chronic sensorimotor axonopathy (GBS-like).
- ▶ **Death is from respiratory failure** (bronchorrhoea + respiratory-muscle paralysis + CNS depression).
- ▶ Cholinesterase activity <50% of **normal** supports significant poisoning; plasma BuChE falls first, RBC AChE reflects synaptic inhibition.

SOURCE & COVERAGE

- ▶ Tintinalli's Emergency Medicine — “Pesticides” (Organophosphates: pathophysiology, four syndromes, cholinesterase assays, atropine/pralidoxime regimens, carbamate contrast) — primary depth source.
- ▶ Harrison's Principles of Internal Medicine, 22e — “Poisoning and Drug Overdose” (cholinergic toxidrome; acetylcholinesterase-inhibitor mechanism; atropine + 2-PAM principles).
- ▶ CMDT 2026 — “Poisoning: Pesticides — Cholinesterase Inhibitors” (current atropine 2 mg escalating-dose and pralidoxime 1–2 g load/200–500 mg/h regimens; decontamination; pralidoxime + atropine for OP-induced seizures).

Clinical features, management and complications of scorpion envenomation

Asked in: Paper IV Oct 2025 — RGUHS MD General Medicine

Definition / Introduction — Scorpion envenomation (scorpionism) is systemic poisoning following the sting of an arachnid of the order Scorpiones, which injects peptide-rich venom from the **aculeus** (**stinger**) at the tip of the tail (telson). Of ~1000–1500 known species, only about 30 (almost all of the family *Buthidae*) are dangerous to humans, together causing several thousand deaths annually. The clinical hallmark is an “**autonomic storm**” — a massive, biphasic outpouring of acetylcholine and catecholamines — so that systemic and especially **cardiorespiratory** features are grossly out of proportion to the trivial local sting. In India the lethal species is the *Indian red scorpion* (*Mesobuthus* /

Hottentotta tamulus), against which the α 1-blocker **prazosin** is the pharmacological cornerstone of treatment.

Epidemiology & medically important species

- ▶ Worldwide an estimated >1.2 million serious stings and ~3250 deaths per year; children and the elderly suffer the most severe envenomation and highest mortality.
- ▶ Scorpions are nocturnal, hiding by day under rocks, bark, woodpiles or inside shoes, clothing and bedding; they sting only when threatened.
- ▶ The dangerous species belong almost exclusively to the family **Buthidae**.

Region	Important species	Distinguishing toxicity
India / South Asia	<i>Mesobuthus (Hottentotta) tamulus</i> — Indian red scorpion	Catecholamine storm, myocarditis, pulmonary oedema
Middle East / N. Africa	<i>Leiurus quinquestriatus</i> , <i>Androctonus</i> spp.	Catecholamine excess, hypertensive crisis, arrhythmias
Brazil	<i>Tityus serrulatus</i> (<i>tityustoxin</i>)	Childhood deaths; <i>T. trinitatis</i> (Trinidad) → pancreatitis
Iran / Iraq	<i>Hemiscorpius lepturus</i>	Cytotoxic — haemolysis, haemoglobinuria, AKI, skin necrosis
South Africa	<i>Parabuthus</i> , <i>Buthotus</i> spp.	CNS toxicity
SW USA (Arizona)	<i>Centruroides sculpturatus / exilicauda</i> — bark scorpion	Neuromuscular & cranial-nerve dysfunction

Venom & pathophysiology — the “autonomic storm”

- ▶ Venom contains low-molecular-weight **peptide neurotoxins** plus 5-hydroxytryptamine, histamine and kinins.
- ▶ Neurotoxins act on **voltage-gated sodium channels**, holding them **open** (prolonged depolarisation), and **block potassium channels** → repetitive, uncontrolled firing of autonomic and somatic nerves.
- ▶ This drives **massive release of acetylcholine and endogenous catecholamines** at autonomic ganglia, adrenal medulla and neuromuscular junctions, producing the characteristic **biphasic response**:
 - *Early transient parasympathetic (cholinergic) phase* — vomiting, profuse salivation, lacrimation, sweating, bronchorrhoea, bradycardia, hypotension, priapism.
 - *Sustained sympathetic (adrenergic) phase* — hypertension, tachycardia, cool clammy peripheries, mydriasis, myocardial injury and pulmonary oedema.

- ▶ *Tityustoxin* binds Na^+/K^+ channels causing sialorrhoea, lacrimation and rhinorrhoea; *Hemiscorpius* venom (**hemicalcin**) acts on ryanodine-sensitive calcium channels and is cytotoxic/haemolytic.

Clinical features

- ▶ **Local** — immediate, severe **burning pain** and **hyperaesthesia**; swelling, erythema and ecchymosis are usually minimal and *out of proportion* to symptoms. Pain is accentuated by gently tapping the site (positive “**tap test**”). Pain may persist for days to weeks.
- ▶ **Autonomic** — restlessness, profuse sweating, hypersalivation, lacrimation, rhinorrhoea, nausea/vomiting; cool extremities, alternating hypotension/hypertension, brady- then tachy-arrhythmia, priapism.
- ▶ **Neuromuscular / cranial nerve** — muscle twitching, jerking and fasciculation (may be **mistaken for seizures**), blurred vision, roving/abnormal eye movements, slurred speech and difficulty handling secretions.
- ▶ **Course** — systemic features progress to maximal severity by ~5 h and usually subside within 1–2 days, though pain and paraesthesia may last weeks. **Appearance of gastrointestinal/autonomic features within the first few hours signals progression to severe envenomation.**
- ▶ Children and the elderly deteriorate fastest; **fatal respiratory arrest** is the dominant mode of death in these groups.

Complications

- ▶ **Cardiovascular** — *scorpion-sting myocarditis* / catecholamine (stress) cardiomyopathy, tachy- and brady-arrhythmias, hypertensive crisis, and **cardiogenic shock**.
- ▶ **Respiratory** — acute **pulmonary oedema** (both cardiogenic from LV dysfunction and capillary-leak/non-cardiogenic) and **respiratory failure/arrest** — the leading cause of death.
- ▶ **Acute pancreatitis** — notably with *Tityus* stings.
- ▶ **Renal / haematological** — **rhabdomyolysis**, intravascular **haemolysis**, haemoglobinuria and **acute kidney injury** (especially *Hemiscorpius lepturus*).
- ▶ **Metabolic** — hyperthermia, lactic acidosis.
- ▶ **Local** (cytotoxic species) — purpura, bullae, tissue necrosis and ulceration.
- ▶ Allergic reactions to venom (rarely anaphylaxis); secondary bacterial infection.

Management

- ▶ **First aid** — reassure and **keep the patient calm and immobile**; apply a **cold pack / pressure dressing** to the site to slow venom absorption; **infiltrate local anaesthetic without a vasoconstrictor** for pain; clean the wound and give **tetanus prophylaxis**. Avoid incision and tourniquets.

- **Triage** — most stings (non-lethal species) need only ice packs, analgesics or antihistamines and can be observed at home, returning if cranial-nerve or neuromuscular signs appear.

Problem	Drug / intervention
Agitation, involuntary movements	Continuous IV midazolam infusion (monitor for respiratory depression)
Hypertension & pulmonary oedema	Prazosin (drug of choice), nifedipine, hydralazine, sodium nitroprusside
Bradycardia	IV atropine
Severe / systemic envenomation	Species-specific antivenom (e.g. FDA-approved equine <i>Centruroides</i> IgG F(ab') ₂)
Cardiogenic pulmonary oedema / shock	Oxygen, vasodilators/afterload reduction, inotropes, ventilatory support, ICU care

- **Prazosin** — the pharmacological antidote of choice for the **Indian red scorpion autonomic storm**: this α_1 -adrenergic blocker abolishes catecholamine-driven vasoconstriction, reduces preload and afterload, and **reverses/prevents pulmonary oedema**, giving accelerated recovery with preserved myocardial function. (Conventional Indian teaching: oral ~30 $\mu\text{g/kg}$, repeated ~3-hourly until peripheries are warm, dry and the patient stabilises — see Coverage note.)
- **Antivenom** — available in endemic regions and, with supportive care, reduces morbidity and mortality from severe envenomation; IV administration rapidly reverses cranial-nerve and neuromuscular dysfunction. (Its role relative to prazosin in *M. tamulus* envenomation is debated; prazosin remains the Indian mainstay.)
- **Supportive/ICU** — close cardiorespiratory monitoring, oxygen and mechanical ventilation for pulmonary oedema/respiratory failure, fluid and electrolyte correction, and treatment of rhabdomyolysis/AKI and pancreatitis as they arise.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- **Scorpion external morphology (labelled)**: pedipalps/pincers (chela), cephalothorax (prosoma), four pairs of legs, mesosoma (abdomen), metasoma (segmented “tail”), and **telson bearing the aculeus (stinger)** with venom gland.
- **“Autonomic storm” flow diagram**: *Venom neurotoxin* $\rightarrow$ *Na⁺ channel held open + K⁺ channel block* $\rightarrow$ *repetitive nerve firing* $\rightarrow$ *massive ACh + catecholamine release* $\rightarrow$ *biphasic response* — label the **parasympathetic/cholinergic (early)** limb (vomiting, salivation, lacrimation, sweating, bradycardia) and the **sympathetic/adrenergic (late)** limb (hypertension, tachycardia, myocarditis, pulmonary oedema); show **prazosin blocking the α_1 receptor**.

Clinical / Diagnostic significance

- ▶ Diagnosis is **clinical** (history of sting + autonomic storm); **identifying the species** guides prognosis and the need for antivenom.
- ▶ Suspect **myocarditis/cardiomyopathy** in any stung child with tachypnoea, gallop or pulmonary oedema — obtain ECG (ST–T changes, arrhythmia), **echocardiography** (global LV hypokinesia), and cardiac biomarkers.
- ▶ Monitor for **rhabdomyolysis and AKI** (CK, urine myoglobin, creatinine), and consider **serum amylase/lipase** where *Tityus*-type pancreatitis is plausible.
- ▶ The combination of **minimal local signs with florid systemic/cranial-nerve toxicity** is the key clue distinguishing dangerous scorpionism from a trivial sting.

High-yield exam pointers

- ▶ Lethal species belong to family **Buthidae**; India = ***Mesobuthus (Hottentotta) tamulus*** (Indian red scorpion).
- ▶ Mechanism = neurotoxin keeps **Na⁺ channels open** + blocks **K⁺ channels** → **autonomic storm** (cholinergic then adrenergic).
- ▶ Local signs are **out of proportion** to severe pain; **positive tap test**.
- ▶ **Pulmonary oedema, myocarditis and respiratory arrest** are the chief killers; children/elderly worst affected.
- ▶ **Prazosin** is the drug of choice for the Indian red scorpion (reverses autonomic storm, preserves myocardium).
- ▶ **IV midazolam** for agitation/involuntary movements; **atropine** for bradydysrhythmia; **nifedipine/nitroprusside/hydralazine** for hypertensive pulmonary oedema.
- ▶ Species-specific **antivenom** (equine *Centruroides* F(ab')₂ is FDA-approved) reverses cranial-nerve/neuromuscular signs.
- ▶ Remember **pancreatitis** (*Tityus*) and **haemolysis + AKI + skin necrosis** (*Hemiscorpius lepturus*).
- ▶ First aid = reassurance, immobilisation, cold pack/pressure dressing, local anaesthetic **without vasoconstrictor**, tetanus prophylaxis; **avoid incision/tourniquet**.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Ectoparasite Infestations and Arthropod Injuries” (Scorpion Stings section: species, sodium-channel mechanism, catecholamine release, complications, and treatment including midazolam, prazosin, nifedipine, nitroprusside, atropine and antivenom).
- ▶ ***Bologna, Dermatology, 5e** — “Bites and Stings” (*clinically important scorpion species table; symptoms out of proportion to cutaneous signs; cardiorespiratory deaths in children <10 y; pancreatitis; prazosin reverses the autonomic storm of Hottentotta tamulus****).

- ▶ **Rook's Textbook of Dermatology, 10e** — “Arthropods” (Buthidae, venom components, epidemiology ~1.2 million serious stings/~3250 deaths, tityustoxin and hemicalcin mechanisms, biphasic clinical features, antivenom/supportive management).
- ▶ **CMDT 2026** — “Poisoning: Spider Bites & Scorpion Stings” (*Centruroides* features; FDA-approved species-specific antivenom; analgesia).

Coverage note: The corpus covers scorpion envenomation only moderately and from a largely non-Indian standpoint. It confirms *Mesobuthus tamulus* as the Indian species and **prazosin** as the antidote for its autonomic storm, but does **not** state the prazosin dose or any formal severity grading; the dose given (~30 µg/kg orally, ~3-hourly) and the biphasic cholinergic→adrenergic framing reflect standard, widely accepted Indian internal-medicine teaching (Bawaskar protocol) and should be applied per local guidelines rather than as verbatim corpus content.

Discuss clinical features and management of Organophosphorus poisoning

Asked in: Paper IV 17 Apr 2026 — RGUHS MD General Medicine

Definition / Introduction — Organophosphorus (OP) compounds are **cholinesterase inhibitors** (“anticholinesterases”) widely used as agricultural and household insecticides (parathion, malathion, diazinon, chlorpyrifos) and weaponised as chemical-warfare **nerve agents** (GA *tabun*, GB *sarin*, GD *soman*, VX). They irreversibly inhibit acetylcholinesterase, producing accumulation of acetylcholine at **muscarinic, nicotinic and central** cholinergic synapses — a life-threatening cholinergic toxidrome. OP self-poisoning is one of the commonest causes of fatal poisoning in South Asia, killing chiefly through respiratory failure; management rests on aggressive resuscitation, **atropine** and the oxime **pralidoxime** (2-PAM).

Toxicology and mechanism

- ▶ **Agents** — OP insecticides (diazinon, chlorpyrifos-ethyl, malathion, parathion); related **carbamate** insecticides (aldicarb, carbaryl, propoxur) and medicinals (neostigmine, physostigmine); nerve gases (sarin, soman, tabun, VX).
- ▶ **Mechanism** — Inhibition of **acetylcholinesterase** leads to increased synaptic acetylcholine at muscarinic and nicotinic cholinergic receptor sites, causing stimulation of CNS, postganglionic parasympathetic (muscarinic) receptors, autonomic ganglia and the neuromuscular junction (nicotinic) receptors.
- ▶ **Pharmacokinetics** — Most OPs are **poorly water-soluble**, commonly formulated with an **aromatic hydrocarbon solvent** (e.g. **xylene**), and are **well absorbed through intact skin**, as well as by ingestion and inhalation — hence decontamination and staff protection are essential.

- **Persistence / “aging”** — Highly lipid-soluble agents (e.g. **fenthion, dimethoate**) cause prolonged or recurrent toxicity over days. Over time the OP–enzyme bond becomes covalent and irreversible (“aging”), after which oxime reactivation fails — the rationale for giving pralidoxime early. Carbamates inhibit cholinesterase only **transiently** and do not age, so are generally self-limiting.

Clinical features

The toxidrome reflects acetylcholine excess at three receptor populations.

Receptor / site	Clinical features
Muscarinic (postganglionic parasympathetic)	Miosis; excessive secretions — lacrimation, salivation, bronchorrhoea, wheezing/bronchospasm, diaphoresis ; nausea, vomiting, diarrhoea, abdominal cramps, faecal and urinary incontinence; bradycardia
Nicotinic (ganglia + neuromuscular junction)	Initial hypertension and tachycardia ; muscle cramps, fasciculations, weakness and paralysis
CNS	Anxiety, agitation, confusion, seizures , respiratory-centre depression, coma

- **Diagnostic clues** — The triad of **miosis, sweating and diarrhoea** should raise immediate suspicion; the patient may smell of solvent/garlic.
- **Cardiovascular sequence** — **Initial tachycardia is usually followed by bradycardia.**
- **Cause of death** — Usually **respiratory failure** from the combination of bronchorrhoea, bronchospasm, central apnoea and skeletal-muscle (including diaphragmatic) weakness.
- **Course** — Signs may **persist or recur over several days**, especially with lipophilic agents (fenthion, dimethoate).
- **Recognised later neuromuscular syndromes** (see Coverage note):
 - **Intermediate syndrome** — 24–96 h after the cholinergic phase: proximal limb, neck-flexor, cranial-nerve and **respiratory muscle weakness**, requiring ventilatory support.
 - **OP-induced delayed polyneuropathy (OPIDP/OPIDN)** — 1–3 weeks later: distal sensorimotor neuropathy from inhibition of *neuropathy target esterase*.

Investigations

- **Cholinesterase assay** — **Serum (plasma/butryl) and RBC (true) cholinesterase activity is depressed $\geq 50\%$ below baseline** in severe intoxication; RBC cholinesterase correlates better with synaptic enzyme and with severity, plasma cholinesterase recovers faster. Confirms diagnosis and guides recovery.
- **Supportive labs** — Electrolytes, glucose, ABG (hypoxia, acidosis), renal function, creatine kinase, and ECG (sinus bradycardia, prolonged QT, AV block, ventricular dysrhythmias).

- Diagnosis is fundamentally **clinical** — therapeutic atropine must never be delayed pending laboratory confirmation.

Management

Management follows the universal poisoning framework — **support of vital signs, decontamination, specific antidotes, and prevention of re-exposure** — with two specific antidotes (atropine + pralidoxime).

A. Resuscitation and supportive care (first priority)

- **Airway protection, high-flow oxygen and ventilation** — suction copious secretions; intubate and ventilate early for respiratory failure (avoid **suxamethonium**, which is metabolised by the inhibited cholinesterase and causes prolonged paralysis — standard caveat).
- Treat **seizures** with benzodiazepines/barbiturates; correct hypoxia and metabolic derangements; haemodynamic support.

B. Decontamination and staff protection

- **Skin/hair** — remove contaminated clothing and **wash repeatedly with soap/shampoo and water**; staff must wear **gloves and waterproof aprons** to avoid secondary exposure. **Dilute hypochlorite (household bleach 1:10)** helps break down OP/nerve agents on equipment.
- **GI** — if recently ingested, consider **nasogastric aspiration** of the liquid followed by **activated charcoal**.

C. Specific antidote 1 — Atropine (physiological antidote)

- **Reverses excessive muscarinic stimulation** — dries bronchial secretions, relieves bronchospasm/wheeze, abdominal cramps and sweating. It **does not act at nicotinic (ganglionic/neuromuscular) receptors and has no direct effect on muscle weakness**.
- **Dose**: give **2 mg IV**; if no response after 5 minutes, repeat in **rapidly escalating (doubling) boluses** until secretions dry and wheeze clears. Severe poisoning may require **several hundred milligrams**; an infusion is used once atropinised.
- **End-point of atropinisation**: clear chest on auscultation/drying of secretions, with heart rate and blood pressure maintained (avoid over-atropinisation — delirium, hyperthermia, ileus, urinary retention).

D. Specific antidote 2 — Pralidoxime (2-PAM, Protopam — cholinesterase reactivator)

- **Reactivates acetylcholinesterase** by reversing OP binding to the enzyme; being an oxime it works at the **neuromuscular junction (nicotinic)** as well as muscarinic/nicotinic sites, thereby treating **muscle weakness/fasciculations** that atropine cannot.
- Most effective if **started very soon after exposure**, before irreversible “aging” permanently binds the OP to cholinesterase.

- ▶ **Dose:** 1–2 g IV loading, then continuous infusion 200–500 mg/hour titrated to clinical response; continue as long as there is evidence of acetylcholine excess. (The WHO-recommended regimen of a 30 mg/kg bolus followed by ≥ 8 mg/kg/h infusion is also widely used — standard, see Coverage note.)
- ▶ **Carbamate poisoning:** pralidoxime is of **questionable benefit** because carbamates inhibit cholinesterase only transiently; atropine alone usually suffices.
- ▶ **Evidence:** randomised trials have given **conflicting results** on whether pralidoxime reduces mortality, but it remains standard alongside atropine.

E. Adjunctive / unproven therapies

- ▶ **Magnesium sulphate, sodium bicarbonate, clonidine and extracorporeal removal** have been tried but remain unproven.
- ▶ Observe for **delayed deterioration** (intermediate syndrome) and provide prolonged ventilatory support as needed.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Cholinergic synapse schematic** — label: *presynaptic terminal, acetylcholine (ACh) vesicles, synaptic cleft with accumulated ACh, acetylcholinesterase (inhibited by OP), muscarinic receptor (postganglionic parasympathetic), nicotinic receptor (ganglion + neuromuscular junction), pralidoxime reactivating the enzyme, atropine blocking the muscarinic receptor.*
- ▶ **Toxidrome “stick-man”** — label muscarinic effects (*miosis, lacrimation, salivation, bronchorrhoea, bradycardia, vomiting/diarrhoea, incontinence, sweating*) on one side and nicotinic effects (*fasciculations, weakness, paralysis, tachycardia, hypertension*) on the other, with central effects (*seizures, coma, respiratory depression*) at the head.

Clinical / Diagnostic significance

- ▶ The combination **miosis + sweating + diarrhoea + bronchorrhoea** is a near-pathognomonic bedside toxidrome — treat empirically with atropine.
- ▶ **Respiratory failure** (bronchorrhoea + bronchospasm + neuromuscular weakness) is the principal killer — early airway control saves lives.
- ▶ **RBC and plasma cholinesterase** confirm diagnosis and severity and track recovery; do not await them to start atropine.
- ▶ Distinguish OP (irreversible, may “age”, oxime indicated) from **carbamate poisoning** (reversible, self-limiting, oxime of questionable value).
- ▶ Anticipate **biphasic/recurrent toxicity** with lipophilic agents and the **intermediate syndrome** — keep the patient monitored and ready for re-ventilation.

High-yield exam pointers

- ▶ OP = **acetylcholinesterase inhibitor** → ACh excess at **muscarinic + nicotinic + CNS** receptors.
- ▶ Muscarinic toxidrome mnemonics: **DUMBELS** (Defecation, Urination, Miosis, Bradycardia/Bronchorrhoea, Emesis, Lacrimation, Salivation) / **SLUDGE**; the lethal “**killer Bs**” = bronchorrhoea, bronchospasm, bradycardia.
- ▶ Nicotinic features: **fasciculations, weakness, paralysis, tachycardia, hypertension** — atropine does NOT correct these; **pralidoxime** does.
- ▶ **Atropine** 2 mg IV, **double-dose escalation** to dry secretions; end-point = clear chest.
- ▶ **Pralidoxime (2-PAM)** reactivates the enzyme — give **early, before “aging”**; 1–2 g IV load then 200–500 mg/h infusion.
- ▶ Serum/RBC cholinesterase **<50% of normal** in severe poisoning.
- ▶ **Avoid suxamethonium**; death is from **respiratory failure**.
- ▶ Carbamates: transient inhibition → atropine yes, **oxime usually unnecessary**.
- ▶ Decontaminate skin/clothing; protect staff (gloves/aprons, dilute bleach on equipment).

SOURCE & COVERAGE

- ▶ **Harrison’s Principles of Internal Medicine, 22e** — “Poisoning and Drug Overdose” (cholinergic / acetylcholinesterase-inhibitor toxidrome — muscarinic vs nicotinic features, atropine and 2-PAM, cholinesterase <50%; general fundamentals of poisoning management).
- ▶ **CMDT 2026** — “Poisoning” — *Pesticides: Cholinesterase Inhibitors* (agents, pharmacokinetics, clinical findings, atropine and pralidoxime dosing, carbamate caveat) and the *Cholinergic Syndrome* toxidrome.

Coverage note: The Harrison corpus covers the OP/anticholinesterase toxidrome largely in tabular form, and neither Harrison nor CMDT in this corpus explicitly details the **intermediate syndrome**, **OP-induced delayed polyneuropathy (OPIDP)**, the **suxamethonium caveat**, or the **WHO pralidoxime regimen / atropinisation end-points**. These are included as universally accepted standard internal-medicine teaching and are flagged here; all drug names, doses (atropine 2 mg with double-dose escalation; pralidoxime 1–2 g load + 200–500 mg/h), the $\geq 50\%$ cholinesterase fall, and the muscarinic/nicotinic feature lists are verbatim-grounded in CMDT 2026 and Harrison 22e.

Management of Paracetamol (Acetaminophen) Overdose

Asked in: Paper IV Oct 2025 — RGUHS MD General Medicine

Definition / Introduction — Paracetamol (acetaminophen) is the analgesic-antipyretic most frequently implicated in self-poisoning and is the single commonest cause of drug-induced **acute liver failure**

(ALF) in the Western world, accounting for at least 45% of ALF cases. Toxicity is **dose-related and predictable**: it follows a single acute ingestion of >150–200 mg/kg ($\approx$ 8–10 g in an average adult) or repeated supratherapeutic dosing. Hepatic necrosis is caused by the reactive metabolite **NAPQI** once hepatic glutathione is depleted. Because a proven, safe antidote (**N-acetylcysteine, NAC**) exists and is highly effective when given early, management hinges on rapid risk-stratification using the serum level and timely antidote administration.

Toxicokinetics and mechanism (basis of treatment)

- ▶ Paracetamol is normally metabolised by **phase II conjugation** — glucuronidation and sulfation — to innocuous, water-soluble metabolites excreted in urine.
- ▶ A small fraction undergoes **phase I oxidation** by cytochrome P450 CYP2E1 to the highly reactive electrophile **N-acetyl-p-benzoquinone-imine (NAPQI)**.
- ▶ NAPQI is normally detoxified by conjugation with **hepatic glutathione** to harmless **mercapturic acid** (renally excreted).
- ▶ In overdose the conjugation pathways saturate, glutathione is **depleted and overwhelmed**, and NAPQI binds covalently to nucleophilic hepatocyte macromolecules (forming **acetaminophen-protein adducts**), producing **dose-related centrilobular (zone 3) hepatic necrosis**.
- ▶ **NAC works by repleting/substituting glutathione** (provides sulfhydryl groups), detoxifying NAPQI; it also has antioxidant and microcirculatory benefits in established failure — the rationale for its use even late.
- ▶ **Potentiating factors** (lower the toxic threshold): chronic alcohol use and isoniazid (**induce CYP2E1**), phenobarbital, and **glutathione-depleting states** — starvation, fasting during febrile illness, malnutrition. In chronic alcoholics the toxic dose may be as low as ~2 g; the FDA has lowered the maximum daily dose recommendation from 4 g to 3 g and capped the paracetamol component of opioid-combination tablets at **325 mg**.

Clinical course — the four phases

Phase	Time after ingestion	Features
I (pre-injury)	0.5–24 h (often 4–12 h)	Nausea, vomiting, anorexia, diaphoresis, malaise; <i>often asymptomatic</i> — normal LFTs
II (latent / early hepatic)	24–48 h	Initial symptoms abate; right-upper-quadrant pain; aminotransferases begin to rise, INR rising
III (hepatic)	72–96 h (3–5 days)	Peak injury: AST/ALT often >10,000 IU/L (towering), jaundice, coagulopathy,

Phase	Time after ingestion	Features
		encephalopathy, AKI, lactic acidosis; $\pm$ myocardial injury
IV (recovery / outcome)	4 days–2 weeks	Resolution in survivors (rarely any sequela) or progressive ALF and death

- ▶ **Biochemical signature:** very high aminotransferases with *disproportionately low bilirubin* early — characteristic of this hyperacute injury.
- ▶ **AKI** complicates ~75% of severe cases and is virtually always self-limited.
- ▶ **Massive ingestion** (serum levels ~500–1000 mg/L) can rarely cause early-onset coma, seizures, hypotension and **anion-gap metabolic acidosis** *unrelated* to hepatic injury.

Risk assessment and investigations

- ▶ **Serum paracetamol level:** the key investigation — draw ≥ 4 h after a single acute ingestion and plot on the **Rumack-Matthew (acetaminophen) nomogram** against time.
 - Treat if the level lies **above the nomogram treatment line**; Harrison cites levels >200 $\mu\text{g/mL}$ at 4 h or >100 $\mu\text{g/mL}$ at 8 h as indications. Levels >300 $\mu\text{g/mL}$ at 4 h predict severe damage; <150 $\mu\text{g/mL}$ suggest injury is highly unlikely.
 - **Nomogram limitations:** valid only for a *single acute ingestion within a known 24-h window*. It **cannot be used** for staggered/chronic overdose, unknown time of ingestion, or sustained-release/anticholinergic co-ingestion (delayed peaks). In such cases treat empirically based on dose history and LFTs.
- ▶ **Baseline and serial labs:** LFTs (AST/ALT, bilirubin, ALP), INR/PT, serum creatinine and urea, blood glucose (hypoglycaemia), arterial blood gas/pH and lactate, phosphate, ammonia, and a pregnancy test. Importantly, **paracetamol is undetectable in plasma in ~50%** of patients who already present in liver failure.

Management — stepwise

1. Resuscitation and supportive care (priority).

- ▶ Secure airway, breathing, circulation; intubate for grade 3–4 encephalopathy.
- ▶ IV fluids to maintain intravascular volume; **correct hypoglycaemia**, acidosis and electrolyte disturbance; **norepinephrine** is the preferred vasopressor in ALF.

2. Gastrointestinal decontamination.

- ▶ **Activated charcoal** if the patient presents within 1–2 h of ingestion (especially large/co-ingestions). Charcoal's interference with oral NAC absorption is *not clinically significant*.
- ▶ **Gastric lavage** is rarely used today; if performed it should precede oral agents.

3. Specific antidote — N-acetylcysteine (NAC). *The cornerstone of treatment.*

- ▶ **Start within 8–10 h** for maximal effect; routine use has substantially reduced fatal hepatotoxicity. NAC is still at least **partially effective up to 24–36 h**, and benefits even *established* ALF — when in doubt, give it.
- ▶ **Indications:** level above the nomogram line; or presentation >8 h with a history of significant ingestion (start NAC, then check level); or staggered/late presentation with abnormal LFTs; or any established hepatotoxicity.

Route	Regimen
IV (FDA-approved 21-h, “three-bag” Acetadote)	150 mg/kg over 60 min → 50 mg/kg over 4 h → 100 mg/kg over 16 h (total ~300 mg/kg/21 h)
Oral (traditional 72-h protocol)	Loading 140 mg/kg, then 70 mg/kg every 4 h × 17 doses; dilute to ~5%

- ▶ IV is generally preferred (vomiting often limits oral NAC); give IV if oral is not tolerated.
- ▶ **High-risk ingestions** (reported >30 g, or measured level >twice the nomogram line): higher/extended NAC dosing — **contact a poison-control centre / medical toxicologist.**
- ▶ **Endpoint of therapy:** continue (and extend, for massive overdose) until **serum paracetamol is undetectable, aminotransferases are normal or clearly falling, and INR is improving** with a clinically well patient.
- ▶ **Adverse effect:** IV NAC can cause rate-related **anaphylactoid (histaminoid) reactions** — flushing, urticaria, bronchospasm; managed by pausing the infusion and antihistamine, then resuming slower.
- ▶ **Fomepizole** (a CYP2E1 inhibitor) has been proposed as an adjunct in massive overdose but is **not routinely used**; haemodialysis is rarely needed except in massive ingestion with very high levels/coma.

4. Management of established acute liver failure.

- ▶ **Early transfer to a liver-transplant centre** is essential; continue NAC.
- ▶ **Cerebral oedema / intracranial hypertension** (leading cause of death): head-of-bed elevation to 30°, intubate stage 3–4 encephalopathy, **mannitol 0.5 g/kg** or hypertonic saline (target Na⁺ 145–155 mmol/L) for raised ICP. **Lactulose/rifaximin are of uncertain value.**
- ▶ **Coagulopathy** should generally **not** be routinely corrected (it guides prognosis); treat clinically significant bleeding only.
- ▶ **AKI:** use **continuous renal replacement therapy** if needed — *avoid intermittent haemodialysis*, which raises ICP.
- ▶ Stress-ulcer prophylaxis (PPI/H₂ blocker); sepsis surveillance cultures with broad-spectrum cover for suspected infection (prophylactic antibiotics do not improve survival); maintain glucose; enteral protein 1–1.5 g/kg/day.

5. Liver transplantation — prognostication.

- ▶ Refer for emergency transplantation using the **King's College Hospital** criteria for paracetamol-induced ALF:
 - **Arterial pH <7.3** (after adequate fluid resuscitation), **OR**
 - **All three of: INR >6.5, serum creatinine >3.4 mg/dL (>300 µmol/L), and grade III–IV encephalopathy.**
- ▶ **Early arterial lactate >3.5 mmol/L** also identifies patients likely to need transplantation. A *rising* α-fetoprotein predicts a favourable (regenerating) outcome. With modern care, transplant-free survival in paracetamol ALF is ~75%.

6. **Psychosocial care.** After intentional overdose, arrange **psychiatric assessment** and risk-of-suicide evaluation before discharge; counsel and warn about combination products to prevent re-exposure.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Metabolic pathway of paracetamol.** Boxes/arrows: *Paracetamol* → (major, ~90%) **Glucuronidation + Sulfation** → non-toxic conjugates → renal excretion; and → (minor, **CYP2E1**) → **NAPQI (toxic)**. From NAPQI: + **Glutathione** → **Mercapturic acid** (non-toxic, urine). Label: “*Glutathione depleted* → *NAPQI binds hepatocyte macromolecules* → *centrilobular necrosis*.” Show **NAC** arrow replenishing glutathione. Label inducers: *alcohol, isoniazid, starvation*.
- ▶ **Rumack-Matthew nomogram.** Axes: x = *time since ingestion (4–24 h)*; y = *serum paracetamol (µg/mL, log scale)*. Draw the descending “**treatment line**” (≈150 µg/mL at 4 h falling to ≈4.7 at 24 h); shade the region **above the line** = “**Treat with NAC.**” Mark the **4-h sampling point**.

Clinical / Diagnostic significance

- ▶ The **single 4-h (or later) level on the nomogram** is the decisive triage tool — it converts an asymptomatic patient into a defined risk category and dictates antidote need.
- ▶ **Time-to-NAC is the strongest modifiable determinant of outcome** — never delay NAC awaiting a level if presentation is late or ingestion is large.
- ▶ The **AST/ALT >10,000 IU/L with low bilirubin** pattern should prompt suspicion of paracetamol toxicity even when the history is denied or obscure.
- ▶ NAC also has evidence of benefit in **non-paracetamol ALF** with early-stage encephalopathy (off-label).
- ▶ Persistent acidosis, rising INR/creatinine and encephalopathy mandate **transplant-centre referral** by King's College criteria.

High-yield exam pointers

- ▶ Toxic threshold: >150–200 mg/kg or ~8–10 g acute; fatal fulminant disease usually ≥ 25 g; maximum therapeutic dose 4 g/day (FDA-advised 3 g; ~2 g toxic in alcoholics).
- ▶ Toxic metabolite = NAPQI, generated via CYP2E1, detoxified by **glutathione**; necrosis is **centrilobular** (zone 3).
- ▶ Antidote = N-acetylcysteine; most effective <8 h, useful up to 24–36 h and in established failure.
- ▶ IV three-bag NAC: 150 mg/kg/1 h $\rightarrow$ 50 mg/kg/4 h $\rightarrow$ 100 mg/kg/16 h. Oral: 140 mg/kg then 70 mg/kg q4h $\times$ 17 doses.
- ▶ Rumack-Matthew nomogram guides treatment; **invalid** for staggered/chronic/unknown-time ingestions.
- ▶ Activated charcoal useful within 1–2 h; does not meaningfully impair NAC.
- ▶ King's College criteria (paracetamol ALF): pH <7.3, or the triad INR >6.5 + creatinine >3.4 mg/dL + grade III–IV encephalopathy; lactate >3.5 mmol/L predicts need for transplant.
- ▶ IV NAC can cause **anaphylactoid reactions**; paracetamol is **undetectable** in ~50% of patients already in liver failure.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Toxic and Drug-Induced Hepatitis” (acetaminophen hepatotoxicity: NAPQI/CYP2E1 mechanism, dose thresholds, NAC regimen, nomogram thresholds) and “Poisoning and Drug Overdose” (general approach: supportive care, decontamination, antidotes).
- ▶ **CMDT 2026** — “Poisoning: Acetaminophen” (risk stratification, nomogram, activated charcoal, IV/oral NAC regimens, fomepizole) and “Acute Liver Failure” (ALF management, prognostic indices/poor-outcome thresholds, transplantation).
- ▶ *Coverage note:* The corpus supplies all clinical components but does not use the exact labels “Rumack-Matthew nomogram,” the named “four phases,” or “King's College criteria” verbatim — these are universally accepted standard internal-medicine eponyms used here for organisation; their underlying values (pH <7.3, INR >6.5, creatinine >3.4 mg/dL, grade III–IV encephalopathy; nomogram cut-offs; phase timings) are all grounded in the cited chapters.

Ethylene glycol poisoning

Asked in: Paper IV Nov 2021 — RGUHS MD General Medicine

Definition / Introduction — Ethylene glycol (EG) is a colourless, sweet-tasting toxic alcohol used in antifreeze, brake fluid and windshield washer/de-icer fluids; poisoning follows accidental, suicidal or substitute-alcohol ingestion. EG itself is relatively non-toxic and produces only an ethanol-like

inebriation, but its sequential oxidation by **alcohol dehydrogenase (ADH)** generates organic-acid metabolites (glycolate, oxalate) that cause a life-threatening **high-anion-gap metabolic acidosis (AGMA)** with damage to the CNS, heart, lungs and kidneys. The combination of a **high anion gap plus a high osmolar gap** is the diagnostic signature, and rational therapy (fomepizole, hemodialysis, cofactors) is built around blocking and removing the toxic metabolites.

SOURCE & COVERAGE

- ▶ **Sources:** antifreeze, brake fluid, windshield washer/de-icer fluids. EG is a low-molecular-weight solute, so it raises serum osmolality and the **osmolal gap** while the parent compound predominates.
- ▶ **Parent vs metabolite toxicity:** EG is one of the agents whose *metabolites are more toxic than the parent compound* (alongside acetaminophen and methanol) — hence early high blood levels mandate antidote/dialysis even before symptoms peak.
- ▶ **Metabolic cascade (rate-limiting step = ADH):** EG → (ADH) → glycoaldehyde → (aldehyde dehydrogenase) → **glycolic acid (glycolate)** → glyoxylic acid → **oxalic acid (oxalate)**.
- ▶ **Mechanisms of injury (Harrison Ch 470):**
 - EG causes **CNS depression** and **increased serum osmolality**.
 - Metabolites — *primarily glycolic acid* — cause the **AGMA, CNS depression and renal failure**.
 - Lactic acid (l-lactate) production rises because metabolites inhibit the **tricarboxylic acid cycle** and alter the intracellular redox state, adding to the anion gap.
 - **Oxalic acid** precipitates as **calcium oxalate** in tissues and urine → **hypocalcaemia**, tissue oedema and **crystalluria**; acute tubular injury is caused *initially by glycolate* and *later amplified by tubular obstruction from oxalate crystals*.

Clinical features — the evolving stages

EG poisoning classically evolves through overlapping phases; the parent alcohol intoxicates early, while delayed metabolite toxicity drives the acidosis, cardiopulmonary collapse and renal failure.

Phase	Dominant mediator	Clinical features
Neurological (early)	Parent EG	“Ethanol-like” intoxication <i>without the smell of alcohol</i> , nausea, vomiting, increased osmolar gap , early calcium-oxalate crystalluria; severe cases → coma, seizures
Cardiopulmonary	Glycolate / organic acids	Tachypnoea (Kussmaul breathing), hypotension , cardiac

Phase	Dominant mediator	Clinical features
		dysfunction, ARDS in severe cases
Renal (delayed)	Oxalate / glycolate	Delayed AGMA, flank/back pain, oliguria and acute renal failure (ATN), hypocalcaemia ($\pm$ tetany)

Biochemical hallmarks — the dual “gap”

- ▶ **High anion-gap metabolic acidosis:** EG is a leading toxic cause of severe AGMA (with methanol and salicylates). The unmeasured anions are **glycolate and oxalate**, so the measured **anion gap exceeds the lactate level** (a clue that the acidosis is *not* primarily lactic).
- ▶ **Osmolal gap:** difference of >10 mmol/L between **measured osmolality** (by freezing-point depression) and **calculated osmolality** = $2[\text{Na}^+] + [\text{glucose}]/18 + [\text{BUN}]/2.8$. EG (a low-MW glycol) widens this gap.
- ▶ **Temporal dissociation of the two gaps:** the **osmolar gap rises early** (parent EG present) and **falls as it is metabolised**, while the **anion gap rises later** as glycolate/oxalate accumulate — so a *normal osmolar gap does not exclude EG late after ingestion*, and a high AG may appear once the osmolar gap has fallen.
- ▶ The combination of **high AG + high osmolar gap** is *highly suspicious for EG or methanol* and should be taken as **evidence of EG toxicity before confirmatory EG levels return** — **do not delay treatment** awaiting the level.

Diagnosis and investigations

- ▶ **History** of antifreeze/solvent ingestion or unexplained inebriation with severe acidosis.
- ▶ **ABG + electrolytes:** severe metabolic acidosis with a **high anion gap**; calculate the AG.
- ▶ **Serum osmolality** (measured, freezing-point depression) vs calculated $\rightarrow$ **osmolal gap**.
- ▶ **Quantitative EG level** — useful but treatment is not deferred for it; levels guide antidote/dialysis thresholds.
- ▶ **Serum calcium** — **hypocalcaemia** (also seen in fluoride and oxalate poisoning); check ECG for QT prolongation.
- ▶ **Renal function / urinalysis** — rising creatinine, ATN; **calcium-oxalate crystalluria** (envelope-shaped / needle crystals).
- ▶ **Lactate** — may be mildly elevated; the AG typically *exceeds* measured lactate.
- ▶ Some EG products fluoresce under **Wood’s lamp** (fluorescein additive) — supportive, *standard toxicology, not in the provided chapters*.

Management

Therapy targets three goals: **block ADH** (stop metabolite formation), **correct acidaemia** and **divert metabolism with cofactors**, and **remove EG/metabolites by dialysis**. (Harrison Ch 58 treatment box + Ch 470 table.)

Intervention	Detail / indication
Supportive	IV isotonic fluids; airway protection/ventilation for CNS depression, seizures; treat shock
Correct acidaemia	IV sodium bicarbonate for severe acidaemia
ADH blockade — antidote of choice	Fomepizole (4-methylpyrazole): 15 mg/kg IV over 30 min loading dose, then 10 mg/kg every 12 h for four doses. Predictable fall in EG level without the obtundation seen with ethanol. Continue until blood pH normal or osmolar gap <10 mOsm/kg H ₂ O
Ethanol (alternative)	Of historic interest; competes with EG for ADH; used only if fomepizole is unavailable
Antidote thresholds	Start ethanol/fomepizole for AGMA, crystalluria/renal dysfunction, EG level >3 mmol/L (20 mg/dL), or ethanol-like intoxication / raised osmolal gap when the level is not readily obtainable
Cofactors (divert metabolism)	Thiamine, high-dose pyridoxine, magnesium and folinic acid — push glyoxylate toward non-toxic glycine/α-hydroxy-β-ketoadipate rather than oxalate
Hemodialysis	Indicated when arterial pH <7.3, persistent high-AG acidosis, osmolar gap >20 mOsm/kg H ₂ O, or end-organ damage (CNS, renal failure); also enhances EG elimination and shortens treatment when EG level >8 mmol/L (50 mg/dL)

- ▶ Fomepizole and ethanol both act by **competing with EG for alcohol dehydrogenase**; fomepizole is preferred (no CNS depression, no level monitoring, predictable kinetics).
- ▶ Hemodialysis removes both the parent EG and the dialysable metabolites/anions and corrects the acidosis simultaneously.

Toxic alcohols compared

Feature	Ethylene glycol	Methanol	Isopropyl alcohol
Key enzyme	Alcohol dehydrogenase	Alcohol dehydrogenase	Alcohol dehydrogenase
Toxic metabolite	Glycolate, oxalate	Formic acid	Acetone (parent toxic)
Anion gap	High AGMA	High AGMA	No high AG (unless shock)

Feature	Ethylene glycol	Methanol	Isopropyl alcohol
Osmolar gap	Raised	Raised	Raised
Target organ	CNS, heart, lungs, kidney	Optic nerve / retina, CNS	CNS; haemorrhagic gastritis
Specific cofactor	Thiamine, pyridoxine, Mg, folinic acid	Folinic acid / folate	(none; supportive)
Antidote / dialysis	Fomepizole + HD	Fomepizole + HD	Supportive + HD if level >400 mg/dL

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Metabolic pathway with antidote block (label exactly):** *Ethylene glycol* → [Alcohol dehydrogenase (ADH)] → *Glycoaldehyde* → [Aldehyde dehydrogenase] → *Glycolic acid (glycolate)* → *Glyoxylic acid* → *Oxalic acid (oxalate)* → *Calcium oxalate crystals*. Mark *Fomepizole / Ethanol* = ADH inhibition (block) at the first step; show *Thiamine and Pyridoxine* diverting *Glyoxylate* to non-toxic α -hydroxy- β -keto adipate / *Glycine*. Annotate metabolite effects: AGMA, renal failure, hypocalcaemia.
- ▶ **Time-course graph of the two gaps:** x-axis = *time after ingestion (hours)*; two curves — *Osmolar gap* (peaks early, then declines) and *Anion gap* (rises later); shade overlap labelled *high osmolar gap + high anion gap = window of EG toxicity*.

Clinical / Diagnostic significance

- ▶ A patient with severe high-AG metabolic acidosis + high osmolar gap + calcium-oxalate crystalluria + hypocalcaemia is EG poisoning until proven otherwise.
- ▶ Empirical fomepizole + bicarbonate must not be delayed for confirmatory EG levels — early ADH blockade prevents metabolite-driven renal failure and death.
- ▶ The osmolar gap normalises before the anion gap, so timing of presentation changes which gap is abnormal; rely on the clinical picture, not a single gap.
- ▶ Hemodialysis is both detoxifying (removes EG + anions) and corrective (treats acidosis/renal failure) — a key therapeutic decision point.
- ▶ EG is a “toxic time-bomb”: an apparently well, inebriated patient can deteriorate hours later as metabolites accumulate — observe and re-check gaps.

High-yield exam pointers

- ▶ Source = antifreeze; ADH converts EG to glycolate (acidosis) and oxalate (renal failure + hypocalcaemia).
- ▶ Diagnostic dyad = high anion gap + high osmolar gap; calcium-oxalate crystalluria is the urinary clue.

- ▶ Calculated osmolality = $2\text{Na}^+ + \text{glucose}/18 + \text{BUN}/2.8$; osmolal gap $>10 \text{ mmol/L}$ is significant (measured by freezing-point depression).
- ▶ Fomepizole 15 mg/kg load, then 10 mg/kg q12h $\times 4$ doses — antidote of choice; continue until pH normal or osmolar gap <10 .
- ▶ Hemodialysis if pH <7.3 , osmolar gap >20 , end-organ damage, or EG level $>8 \text{ mmol/L}$ (50 mg/dL); antidote threshold EG $>3 \text{ mmol/L}$ (20 mg/dL).
- ▶ Cofactors: thiamine, pyridoxine, magnesium, folinic acid; alkali with NaHCO_3 .
- ▶ Ethanol is now second-line, used only when fomepizole is unavailable.
- ▶ Distinguish from methanol (formate $\rightarrow$ blindness, folinic acid) and isopropanol (acetone, *no* high AG).

SOURCE & COVERAGE

Harrison's Principles of Internal Medicine, 22e — Ch 470 "Poisoning and Drug Overdose" (EG mechanism/clinical/treatment table, osmolal-gap and AGMA discussion) and Ch 58 "Acidosis and Alkalosis" (toxic-alcohol section, osmolar-gap calculation, fomepizole dosing and hemodialysis criteria). *Coverage note:* the precise phase **timing windows** (hours), Wood's-lamp fluorescence, urinary crystal morphology, and the named intermediates *glycoaldehyde/glyoxylic acid* are standard textbook toxicology not spelled out in the provided chapters (the chapters explicitly name ADH, glycolate, oxalate); they are accurate, universally accepted additions for completeness.

List the delayed effects of organophosphorus (OP) toxicity. Discuss the management options for OP poisoning

Asked in: Paper IV May 2025 — RGUHS MD General Medicine

Definition / Introduction — Organophosphorus (OP) compounds are anticholinesterase agents used chiefly as agricultural insecticides (parathion, malathion, chlorpyrifos, diazinon, fenthion, dimethoate) and as chemical-warfare "nerve agents" (tabun [GA], sarin [GB], soman [GD], VX). They are well absorbed through intact skin, by inhalation and by the gastrointestinal route, and **phosphorylate acetylcholinesterase (AChE)**, causing accumulation of acetylcholine at muscarinic, nicotinic and CNS synapses. The acute illness is a cholinergic crisis, but OP toxicity is biphasic/triphasic — a constellation of **delayed neurological syndromes** (intermediate syndrome, OP-induced delayed polyneuropathy, chronic neuro-behavioural sequelae) may emerge days to weeks after the acute episode, and lipophilic agents may produce a **relapsing** cholinergic phase. This makes OP poisoning a sustained ICU and rehabilitative challenge, not a single-event intoxication.

Acute cholinergic toxidrome (context for the delayed phase)

- ▶ **Muscarinic (DUMBBELS):** *Diarrhoea/Defaecation, Urination, Miosis, Bradycardia/Bronchorrhoea/Bronchospasm, Emesis, Lacrimation, Salivation/Sweating* — plus abdominal cramps and wheeze.
- ▶ **Nicotinic:** muscle fasciculations, weakness, paralysis, tachycardia, hypertension; initial tachycardia is usually followed by bradycardia.
- ▶ **CNS:** anxiety, headache, seizures, coma; **death is usually due to respiratory failure** (bronchorrhoea + bronchospasm + respiratory-muscle weakness).
- ▶ **Diagnosis** is clinical (miosis, sweating, diarrhoea) and confirmed by **plasma (pseudo-/butyryl-) and RBC (true) cholinesterase activity depressed $\geq 50\%$ below baseline** in significant intoxication.

Delayed effects of OP toxicity (the core list)

Delayed syndrome	Onset after exposure	Receptor / mechanism	Cardinal features
Intermediate syndrome (IMS)	Within ~24–96 h (≤ 4 days), after the cholinergic crisis resolves	Persistent nicotinic AChE inhibition at the neuromuscular junction	Proximal limb, neck-flexor, bulbar, cranial-nerve and respiratory-muscle weakness → respiratory failure; resolves in 2–3 weeks
OP-induced delayed polyneuropathy (OPIDN)	~2–3 weeks (even without preceding cholinergic toxicity)	Phosphorylation + inhibition and “ageing” of neuropathy target esterase (NTE)	Distal sensorimotor axonopathy: calf cramps, paraesthesiae, ascending distal→proximal weakness, areflexia; later upper-motor-neuron signs
Recurrent / prolonged cholinergic toxicity	Hours–days, fluctuating	Re-release of agent stored in fat	Recurrent muscarinic/nicotinic signs, esp. highly lipid-soluble agents (fenthion, dimethoate)
Chronic neuro-behavioural sequelae (COPIND)	Weeks–months	Uncertain; ?central axonal injury, hypoxic insult	Persisting cognitive/behavioural dysfunction; “dipper’s flu” after low-level exposure
Extrapyramidal / central effects	Days–weeks	Basal-ganglia/corticospinal involvement	Dystonia, parkinsonism; spasticity unmasked as the neuropathy recovers

Intermediate syndrome (IMS) — detail

- ▶ Occupies the **interval between the acute cholinergic crisis and the delayed neuropathy**, typically becoming manifest within ~4 days of exposure and resolving over 2–3 weeks (originally described by *Senanayake and Karalliedde*).
- ▶ Reflects **excessive cholinergic stimulation of nicotinic receptors** and **prolonged inhibition of AChE activity**; it correlates with severity of poisoning but **not** with the later development of OPIDN.
- ▶ Clinically: **respiratory and bulbar weakness with proximal limb weakness** (neck flexors, ocular and cranial muscles); the danger is unheralded **respiratory arrest**, so it is an indication for close respiratory monitoring/elective ventilation.

OP-induced delayed polyneuropathy (OPIDN) — detail

- ▶ A **delayed polyneuropathy** appearing ~2–3 weeks after acute exposure, even in the absence of **cholinergic toxicity**. The classic historical epidemic was contamination of illicit alcohol (“*Jake*”/Ginger-Jake leg) with **tri-ortho-cresyl phosphate (TOCP)**; other culprits include **leptophos, trichlorfon and mipafox**.
- ▶ **Clinical course**: paraesthesiae in the feet and **calf-muscle cramps**, followed by progressive weakness beginning **distally** and spreading proximally; maximal deficit within ~2 weeks; **quadriplegia in severe cases**. Sensory complaints are inconspicuous though deficits are found on examination. The **Achilles reflex is typically lost**; **cranial-nerve function is spared**. With time the peripheral neuropathy improves but **upper-motor-neuron involvement is then unmasked** and determines functional prognosis.
- ▶ **Mechanism**: phosphorylation and inhibition of **neuropathy target esterase (NTE)**, followed by “**ageing**” (loss of a side-group leaving a negatively charged phosphoryl-protein) — ageing of inhibited NTE is required for the neuropathy to develop. Pathologically there is a **central–peripheral distal axonopathy** with degeneration of the **gracile fasciculus and corticospinal tracts** in addition to peripheral nerve.
- ▶ **Electrodiagnosis**: an **axonopathy** — partial denervation, small/absent compound muscle action potentials, with **normal or only minimally reduced motor conduction velocity**.
- ▶ **There is no specific treatment** to arrest progression or hasten recovery; management is supportive and rehabilitative. Lymphocyte NTE has been used to monitor occupational exposure.

Other delayed / chronic effects

- ▶ **Relapsing cholinergic crisis**: with highly lipid-soluble OPs (fenthion, dimethoate), symptoms may **persist or recur over several days** as the agent is redistributed from fat — mandating prolonged atropine therapy and observation.
- ▶ **Chronic OP-induced neuropsychiatric disorder (COPIND)** and “**dipper’s flu**” (headache, rhinitis, pharyngitis, myalgia, flu-like symptoms in sheep-dippers): a meta-analysis has linked

low-level exposure to impaired neuro-behavioural function, although causation after a single acute exposure remains uncertain.

- ▶ **Susceptibility:** **paraoxonase (PON1)** status (a hepatic/serum enzyme that hydrolyses OPs) is a biomarker modulating individual vulnerability to acute toxicity.

Management of OP poisoning

Care proceeds along four axes — **resuscitation/decontamination, antidotes (atropine + an oxime), control of seizures, and monitoring for the delayed syndromes.**

1. Resuscitation & supportive care (priority)

- ▶ **Airway, oxygenation and ventilation first** — secure the airway, give high-flow O₂, suction copious secretions; intubate and mechanically ventilate for respiratory failure (bronchorrhoea, weakness, IMS). *Ensure adequate ventilatory support before giving atropine.*
- ▶ Treat seizures with **benzodiazepines** (diazepam/lorazepam); correct hypotension, arrhythmias and metabolic derangements.

2. Decontamination

- ▶ **Skin/hair:** remove contaminated clothing and **wash repeatedly with soap/shampoo and water**; staff must wear **gloves and waterproof aprons** to avoid secondary exposure (dilute hypochlorite ~1:10 helps degrade OP on equipment/clothing).
- ▶ **GI** (recent ingestion): consider **nasogastric aspiration of liquid followed by activated charcoal**; eye decontamination if ocular exposure.

3. Specific antidotes

Antidote	Action	Regimen (per CMDT)
Atropine	Competitively blocks muscarinic effects (dries secretions, relieves bronchospasm/bradycardia); no effect on nicotinic weakness	2 mg IV ; if no response in 5 min, repeat doubling boluses rapidly, titrated to drying of bronchial secretions and reduced wheeze — <i>several hundred mg</i> may be needed in severe cases
Pralidoxime (2-PAM)	Reactivates phosphorylated cholinesterase by removing the OP — acts at nicotinic and muscarinic sites	1–2 g IV loading dose , then continuous infusion 200–500 mg/h , titrated and continued as long as acetylcholine excess persists

- ▶ **Atropine** controls the muscarinic crisis but does not reverse muscle weakness; the **oxime** is the agent that can reverse the nicotinic component and so attenuate weakness/respiratory paralysis.
- ▶ **Timing is critical:** pralidoxime is most effective **given very early**, before “ageing” makes OP–enzyme binding permanent (irreversible); efficacy data in trials are conflicting on mortality, but it remains standard for OP and nerve-agent poisoning.

- ▶ Pralidoxime is of questionable benefit in carbamate poisoning — carbamates inhibit AChE only transiently (no ageing); carbamate toxicity is milder and atropine alone usually suffices.

4. Monitoring and delayed-phase care

- ▶ Prolonged ICU observation: watch for IMS (respiratory failure within 1–4 days) and recurrent cholinergic toxicity with lipophilic agents; serial cholinesterase levels guide recovery.
- ▶ OPIDN/IMS care is supportive — ventilatory support, physiotherapy and rehabilitation; there is no antidote for the established neuropathy.
- ▶ Unproven adjuncts mentioned in the literature include magnesium, sodium bicarbonate, clonidine and extracorporeal removal — not established therapy.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ “Phases / timeline of OP toxicity” arrow diagram (a horizontal time axis from exposure): label Acute cholinergic crisis (minutes–hours: muscarinic + nicotinic + CNS) → Intermediate syndrome (24–96 h / ≤4 days: proximal, neck-flexor, bulbar & respiratory-muscle weakness) → OPIDN (2–3 weeks: distal sensorimotor axonopathy → later UMN signs) → Chronic neuro-behavioural sequelae (weeks–months).
- ▶ Synapse schematic of AChE inhibition: label presynaptic terminal, acetylcholine, synaptic cleft, acetylcholinesterase, OP phosphorylating AChE, “ageing” → irreversible enzyme, muscarinic receptor (→ atropine block), nicotinic receptor (→ pralidoxime reactivation).

Clinical / Diagnostic significance

- ▶ Diagnosis rests on the toxidrome (miosis, sweating, diarrhoea, bronchorrhoea, fasciculations) plus RBC and plasma cholinesterase depressed ≥50%; RBC (true) cholinesterase best reflects synaptic enzyme and recovery.
- ▶ Recognising the delayed phases changes disposition — an apparently recovering patient can develop IMS-related respiratory arrest, so early extubation and ward transfer are hazardous.
- ▶ OPIDN mimics Guillain–Barré/toxic neuropathy but is distal, motor-predominant, areflexic with cranial sparing and may later show spasticity (corticospinal degeneration) — an important neurology cross-over.
- ▶ Early, adequately titrated atropinisation + oxime + ventilation are the determinants of survival in the acute phase.

High-yield exam pointers

- ▶ Three classic delayed effects: Intermediate syndrome (1–4 days, nicotinic, respiratory/bulbar/proximal weakness), OPIDN (2–3 weeks, NTE inhibition + ageing, distal

axonopathy), chronic neuro-behavioural sequelae ($\pm$ relapsing cholinergic crisis with lipophilic agents).

- ▶ **OPIDN agents:** tri-ortho-cresyl phosphate (Ginger-Jake/"Jake"), leptophos, trichlorfon, mipafox; lesion = **central–peripheral distal axonopathy** (gracile fasciculus + corticospinal tracts).
- ▶ **Mechanism keyword for OPIDN:** inhibition + “ageing” of neuropathy target esterase (NTE) — *not* AChE.
- ▶ **Atropine** reverses muscarinic signs (endpoint = **dry chest/secretions**); **pralidoxime (2-PAM)** reverses the **nicotinic/weakness** component and must be given **early** (before ageing).
- ▶ **Atropine 2 mg IV, doubling boluses; pralidoxime 1–2 g IV load then 200–500 mg/h infusion.**
- ▶ **Carbamates:** shorter-acting, milder, atropine usually sufficient, oxime of questionable benefit (no ageing).
- ▶ **Death is usually from respiratory failure;** ventilate early. **PON1 (paraoxonase)** modulates susceptibility.
- ▶ **Decontamination:** remove clothes, soap-and-water skin wash, **protect staff (gloves/aprons)**; NG aspiration + activated charcoal for ingestion.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Poisoning and Drug Overdose” (anticholinesterase/cholinergic toxidrome, cholinesterase $\geq 50\%$ depression, fundamentals of poisoning management) and “Peripheral Neuropathy” (OP binding/inhibition of neuropathy target esterase; gracile-fasciculus + corticospinal axonal degeneration).
- ▶ **Bradley's Neurology in Clinical Practice, 8e** — “Effects of Toxins and Physical Agents on the Nervous System” (intermediate syndrome timing/features; OPIDN — TOCP/leptophos/trichlorfon/mipafox, NTE inhibition and ageing, clinical course, electrodiagnosis; dipper's flu; PON1) and “Disorders of Peripheral Nerves.”
- ▶ **CMDT 2026** — “Poisoning: Pesticides – Cholinesterase Inhibitors” (clinical findings, decontamination, atropine and pralidoxime regimens, recurrence with fenthion/dimethoate, carbamate caveat, unproven adjuncts).
- ▶ *Coverage note:* Harrison 22e covers OP only within the general poisoning chapter (toxidrome and antidote table); the deep delayed-effect detail (IMS, OPIDN mechanism, ageing) is drawn from Bradley's Neurology and the management regimens from CMDT 2026 — together these fully support the answer.

Management of Poisonous Snake Bite

Asked in: Paper IV May 2022 — RGUHS MD General Medicine

Definition / Introduction — Snake envenomation is the injection of venom — a complex mixture of enzymes, polypeptides, glycoproteins and other constituents — through hollow or grooved maxillary fangs, producing **local tissue necrosis, coagulopathy, organ dysfunction and/or neuromuscular-junction paralysis**. Globally there are an estimated 1.2–5.5 million snakebites/year with 421,000–1,200,000 envenomations, and the WHO aims to halve snakebite deaths by 2030. Notably, ~20–25% of pit-viper bites (and up to 75% of sea-snake bites) are “**dry**” bites with no venom delivered, so management is driven by *evidence of envenomation*, not the fact of the bite alone. The cornerstone of treatment is rapid transport to a facility with airway support and **species-appropriate antivenom**, which is the only specific antidote.

Venomous snakes & clinical syndromes (orientation)

- ▶ **Viperids** (pit vipers, Russell’s viper *Daboia russelii*, saw-scaled viper): triangular head, elliptical pupils, long mobile fangs, loreal heat-pits — predominantly **cytotoxic + haemotoxic** (local swelling/necrosis, coagulopathy, bleeding).
- ▶ **Elapids** (cobras *Naja*, kraits *Bungarus*, coral snakes *Micrurus*): fixed small erect fangs (fewer puncture marks), predominantly **neurotoxic** — descending paralysis.
- ▶ **Sea snakes**: predominantly **myotoxic** — myalgia, trismus, rhabdomyolysis, flaccid paralysis (often delayed hours).

Syndrome	Key features (source-grounded)
Local (cytotoxic)	Pain, soft-tissue swelling, ecchymosis, haemorrhagic/serum-filled vesicles & bullae, tissue loss/necrosis
Haemotoxic	Spontaneous bleeding, haemolysis, venom-induced consumptive coagulopathy, thrombocytopenia
Neurotoxic	Nausea/headache/paraesthesia → cranial-nerve signs (<i>ptosis</i> , dysphagia) → peripheral weakness → diaphragmatic paralysis & respiratory failure
Systemic	Fatigue, vomiting, taste change, mouth numbness, tachy-/bradycardia, hypotension, fasciculations, pulmonary oedema, renal dysfunction, rhabdomyolysis

First-aid / Field management (pre-hospital)

- ▶ **Rapid transport** to a medical facility equipped to provide airway/breathing/circulation support and antivenom is the single most important step; discourage delay with traditional healers.
- ▶ **Reassure and immobilise**: remove jewellery/tight clothing (anticipated swelling), clean wound with soap and running water, cover with a sterile dressing — but *wound care must not delay transport*.

- ▶ **Splint** the bitten extremity to limit movement; keep it in a neutral position of comfort at approximately heart level.
- ▶ Do **not** attempt to capture the snake — take digital photographs from a safe distance to aid identification.
- ▶ **Abandon harmful traditional measures**: do NOT incise or apply suction (worsens tissue damage, infection, ineffective); do NOT apply tourniquets or lympho-occlusive bandages (“venom sequestration devices”) — they intensify local necrosis and risk ischaemia/loss of function.
- ▶ **Pressure-immobilisation bandage**: reserved **ONLY** for bites by a *reliably identified, primarily neurotoxic elapid* with no local tissue effect — wrap the entire limb and immobilise to restrict lymphatic spread; **never for viperid bites**. Wrap pressure 40–70 mmHg (upper limb), 55–70 mmHg (lower limb) — snug but loose enough to slip a finger under; the victim must be *carried* (walking pumps venom systemically).

Hospital management — resuscitation, monitoring & investigations

- ▶ **ABC first**: bites to face/neck may need **early endotracheal intubation** before swelling occludes the airway. Monitor vitals, cardiac rhythm, SpO₂ and urine output.
- ▶ Establish **two large-bore IV lines in unaffected limbs**; because of coagulopathy, minimise venipunctures and avoid non-compressible sites (e.g. subclavian).
- ▶ **Hypotension**: early shock is due to bradykinin-potentiating factors (vasodilation, splanchnic/pulmonary pooling), systemic bleeding, haemolysis and third-spacing → give isotonic crystalloid (**normal saline or Ringer’s lactate 20–40 mL/kg IV**). Add a **vasopressor (noradrenaline/adrenaline)** only if shock persists after volume + antivenom (consider concurrent anaphylaxis).
- ▶ Remove any field bandages **cautiously** (sudden release of stagnant acidotic venom-laden blood can cause hypotension/dysrhythmia).
- ▶ **Mark and measure**: outline the leading edge of swelling/ecchymosis/tenderness and measure limb circumference at three points **every 15 min until stable**, then 1–2 hourly; keep the limb above heart level. Watch neurotoxic victims for *ptosis* heralding airway compromise.
- ▶ **Investigations**: CBC (haemorrhage/haemolysis/thrombocytopenia), blood group & cross-match, renal & hepatic panel, PT/INR, **fibrinogen**, **FDP/D-dimer**, CK (rhabdomyolysis), urine for blood/myoglobin; ECG and chest X-ray in severe cases. In resource-limited settings the **20-minute whole-blood clotting test (20WBCT)** detects coagulopathy: 1–2 mL venous blood in a clean dry glass tube left undisturbed 20 min — *failure to clot = coagulopathy*. Recheck labs every 6 h after antivenom.

Antivenom therapy (the mainstay)

- ▶ **Principle:** antivenoms are antibodies (or Fab/F(ab')₂ fragments) raised in horses or sheep that bind and neutralise *circulating, unbound* venom before it reaches target tissue. They may be **monospecific** or **polyspecific**; selection must match the offending species (no cross-protection unless venoms are homologous).
- ▶ **Key limitation:** antivenom reverses only *active* venom toxicity — it does **not** reverse established effects such as established paralysis or renal failure (these need time + supportive care).
- ▶ **Indications —**
 - *Viperid / cytotoxic bites:* progressive local findings (rapidly spreading swelling, swelling >½ the limb, extensive blistering/bruising, severe pain) **or** any systemic envenomation (systemic symptoms or laboratory abnormality).
 - *Neurotoxic elapid bites:* give at the **first sign of neurotoxicity** (cranial-nerve dysfunction, peripheral neuropathy).
 - Isolated mild pain/swelling after an unidentified bite may be from a harmless species — antivenom is then useless and potentially harmful.
- ▶ **Administration:** **IV only**, started *slowly* with the clinician at the bedside, then titrated up to deliver the full starting dose over ~1 h; redose if the patient worsens or venom effects recur. Antivenom should generally continue for viperid bites until definite improvement (reduced pain, stable vitals, restored coagulation).

Severity (US grading)	Findings	Antivenom approach
None	Fang marks only (“dry” bite)	None; observe
Mild	Local findings only, non-progressive	Usually none; observe
Moderate	Progressing swelling, systemic symptoms/signs, lab abnormality	Antivenom (e.g. CroFab 4–6 vials)
Severe	Neurologic dysfunction, respiratory distress, CV instability/shock	Antivenom (e.g. CroFab 6 vials); ICU

Antivenom reactions & their treatment

- ▶ **Early (anaphylactic / anaphylactoid):** tachycardia, rigors, vomiting, urticaria, dyspnoea, laryngeal oedema, bronchospasm, hypotension. **Skin testing is neither sensitive nor specific and is not recommended;** prophylactic antihistamines/glucocorticoids are *not* proven beneficial (limited Sri Lankan data support low-dose SC adrenaline pretreatment 0.25 mg of 1:1000). Adrenaline and airway equipment must always be ready.
- ▶ **Treatment of acute reaction:** STOP the infusion → **IM adrenaline 0.01 mg/kg (max 0.5 mg) + IV antihistamine (diphenhydramine 1 mg/kg, max 50 mg) + IV glucocorticoid (hydrocortisone 2 mg/kg, max 100 mg).** Once controlled, **restart antivenom at 5–10 mL/h** and titrate up; for

refractory hypotension run a concomitant IV adrenaline infusion in a monitored (ED/ICU) setting.

- ▶ **Late (serum sickness):** 1–2 weeks later — myalgia, arthralgia, fever, chills, urticaria, lymphadenopathy, renal/neurologic dysfunction. Treat with **oral prednisone 1–2 mg/kg/day** until resolution, then taper over 1–2 weeks, plus antihistamines/analgesics.

Management of complications & supportive care

- ▶ **Coagulopathy / bleeding:** blood products are *rarely* needed and factors rebound after adequate antivenom — give FFP/platelets **only after adequate antivenom** (otherwise they fuel ongoing consumption).
- ▶ **Neurotoxicity:** for **post-synaptic** neurotoxin bites (e.g. cobra) give a trial of an **acetylcholinesterase inhibitor** — pretreat with **atropine 0.6 mg IV**, then **edrophonium 10 mg IV** (or **neostigmine 0.02 mg/kg IV/IM**); if objective improvement at 30 min, continue **neostigmine 0.5 mg IV/IM/SC hourly**. These are *adjuncts*, not substitutes for intubation/antivenom; intubate and ventilate established paralysis (may need days–weeks).
- ▶ **Rhabdomyolysis / AKI:** IV fluids and urine-output monitoring; AKI (usually reversible acute tubular necrosis) may need **haemodialysis/peritoneal dialysis**; bilateral cortical necrosis carries a poorer renal prognosis.
- ▶ **Compartment syndrome** (deep IM venom; pain, weakness, altered sensation, cyanosis, apparent pulselessness): measure intracompartmental pressure — **>30–40 mmHg → give more antivenom and elevate the limb**. Fasciotomy is NOT recommended for North-American crotalids (no benefit, increased morbidity) and is a last resort even where Asian-species data allow it; true compartment syndrome requiring fasciotomy occurs in <1%.
- ▶ **Wound care & adjuncts:** clean with soap/water, sterile dressing, splint with padding between digits, elevate after antivenom started; **tetanus immunisation**; analgesia with **paracetamol or opioids** — **avoid salicylates/NSAIDs** (impair clotting). Prophylactic antibiotics are usually unnecessary after North-American bites but warranted where secondary infection is common or if first-aid included incision/suction. Debride frank necrosis only after coagulopathy reverses; leave intact blebs alone; start **physiotherapy** early.
- ▶ **Observation/disposition:** observe any envenomed patient ≥24 h; an apparently “dry” viperid bite ≥8–12 h (delayed toxicity); observe ≥24 h after coral-snake (*Micrurus*), hump-nosed pit viper (*Hypnale*) and sea-snake bites (delayed onset). ICU for progressive findings despite antivenom, head/neck bites or antivenom hypersensitivity. **At discharge** warn about wound infection, serum sickness, recurrent coagulopathy and long-term sequelae such as **pituitary insufficiency after Russell’s viper (Daboia russelii) envenomation**.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Algorithm box (“Management of snakebite”)** with labelled arrows: *Bite* → *Reassure/immobilise/splint, remove constrictions* → *Transport (avoid incision/suction/tourniquet)* → *ABC + 2 IV lines + crystalloid* → *Assess envenomation (local progression / 20WBCT / labs)* → *Antivenom if local-progressive or systemic/neurotoxic* → *Treat reactions (adrenaline)* → *Manage complications (intubation, ACh-esterase inhibitor, dialysis, blood products)* → *Observe ≥24 h* → *Discharge advice*.
- ▶ **Labelled snake-head identification figure:** labels — *Viperid: triangular head, elliptical pupil, long mobile fang, loreal pit; Elapid: rounded head, round pupil, short fixed fang; mark fang/puncture marks and local swelling/ecchymosis at bite site.*

Clinical / Diagnostic significance

- ▶ The decision to give antivenom rests on **objective evidence of envenomation** (progressive local signs, systemic features, abnormal 20WBCT/coagulation, neurotoxic signs) — not on the bite alone, since dry bites are common.
- ▶ The **20WBCT** is a cheap, bedside, resource-independent test that confirms venom-induced consumptive coagulopathy and guides antivenom in district/rural settings.
- ▶ *Ptosis* and bulbar weakness are early warnings of impending respiratory failure — secure the airway **before** decompensation.
- ▶ Antivenom both treats and *causes* anaphylaxis; readiness with adrenaline at the bedside is mandatory before every infusion.

High-yield exam pointers

- ▶ **Antivenom is the only specific treatment** and acts only on circulating (unbound) venom — give early; useless for established paralysis/renal failure.
- ▶ **Never** incise, suck, or apply a tourniquet/tight bandage; pressure-immobilisation is only for *neurotoxic elapid* bites, never viperid.
- ▶ Crystalloid 20–40 mL/kg for hypotension; vasopressors only after volume + antivenom.
- ▶ Acute antivenom reaction → stop infusion, **IM adrenaline 0.01 mg/kg (max 0.5 mg)** + antihistamine + steroid, restart at 5–10 mL/h.
- ▶ **Serum sickness** at 1–2 weeks → oral prednisone 1–2 mg/kg/day with taper.
- ▶ Neostigmine (with atropine) helps **post-synaptic** neurotoxic (cobra-type) bites; not a substitute for ventilation/antivenom.
- ▶ Snakebite coagulopathy → give blood products **only after** adequate antivenom; avoid NSAIDs/aspirin.
- ▶ Fasciotomy is rarely needed (<1%); rising compartment pressure → **more antivenom**, not the knife.

- ▶ Observe ≥ 24 h (≥ 8 –12 h for “dry” viperid bites); beware delayed toxicity from kraits, coral snakes, hump-nosed viper and sea snakes; warn of late Russell’s-viper hypopituitarism.

SOURCE & COVERAGE

Harrison 22e — Ch 471 “Disorders Caused by Venomous Snakebites and Marine Animal Exposures” (incl. Tables 471-1 and 471-2). **Coverage note:** Harrison’s management protocol and named antivenoms (CroFab/Anavip, *Micrurus* antivenin) are US/Canada-specific and, as the text states, should not be transposed to other regions. India-specific standards relevant to RGUHS — the “**Big Four**” (Russell’s viper, common krait, Indian cobra, saw-scaled viper) and **Indian polyvalent anti-snake venom** dosing — are universally-accepted Indian internal medicine but are not detailed in this US-focused chapter; only *Daboia russelii*, kraits (*Bungarus*) and cobras (*Naja*) are explicitly named in the source. Indian polyvalent ASV vial regimens and WHO/national snakebite protocols fall outside the provided text and should be confirmed against a national guideline.

Organophosphorus (Organophosphate) Compound Poisoning

Asked in: Paper IV Nov 2020 — RGUHS MD General Medicine

Definition / Introduction — Organophosphorus (OP) compounds are organic esters of phosphoric/phosphorothioic acid used as insecticides (diazinon, malathion, parathion, chlorpyrifos, acephate) and as chemical-warfare nerve agents (tabun [GA], sarin [GB], soman [GD], VX). They produce poisoning by **irreversibly inhibiting acetylcholinesterase**, causing accumulation of acetylcholine and an overwhelming **cholinergic crisis** at muscarinic, nicotinic and CNS receptors. OP poisoning — most often **deliberate self-poisoning** in agrarian Asia — accounts for the bulk of the >150,000 pesticide-poisoning deaths each year worldwide and is a leading cause of acute-poisoning ICU admission in India.

Pathophysiology — cholinesterase inhibition and “aging”

- ▶ **Two cholinesterases are inhibited:**
 - *Acetylcholinesterase (AChE; “true” or RBC cholinesterase)* — in erythrocyte membranes, nervous tissue and skeletal muscle; the better index of synaptic enzyme inhibition.
 - *Plasma butyrylcholinesterase (BuChE; pseudocholinesterase)* — in serum, liver, pancreas, heart and brain; easier to assay, falls first, but is less specific.
- ▶ OP compounds **phosphorylate** the active (esteratic) site of AChE, inactivating it. Acetylcholine is therefore not hydrolysed and accumulates at synapses → initial **overstimulation** of cholinergic receptors, followed by **depolarising blockade/paralysis** of transmission in the CNS, autonomic

ganglia, parasympathetic and selected sympathetic (sweat-gland) endings, and at the neuromuscular junction.

- ▶ “**Aging**” = loss of an alkyl group from the phosphorylated enzyme, making the OP–enzyme bond *permanent and irreversible*. Time to aging is agent-specific (minutes for **soman**, up to >24–48 h for others). **Oximes can only reactivate the enzyme before aging occurs** — hence the urgency of antidote therapy. Once aged, recovery requires **resynthesis of new enzyme over weeks**.
- ▶ Many formulations contain an **aromatic hydrocarbon solvent (xylene)** and surfactants — these add aspiration (lipoid) pneumonitis and CNS depression, and OP is **well absorbed transdermally**, by inhalation, transconjunctivally and by ingestion.
- ▶ **Carbamates** (carbaryl, aldicarb, propoxur) inhibit the same enzyme but the carbamylated bond is **reversible and does not age**, giving a shorter, generally more benign illness.

Clinical features — cholinergic toxidrome

Most patients are symptomatic within **8 h** of ingestion and nearly all by **24 h**; onset is fastest with inhalation, slowest transdermally. Three receptor groups produce overlapping signs.

Receptor group	Mechanism	Clinical effects (mnemonic)
Muscarinic	Post-ganglionic parasympathetic + sweat glands	* DUMBELS — <i>Defecation, Urination, Miosis, Bradycardia/Bronchorrhoea/Bronchospasm (“Killer Bs”), Emesis, Lacrimation, Salivation. Also SLUDGE*</i> (Salivation, Lacrimation, Urination, Defecation, GI cramps, Emesis), sweating
Nicotinic	Autonomic ganglia, adrenal medulla, NMJ	Muscle fasciculations , cramps, weakness → paralysis (incl. diaphragm); mydriasis, pallor, tachycardia, hypertension
CNS	Central cholinergic receptors	Anxiety, restlessness, tremor, headache, confusion, delirium, seizures, coma

- ▶ *Either picture may dominate* — parasympathetic effects usually predominate, but severe poisoning may present with **nicotinic features first** (tachycardia, hypertension). Classic severe triad: **pinpoint pupils + excessive secretions/sweating + difficulty breathing**, often with a **garlic/hydrocarbon odour**.
- ▶ **Death is due to respiratory failure** — combination of bronchorrhoea, bronchospasm, respiratory-muscle paralysis and central respiratory depression; aspiration of gastric contents/hydrocarbon worsens it. Myocardial ischaemia and pancreatitis may occur.

Four recognised clinical syndromes (high-yield):

- ▶ **1. Acute cholinergic crisis** — minutes to hours; the muscarinic/nicotinic/CNS toxidrome above.

- ▶ **2. Intermediate syndrome** — 1–5 days after exposure (up to ~40% of ingestions); proximal limb, neck-flexor, cranial-nerve and **respiratory-muscle weakness** *without* cholinergic features; may need ventilation; usually resolves within ~7 days. **Not** reported with nerve-gas poisoning.
- ▶ **3. OP-induced delayed neuropathy (OPIDN)** — a **distal, symmetrical sensorimotor axonopathy** appearing ~1–3 weeks later (classically attributed to inhibition of *neuropathy target esterase, NTE*); leg cramps → weakness/paralysis mimicking **Guillain–Barré syndrome**; *not* reversed by atropine/oximes.
- ▶ **4. Chronic toxicity / neuropsychiatric sequelae** — with low-grade repeated exposure: cognitive/memory impairment, mood change, autonomic dysfunction, extrapyramidal signs.

Diagnosis / Investigations

- ▶ **Clinical** — diagnosis rests on history + the cholinergic toxidrome; **do not delay antidote** awaiting enzyme assays.
- ▶ **Cholinesterase assays** —
 - *Plasma BuChE* falls first; in poisoning, plasma/RBC cholinesterase is **<50% of normal**; BuChE normalises in **28–42 days** (if no oxime given).
 - *RBC AChE* is the better marker: reduced to **10–20%** of normal in moderate, **<10%** in severe poisoning; full recovery needs RBC turnover (up to **120 days**).
- ▶ **Cautions:** BuChE is low in liver disease, malnutrition, pregnancy, genetic variants and with certain drugs; RBC AChE is factitiously low with haemoglobinopathy, pernicious anaemia and antimalarials.
- ▶ **Ancillary:** ECG — sinus brady/tachycardia, **prolonged QT, ST/T changes, AV block**, torsades/VT; CXR — pulmonary oedema/aspiration; bloods — hyper-/hypoglycaemia, leucocytosis, amylase (pancreatitis); ABG. EMG can demonstrate NMJ dysfunction/intermediate syndrome.

Management

General principles: secure airway and ventilation, decontaminate, **adequate atropinisation**, and **early oxime** before aging — with intensive supportive care. Therapy must **not** be withheld pending cholinesterase results.

Step	Detail
Resuscitation	Airway, 100% O ₂ , suction secretions; intubate for coma/seizures/respiratory failure/bronchorrhoea. Use a non-depolarising relaxant if paralysis needed — avoid succinylcholine (prolonged apnoea, as it is hydrolysed by BuChE). IV crystalloid for hypotension.

Step	Detail
Decontamination	Staff wear nitrile/neoprene gloves, gown, face shield (latex is inadequate); remove all clothing as hazardous waste; wash skin/hair/nails with soap & water ; dilute 1:10 hypochlorite (bleach) decontaminates equipment. Gastric lavage only within 1 h of large ingestion after airway protection; activated charcoal, lavage and haemodialysis are of no proven benefit.
Atropine (<i>physiological antidote — muscarinic only</i>)	Bolus 1.2–3 mg IV (CMDT: 2 mg); double the dose every 5 min until atropinised — <i>clear chest on auscultation, HR >80/min, SBP >80 mmHg</i> . Tens-hundreds of mg may be needed. Then infusion at 10–20%/h of the total atropinising dose (~0.4–4 mg/h), titrated; watch for toxicity (absent bowel sounds, hyperthermia, delirium). Tachycardia and mydriasis are NOT contraindications/endpoints. <i>Glycopyrrolate</i> is an alternative without CNS effects.
Pralidoxime (2-PAM) (<i>enzyme reactivator — nicotinic + muscarinic; reverses muscle weakness if given before aging</i>)	WHO regimen: 30 mg/kg IV bolus over 5–10 min, then 8 mg/kg/h infusion for 24–48 h. (CMDT: 1–2 g IV load, then 200–500 mg/h.) Give as early as possible ; still worthwhile even 24–48 h post-exposure. Continue while signs of acetylcholine excess persist. Not for asymptomatic or pure-carbamate (carbaryl) poisoning.
Seizures	Benzodiazepines (IV) ; atropine may abort early cholinergic seizures.
Adjuncts (unproven)	Magnesium sulfate and calcium-channel blockers show some benefit but are not routine.

Organophosphate vs Carbamate — key contrasts

Feature	Organophosphate	Carbamate
Enzyme bond	Phosphorylation — irreversible, ages	Carbamylation — reversible, no aging
Duration	Prolonged (weeks for enzyme resynthesis)	Short — recovers in hours (spontaneous, usually <24 h)
CNS penetration / seizures	Yes (adults)	Poor in adults (less CNS toxicity, no seizures)
Pralidoxime	Indicated, early	Usually not needed ; avoid in single-agent carbaryl
Atropine	Yes	Yes — mainstay

Feature	Organophosphate	Carbamate
DIAGRAMS TO DRAW — IMAGE SUGGESTIONS ▶ Cholinergic synapse / mechanism schematic — label: <i>presynaptic neuron, acetylcholine (ACh) vesicles, synaptic cleft, acetylcholinesterase (AChE), postsynaptic muscarinic & nicotinic receptors, OP compound phosphorylating AChE (“aging”), pralidoxime reactivating AChE, atropine blocking muscarinic receptor.</i> ▶ “DUMBELS / SLUDGE + nicotinic + CNS” toxidrome figure — a body silhouette labelled: <i>miosis (pinpoint pupils), lacrimation, salivation, bronchorrhoea, bronchospasm, bradycardia, vomiting, diarrhoea, urination, sweating (muscarinic); fasciculations, weakness, mydriasis, tachycardia, hypertension (nicotinic); seizures/coma (CNS).</i>		

Clinical / Diagnostic significance

- ▶ **Bedside diagnostic clue:** pinpoint pupils + secretions + bradycardia + garlicky breath in a patient who may have agricultural access ⇒ treat empirically.
- ▶ **Atropine titration is the therapeutic art** — dose to the chest and haemodynamics, not the pupils; under-atropinisation kills via bronchorrhoea.
- ▶ **Watch for the intermediate syndrome** at days 1–5: recurrent respiratory failure after apparent recovery — keep ICU/ventilatory vigilance.
- ▶ **Fat-soluble agents** (fenthion, dimethoate) cause prolonged/relapsing illness needing days–weeks of atropine ± oxime infusion.
- ▶ Avoid succinylcholine, ester local anaesthetics and β -blockers, which may worsen toxicity.

High-yield exam pointers

- ▶ OP = irreversible AChE inhibitor; aging makes oximes ineffective — *soman ages in minutes.*
- ▶ RBC AChE more specific; plasma BuChE falls first/easier to measure; activity <50% normal in poisoning.
- ▶ Muscarinic = DUMBELS/SLUDGE + Killer Bs (bradycardia, bronchorrhoea, bronchospasm); Nicotinic = fasciculations, weakness, mydriasis, tachycardia, hypertension; CNS = seizures/coma.
- ▶ Death = respiratory failure (bronchorrhoea + respiratory-muscle paralysis + central depression).
- ▶ Atropine endpoints: clear chest, HR >80, SBP >80; pralidoxime (2-PAM) WHO dose 30 mg/kg bolus + 8 mg/kg/h.
- ▶ Atropine treats muscarinic effects only; pralidoxime reverses nicotinic (muscle) weakness — give both.
- ▶ **Four syndromes:** acute crisis → intermediate syndrome (1–5 d, respiratory/proximal weakness) → OPIDN (~1–3 wk, distal neuropathy, NTE) → chronic neuropsychiatric.

- ▶ **Carbamate** poisoning: reversible, no aging, shorter course, pralidoxime usually unnecessary (avoid in carbaryl).
- ▶ Nerve agents (sarin, soman, tabun, VX) are OP compounds; **do not** cause the intermediate syndrome.

SOURCE & COVERAGE

- ▶ **Harrison's Principles of Internal Medicine, 22e** — “Poisoning and Drug Overdose” (cholinergic/acetylcholinesterase-inhibitor toxidrome and antidote table).
- ▶ **Tintinalli's Emergency Medicine** — “Pesticides” (organophosphate pathophysiology, aging, four clinical syndromes, cholinesterase assays, atropine and pralidoxime regimens, carbamate contrasts) — principal depth source.
- ▶ **CMDT 2026** — “Poisoning: Pesticides — Cholinesterase Inhibitors” (atropine and pralidoxime dosing, decontamination).

Coverage note: The neuropathy-target-esterase (NTE) mechanism and classic 1–3-week timing of OPIDN, and the term “intermediate syndrome,” are universally accepted toxicology teaching; the corpus (Tintinalli) describes these syndromes in detail but frames the delayed/chronic neuropathies with slightly different labels — the standard timing/mechanism is presented here for exam completeness.

Paracetamol (Acetaminophen) Poisoning

Asked in: Paper IV Jul 2021 · Paper IV Nov 2019 (2×) — RGUHS MD General Medicine

Definition / Introduction — Paracetamol (acetaminophen, *N*-acetyl-*p*-aminophenol, APAP) is the most widely used over-the-counter analgesic–antipyretic and, in overdose, the commonest cause of drug-induced acute liver failure in the Western world (accounting for nearly half of all acute liver failure cases). Toxicity is a **dose-dependent direct hepatotoxicity** caused by the reactive metabolite ***N*-acetyl-*p*-benzoquinone-imine (NAPQI)**, which, once hepatic glutathione is depleted, binds covalently to **hepatocyte macromolecules producing** centrilobular (zone 3) hepatic necrosis*. *It is eminently treatable: the antidote N^{*}-acetylcysteine (NAC)*, if given early, is nearly 100% protective, making early recognition and the Rumack–Matthew nomogram central to management.

Pharmacology, metabolism and the basis of toxicity

- ▶ **Pharmacokinetics:** rapid GI absorption; peak therapeutic level at 30 min–2 h (≈ within 2 h after overdose, later with extended-release or anticholinergic/opioid co-ingestants); ~100% bioavailability, ~20% protein-bound, $V_d \approx 0.85 \text{ L/kg}$, elimination half-life ≈ 2.5 h.
- ▶ **Normal (therapeutic) metabolism:** mainly **glucuronidation (40–67%)** and **sulfation (20–46%)** to non-toxic conjugates; <5% excreted unchanged; only 5–15% oxidised by CYP450 (chiefly

CYP2E1) to the reactive electrophile **NAPQI**, which is immediately conjugated by **glutathione** to harmless mercapturic acid and renally excreted.

- ▶ **In overdose:** glucuronidation and sulfation pathways are **saturated**, diverting more drug through CYP2E1, so excess NAPQI is generated. When hepatic **glutathione falls below ~30% of normal**, unconjugated NAPQI **binds covalently to nucleophilic hepatocyte proteins** (“APAP–protein adducts”), causing **centrilobular hepatic necrosis** and hepatocyte death (lysis typically on day 2, releasing transaminases).
- ▶ **Massive ingestion** (>500 mg/kg, peak level >750 µg/mL [>5000 µmol/L]) can cause **early metabolic acidosis with raised lactate and altered sensorium** even before liver failure — due to glutathione-depletion-related 5-oxoproline accumulation and inhibition of mitochondrial respiration.

Toxic dose and risk factors

- ▶ **Toxic exposure (≥6 yr):** a single ingestion of >150–200 mg/kg or >10 g; a single dose of 10–15 g (occasionally less) may produce liver injury; **fatal fulminant disease usually with ≥25 g**.
- ▶ **Repeated supratherapeutic (“staggered”) ingestion:** >6 g/day or 150 mg/kg/24 h; ~8 g/day (twice the recommended maximum) over several days can readily cause liver failure, especially with opioid–acetaminophen combinations.
- ▶ **Factors increasing risk (low glutathione / induced CYP2E1):**

Mechanism	Examples
Glutathione depletion	Chronic alcohol use, malnutrition/starvation, prolonged fasting in febrile illness, AIDS
CYP2E1 / mixed-oxidase induction	Chronic alcohol, isoniazid, anti-tubercular & anticonvulsant drugs, rifampicin, phenobarbital
Underlying liver vulnerability	Hepatitis C co-infection

- ▶ In **chronic alcoholics**, the toxic threshold may fall to as low as **2 g**; the FDA-recommended maximum daily dose has been reduced from 4 g to **3 g** (lower still in heavy alcohol users), and the acetaminophen content of prescription opioid-combination tablets capped at **325 mg/tablet**.

Clinical features — the four stages

Stage	Timing	Clinical features	Laboratory
1	First 24 h	Often asymptomatic; anorexia, nausea, vomiting, malaise, pallor, diaphoresis	Usually normal
2	Days 2–3	GI symptoms improve; right-upper-quadrant	Rising AST/ALT; raised bilirubin & prolonged PT if severe

Stage	Timing	Clinical features	Laboratory
		pain & hepatic tenderness	
3	Days 3–4	Peak hepatotoxicity — recurrent vomiting, jaundice, encephalopathy, fulminant hepatic failure , metabolic acidosis, coagulopathy, AKI/anuria, $\pm$ pancreatitis	AST/ALT may exceed 10,000 IU/L (far higher than viral hepatitis); raised INR, lactate, creatinine; hypoglycaemia
4	After day 5	Recovery (clinical improvement over 7–8 days; complete hepatic regeneration in 1–3 months) or deterioration to multi-organ failure and death	Resolving vs worsening

- ▶ **Diagnostic biochemical signature:** strikingly **high aminotransferases with relatively low bilirubin** in a “hyperacute” picture should raise suspicion of paracetamol even without a clear history.
- ▶ **Acute kidney injury** occurs in up to ~75% of severe cases but is usually self-limited; rare extrahepatic effects include myocardial injury and pancreatitis.

Diagnosis and the Rumack–Matthew nomogram

- ▶ Measure a serum acetaminophen concentration in every patient with intentional overdose (history is unreliable; toxicity is delayed and treatable). Also send AST/ALT, bilirubin, PT/INR, creatinine, glucose, ABG/lactate, and a co-ingestant screen (salicylate level).
- ▶ **Rumack–Matthew nomogram** plots serum level against time since ingestion to predict hepatotoxicity. The **treatment line corresponds to a 4-hour level of 150 $\mu\text{g/mL}$ (1000 $\mu\text{mol/L}$)** (lowered from the original 200 $\mu\text{g/mL}$ line to widen the safety margin); levels **above the line warrant NAC**.
- ▶ Risk by 4-hour level: **>200 $\mu\text{g/mL}$ (>1300 $\mu\text{mol/L}$) $\approx$ 60% hepatotoxicity, ~5% mortality; >300 $\mu\text{g/mL}$ (>2000 $\mu\text{mol/L}$) $\approx$ 90% hepatotoxicity; <150 $\mu\text{g/mL}$ suggests injury is highly unlikely.**
- ▶ **Nomogram limitations** — **does NOT apply to:** levels drawn **<4 h or >24 h** after ingestion, **unknown time of ingestion**, **chronic/staggered ingestion**, **extended-release preparations**, or **IV acetaminophen overdose**. In these settings, treat empirically guided by detectable level (>10 $\mu\text{g/mL}$ [$>66 \mu\text{mol/L}$]) and/or rising transaminases.

Treatment

- ▶ **Resuscitation & supportive care:** secure airway/breathing/circulation; correct hypoglycaemia, electrolytes, acidosis and coagulopathy; manage cerebral oedema in fulminant failure.
- ▶ **GI decontamination:** a single dose of **activated charcoal** if presenting within 1–2 h of ingestion (charcoal's minor interference with oral NAC absorption is not clinically significant). Lavage/whole-bowel irrigation are generally unnecessary given rapid absorption.
- ▶ ****N-acetylcysteine (NAC) — the antidote:****
 - **Mechanism:** acts as a **glutathione precursor/substitute and sulfate precursor**, and can **directly reduce NAPQI** back to acetaminophen; in established toxicity it is also **antioxidant**, improves microcirculatory flow and oxygen delivery, and reduces neutrophil-mediated injury.
 - **Timing:** nearly **100% effective if started within 8 h** of ingestion; efficacy declines with delay but NAC still benefits even when given up to 24 h (and is used in established hepatotoxicity/late presentation).
 - **IV regimen (standard 21-hour):** 150 mg/kg over 1 h → 50 mg/kg over 4 h → 100 mg/kg over 16 h. The IV route is preferred for vomiting, hepatic failure or pregnancy.
 - **Oral regimen (72-hour):** loading 140 mg/kg, then 70 mg/kg every 4 h for 17 doses (with an antiemetic such as ondansetron for the disagreeable taste/nausea).
 - **Adverse effects:** anaphylactoid reactions in 4–17% of IV NAC (mostly in the first 2 h, more in asthmatics); manage by **slowing/temporarily stopping the infusion** and giving diphenhydramine, then resume at a slower rate.
 - **Massive overdose** (>30 g or level >2× the nomogram line): consider enhanced dosing (e.g., higher third-bag dose) and contact a poison centre.
- ▶ **Extracorporeal removal:** haemodialysis is **rarely indicated** — reserved for massive overdose with altered mental status, metabolic acidosis and very high levels; NAC is dialysable, so the dose is increased during dialysis.
- ▶ **Liver transplantation referral** if fulminant failure evolves despite NAC.

King's College Criteria for liver transplantation (paracetamol-induced acute liver failure)

- ▶ Arterial pH <7.30 (after fluid resuscitation), OR
- ▶ All three of: PT >100 s (INR >6.5) + serum creatinine >3.3 mg/dL (>292 µmol/L) + grade III/IV hepatic encephalopathy.
- ▶ Adjunct poor-prognosis markers: **arterial lactate >3.5 mmol/L** (Harrison) after resuscitation, hypoglycaemia, and rising serum phosphate.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Acetaminophen metabolism pathway:** Acetaminophen → branch to **Glucuronidation** (40–67%), **Sulfation** (20–46%), **Renal excretion of unchanged drug** (<5%), and **CYP2E1** (5–15%) → **NAPQI**. From NAPQI draw two arrows: (a) + **Glutathione** → **mercapturic acid** (APAP-mercaptate) → **renal excretion** (non-toxic); (b) **when glutathione <30% normal** → **covalent binding to hepatocyte proteins** → **centrilobular hepatic necrosis / cell death**.
Label: *NAPQI, glutathione, CYP2E1, centrilobular (zone 3) necrosis*.
- ▶ **Rumack–Matthew nomogram:** Y-axis = plasma acetaminophen (µg/mL and µmol/L, log scale), X-axis = hours after ingestion (4–24 h). Draw the **treatment line through 150 µg/mL at 4 h** (sloping down to ~37.5 µg/mL at 12 h); label zones “**Treatment recommended (above line)**” and “**Toxicity unlikely (below line)**”; mark “**take level ≥4 h after ingestion.**”

Clinical / Diagnostic significance

- ▶ A near-asymptomatic stage 1 with a potentially lethal stage 3 means **management is dictated by the level/nomogram and time, not by early symptoms** — never reassure on a “well-looking” patient.
- ▶ The **APAP level must be drawn at ≥4 h** post-ingestion; if the result will not be available within the 8-h window, start NAC **empirically** and reassess once the level returns.
- ▶ **Pregnancy:** treat exactly as in non-pregnant patients — NAC is safe and effective and crosses the placenta; delay in treatment is associated with fetal loss.
- ▶ Suspect paracetamol in any **acute liver failure with very high transaminases and low bilirubin**, and in unexplained early high-anion-gap metabolic acidosis after massive ingestion.
- ▶ All intentional-overdose patients need a **psychiatric evaluation**; report cases to the regional poison-control centre.

High-yield exam pointers

- ▶ Toxic metabolite = **NAPQI**, generated by **CYP2E1**; detoxified by **glutathione**; toxicity when glutathione <30% → **centrilobular (zone 3) necrosis**.
- ▶ **Toxic dose ≥150 mg/kg or >10 g**; fatal usually ≥25 g; alcoholic threshold may be as low as 2 g.
- ▶ **Four stages:** (1) <24 h GI/asymptomatic, (2) days 2–3 RUQ pain + rising LFTs, (3) days 3–4 fulminant hepatic failure, (4) after day 5 recovery or death.
- ▶ **Rumack–Matthew nomogram** treatment line = **150 µg/mL at 4 h**; not valid <4 h, >24 h, staggered, or extended-release ingestions.
- ▶ **NAC is ~100% effective if given within 8 h**; benefit up to 24 h and in established hepatotoxicity.
- ▶ **IV NAC:** 150 mg/kg/1 h → 50 mg/kg/4 h → 100 mg/kg/16 h (21-h protocol); **oral:** 140 then 70 mg/kg × 17 doses (72 h).

- ▶ **NAC anaphylactoid reactions 4–17%** — slow/stop infusion + antihistamine.
- ▶ **King's College Criteria:** pH <7.30 or (PT >100 s + creatinine >3.3 mg/dL + grade III/IV encephalopathy) → transplant referral.
- ▶ **Activated charcoal** only useful early (within 1–2 h); **haemodialysis** rarely needed (massive overdose).

Russell's Viper Envenomation

Asked in: Paper IV Nov 2022 — RGUHS MD General Medicine

Definition / Introduction — Russell's viper envenomation is systemic and local poisoning after bite by *Daboia russelii*, an Old World viperid of major importance in South Asia. The dominant syndrome is **viperid cytotoxic-hemotoxic envenomation** with painful swelling, tissue injury, venom-induced consumptive coagulopathy, spontaneous bleeding, shock, and acute kidney injury; certain Indian Russell's vipers may also cause neurotoxicity. It is an emergency because antivenom reverses circulating venom best before fixed renal failure, established paralysis, and tissue necrosis have developed.

Epidemiology and species importance

- ▶ Russell's viper is a medically important Indian viperid and a classic rural/agricultural hazard; Brenner notes that snake bite in the Indian subcontinent commonly occurs when people work barefoot in fields.
- ▶ Harrison lists **Russell's vipers (Daboia russelii)** among snakes responsible for large numbers of deaths outside North America, together with cobras, saw-scaled/carpet vipers, large African vipers, lancehead pit vipers, and tropical rattlesnakes.
- ▶ In the Indian subcontinent, **AKI develops after viper-family bites**, especially Russell's viper, saw-scaled viper (*Echis carinatus*), and pit vipers.

- ▶ Brenner gives the incidence of AKI after Russell's viper or *E. carinatus* bites in India as 13-32%; a Sri Lankan series of unidentified viper bites reported AKI in 27%.
- ▶ Risk of severe disease rises with large venom load, bite on a vascular area or head/neck, delayed transport, traditional treatment before hospital care, lack of appropriate antivenom, shock, coagulopathy, and established renal injury.

Venom pathophysiology

- ▶ Snake venom is a variable mixture of **enzymes, polypeptides, glycoproteins, and other constituents**; venom composition varies by species, snake age, diet, and geography, so local protocols matter.
- ▶ **Local cytotoxic/vascular injury**: venom increases vascular permeability and damages tissues, causing pain, edema, ecchymosis, bullae, hemorrhagic blebs, necrosis, and later functional loss.
- ▶ **Hemotoxic/procoagulant effect**: viper venom activates and consumes clotting factors, fibrinogen, and platelets, producing **venom-induced consumptive coagulopathy** or a DIC-like state with prolonged clotting times, low fibrinogen, thrombocytopenia, high FDP/D-dimer, and bleeding.
- ▶ **Shock mechanisms**: early hypotension may reflect bradykinin-potentiating vasodilatation, systemic bleeding, hemolysis, and intravascular volume loss into swollen tissues.
- ▶ **Renal injury**: AKI is multifactorial: bleeding, hypotension, circulatory collapse, intravascular hemolysis, hemoglobinuria, DIC/microangiopathic hemolysis, myoglobinuria when present, and direct venom nephrotoxicity.
- ▶ **Renal pathology**: acute tubular necrosis is the predominant lesion in snakebite-associated AKI; cortical necrosis may occur and carries much poorer renal recovery.
- ▶ **Neurotoxicity**: Harrison specifically notes that certain Indian Russell's vipers can cause neurologic dysfunction with ptosis, dysphagia, peripheral weakness, diaphragmatic paralysis, aspiration, and respiratory failure.

Clinical features and severity

- ▶ **Local features**: fang marks, early severe pain, rapidly progressive swelling, tenderness, regional lymphadenopathy, ecchymosis, serum-filled or hemorrhagic bullae, cellulitis-like inflammation, and full-thickness necrosis in severe bites.
- ▶ Swelling may involve the whole limb; hand, forearm, and anterior leg bites require vigilance for compartment pressure, although true fasciotomy-requiring compartment syndrome is uncommon.
- ▶ **Bleeding/coagulopathy**: persistent oozing from fang marks or venipuncture sites, gum bleeding, epistaxis, hematuria, hematemesis, melena, hemoptysis, ecchymoses, muscle/fascial compartment bleeding, serous cavity bleeding, and rarely subarachnoid hemorrhage.

- ▶ **Systemic features:** nausea, vomiting, altered/metallic taste, mouth numbness or perioral tingling, generalized weakness, tachycardia or bradycardia, hypotension/shock, pulmonary edema, spontaneous hemorrhage, and altered sensorium in severe envenomation.
- ▶ **Renal features:** oliguria commonly develops within the first 24 h, but may be delayed 2-3 days; anuria or non-oliguric AKI may occur. Clues include gross or microscopic hematuria, hemoglobinuria, jaundice from intravascular hemolysis, and renal-angle pain preceding oliguria.
- ▶ **Neurologic features:** headache, paresthesias, ptosis, diplopia, dysphagia, bulbar weakness, peripheral motor weakness, respiratory muscle paralysis, and aspiration risk.
- ▶ Practical grading:

Grade	Definition
Dry / none	Fang marks only; no progressive swelling, systemic symptoms, or laboratory abnormality after observation
Mild	Local pain, ecchymosis, and nonprogressive swelling only
Moderate	Progressive swelling, systemic symptoms, or laboratory abnormality such as thrombocytopenia/prolonged clotting
Severe	Shock, major bleeding, severe coagulopathy, neurotoxicity, respiratory distress, AKI, pulmonary edema, or extensive local necrosis

Diagnosis and monitoring

- ▶ Diagnosis is clinical: compatible bite history plus local injury, hematologic abnormality, systemic toxicity, or renal/neurotoxic features. Do not wait for snake identification before treating a compatible syndrome.
- ▶ **Bedside assessment:** ABC, vital signs, mental status, respiratory effort, bulbar function, distal pulses, capillary refill, sensory-motor status, and urine output.
- ▶ Mark the leading edge of swelling/ecchymosis/tenderness; measure limb circumference at the bite site and at joints proximal/distal every 15 min until stable, then every 1-2 h.
- ▶ **Core investigations:** CBC with platelets, blood group and cross-match, PT/INR/aPTT, fibrinogen, FDP or D-dimer, renal function, electrolytes, liver tests, glucose, creatine kinase, urinalysis for blood/myoglobin, ECG, and chest radiograph/ABG when severe or respiratory compromise is suspected.
- ▶ **20-min whole-blood clotting test (20WBCT):** place 1-2 mL venous blood in a clean, dry glass tube, leave undisturbed for 20 min, then invert. Persistent liquid blood/no clot indicates clinically important coagulopathy when formal coagulation tests are unavailable.

- ▶ Repeat CBC/coagulation studies every **4 h** if initial tests are normal but envenomation remains possible; after antivenom, repeat about every **6 h** until swelling, vital signs, and coagulation are stable.
- ▶ Watch for recurrent coagulopathy because venom antigens may outlast antivenom; late bleeding can appear after apparent improvement.

Management: first aid, antivenom and ICU care

- ▶ **First aid:** move away from the snake, reassure, keep the patient still, remove rings/bangles/tight clothing, splint the bitten limb in a neutral position, and transport rapidly to a facility with antivenom, airway support, and laboratory testing.
- ▶ Clean with soap and water and cover with a sterile dressing if this does not delay transport. Do **not** incise, suck, apply electric shock, ice, alcohol, stimulants, tight tourniquets, or massage. Pressure-immobilization is not recommended for viperid/cytotoxic bites because it may worsen local tissue injury.
- ▶ **Initial hospital care:** secure airway and breathing; intubate early for face/neck swelling, bulbar weakness, falling ventilation, or respiratory insufficiency. Monitor ECG, oxygen saturation, blood pressure, urine output, and mental status.
- ▶ Establish two large-bore IV lines in unaffected limbs; minimize venipuncture and avoid noncompressible sites because coagulopathy may be profound.
- ▶ Treat shock with isotonic crystalloid **20-40 mL/kg IV**; if shock persists after fluids and antivenom, use vasopressors such as norepinephrine or epinephrine and reassess for venom or antivenom anaphylaxis.
- ▶ **Antivenom is the mainstay.** Use geographically appropriate antivenom that covers Russell's viper venom; in India this generally means locally supplied polyvalent anti-snake venom according to product and institutional protocol.
- ▶ Indications for antivenom: rapidly progressive swelling; swelling involving more than half the limb; severe pain, bruising, blistering, or necrosis; any systemic toxicity; positive 20WBCT or abnormal PT/INR/aPTT/fibrinogen; thrombocytopenia; active bleeding; shock; neurotoxicity; rhabdomyolysis; AKI; or pulmonary edema.
- ▶ Give antivenom **IV only**, start slowly with clinician at bedside, and increase if no reaction; skin testing is neither sensitive nor specific. Keep epinephrine and airway equipment ready.
- ▶ If acute antivenom reaction occurs, stop temporarily and treat with **IM epinephrine 0.01 mg/kg up to 0.5 mg**, IV antihistamine such as diphenhydramine **1 mg/kg up to 50 mg**, and hydrocortisone **2 mg/kg up to 100 mg**; restart slowly at **5-10 mL/h** if antivenom remains necessary.

- ▶ Blood products are reserved for life-threatening bleeding or dangerously low platelets and should be given **after adequate antivenom**, because early replacement can fuel ongoing consumptive coagulopathy.
- ▶ AKI care: maintain perfusion, avoid nephrotoxins, monitor potassium/acidosis/fluid overload, and involve nephrology early; hemodialysis or peritoneal dialysis is used when indicated. ATN is often reversible; cortical necrosis has a poor renal prognosis.

Complications, disposition and follow-up

- ▶ Major complications: shock, DIC-like coagulopathy, intracranial or gastrointestinal bleeding, pulmonary edema, neuromy paralysis, aspiration, AKI, hyperkalemia/acidosis, local necrosis, compartment syndrome, secondary infection, serum sickness, recurrent coagulopathy, chronic limb disability, and late pituitary insufficiency.
- ▶ Suspect compartment syndrome when severe compartment-localized pain is opioid-resistant with weakness, sensory change, cyanosis, or tense swelling. Measure pressure; if **>30-40 mmHg**, give additional antivenom and elevate. Fasciotomy is last resort after antivenom failure and surgical consultation.
- ▶ Provide wound care, tetanus prophylaxis, acetaminophen or opioids for pain, and avoid NSAIDs/salicylates. Routine prophylactic antibiotics are not required unless there is infection, incision, mouth suction, necrosis, or local protocol supports use.
- ▶ Debride necrotic tissue only after coagulopathy is corrected; intact blebs should usually be left undisturbed, ruptured blebs debrided aseptically, and physiotherapy started early after swelling stabilizes.
- ▶ Admit all envenomated patients for at least **24 h**; ICU is indicated for shock, respiratory/neurotoxic signs, severe coagulopathy/bleeding, AKI, pulmonary edema, head/neck bite, progressive findings despite antivenom, or antivenom anaphylaxis.
- ▶ At discharge, warn about recurrent bleeding/coagulopathy over **2-3 weeks**, serum sickness at **1-2 weeks**, wound infection, chronic functional loss, and symptoms of adrenal/pituitary insufficiency after Russell's viper bite. Arrange repeat CBC, PT/INR, and fibrinogen if coagulopathy occurred.

DIAGRAMS TO DRAW — IMAGE SUGGESTIONS

- ▶ **Russell's viper envenomation flowchart:** bite -> first aid/immobilization -> ABC -> local/systemic/renal/neuro assessment -> 20WBCT + labs -> antivenom indications -> IV antivenom -> monitor coagulation, urine output, swelling, respiration -> complications/follow-up.
- ▶ **Pathophysiology diagram:** *Daboia venom* -> local vascular injury/tissue necrosis; procoagulant VICC/DIC -> bleeding; capillary leak/hemolysis/shock -> AKI; neurotoxicity -> ptosis/bulbar weakness/respiratory failure; late pituitary insufficiency.

Clinical / Diagnostic significance

- ▶ A positive 20WBCT is a treatment-triggering bedside sign of viperid coagulopathy when formal PT/fibrinogen are delayed.
- ▶ Oliguria after Russell's viper bite is renal failure until proved otherwise; check creatinine, potassium, urine blood/myoglobin, acid-base status, and involve nephrology early.
- ▶ Ptosis or dysphagia after a viper bite is dangerous, because certain Indian Russell's vipers can cause neurotoxicity; monitor ventilation and intubate before respiratory arrest.
- ▶ Antivenom neutralizes circulating venom, not established ATN/cortical necrosis, fixed paralysis, or necrotic tissue; delay is the key preventable cause of poor outcome.
- ▶ Blood products before antivenom are a common error unless resuscitation is life-saving; replace components after venom neutralization when bleeding demands it.

High-yield exam pointers

- ▶ Russell's viper = **painful swelling + coagulopathy/bleeding + shock + AKI**; add neurotoxicity for certain Indian bites.
- ▶ Mention Indian renal data: AKI after Russell's viper/*Echis* bites 13-32%; oliguria often within 24 h, sometimes 2-3 days.
- ▶ Must write 20WBCT: 1-2 mL blood, clean dry glass tube, 20 min, no clot = coagulopathy.
- ▶ Antivenom indications: progressive local swelling, bleeding/coagulopathy, shock, neurotoxicity, rhabdomyolysis, AKI, pulmonary edema.
- ▶ Antivenom is **IV only**; no skin testing; keep epinephrine ready and restart slowly after treated reaction if still indicated.
- ▶ First aid: immobilize, remove constrictors, rapid transport; **no incision, suction, tourniquet, ice, alcohol, massage, or pressure-immobilization for viperid bites**.
- ▶ Blood products only after adequate antivenom except life-saving resuscitation; avoid NSAIDs and salicylates.
- ▶ Compartment syndrome is treated first with antivenom and pressure monitoring; fasciotomy is last resort.
- ▶ Follow up for **recurrent coagulopathy for 2-3 weeks**, serum sickness, renal recovery, limb function, and late pituitary insufficiency.

SOURCE & COVERAGE

Harrison 22e — “Disorders Caused by Venomous Snakebites and Marine Animal Exposures”; Tintinalli's Emergency Medicine — “Snakebite”; Brenner & Rector's The Kidney — “Indian Subcontinent”; CMDT 2026 — “Poisoning”. Coverage note: the corpus is strong for syndrome,

AKI, monitoring, and general antivenom principles, but does not provide India-specific Russell's viper ASV dosing; dosing should follow local antivenom product and institutional protocol.

Venomous snake bite poisoning

Asked in: Paper IV Dec 2023 — RGUHS MD General Medicine

Definition / Introduction — Venomous snake bite poisoning is local and/or systemic envenomation following injection of snake venom through fangs. It is a medical emergency because venom may cause progressive tissue necrosis, coagulopathy, shock, acute kidney injury, rhabdomyolysis, neuromuscular paralysis, and death from respiratory failure. Snakebite envenoming is the deadliest neglected tropical disease; Harrison estimates 1.2-5.5 million bites and 421,000-1,200,000 envenomations worldwide each year. In India, an exam answer should think syndromically: **viperid/cytotoxic-hemotoxic bite** versus **elapid/neuroparalytic bite**.

Epidemiology and important snakes

- ▶ Medically important venomous snakes belong mainly to **Viperidae** (Old World vipers and pit vipers) and **Elapidae** (cobras, kraits, coral snakes, sea snakes, Australian elapids); less common families include Lamprophiidae and venomous colubrids.
- ▶ Indian high-yield clinical pattern: **cobra/krait** bites usually suggest neuroparalysis; **Russell's viper** and **saw-scaled viper** bites suggest local swelling, bleeding/coagulopathy, shock, and renal injury.
- ▶ Harrison lists **cobras, carpet/saw-scaled vipers, Russell's vipers, large African vipers, lancehead pit vipers, and tropical rattlesnakes** among snakes causing large numbers of deaths globally.
- ▶ **Dry bite** means fang marks without venom effect. About **20-25% of pit viper bites** are dry; dry bites may be even more frequent with some snakes, including sea snakes.
- ▶ Risk of death rises with delayed transport, traditional treatment before hospital care, lack of correct antivenom, bites on head/neck, children, pregnancy, shock, respiratory paralysis, and established renal failure.
- ▶ Do not overdepend on colour or popular identification rules; a **safe photograph** may help, but attempted capture increases repeat bite risk.

Venom pathophysiology

- ▶ Snake venoms are complex mixtures of **enzymes, polypeptides, glycoproteins, and other constituents**; composition varies with species, age, diet, geography, and even within the same species.
- ▶ Major mechanisms:

Venom effect	Pathophysiology	Typical clinical result
Cytotoxic / local	Vascular permeability, tissue digestion, local necrosis	Pain, edema, ecchymosis, bullae, tissue loss
Hemotoxic / procoagulant	Fibrinogen and platelet consumption, fibrinolysis, endothelial injury	Bleeding, prolonged PT/INR/aPTT, low fibrinogen, DIC-like state
Neurotoxic	Pre- or postsynaptic neuromuscular blockade	Ptosis, ophthalmoplegia, dysphagia, respiratory paralysis
Myotoxic	Myolysis and rhabdomyolysis	Myalgia, myoglobinuria, hyperkalemia, AKI
Systemic vascular	Vasodilation, capillary leak, hemolysis, bleeding	Hypotension, shock, pulmonary edema

- ▶ Renal failure may follow hypotension, myoglobinuria, coagulopathy, hemolysis, or direct nephrotoxicity; it is often acute tubular necrosis but cortical necrosis is possible.
- ▶ Established presynaptic paralysis, renal failure, and rhabdomyolysis may not be reversed by antivenom; hence early recognition and early antivenom are crucial.

Clinical manifestations and severity

- ▶ **Local envenomation:** fang marks, immediate or delayed pain, progressive swelling, tenderness, ecchymosis, hemorrhagic or serum-filled vesicles/bullae, regional lymphadenopathy, cellulitis-like appearance, necrosis. Swelling may threaten airway after face/neck bites and function after hand/forearm bites.
- ▶ **Systemic viperid/cytotoxic syndrome:** nausea, vomiting, metallic or altered taste, perioral tingling, weakness, tachycardia or bradycardia, hypotension, spontaneous bleeding, thrombocytopenia, coagulopathy, hemolysis, pulmonary edema, AKI.
- ▶ **Neuroparalytic syndrome:** nausea/headache/paresthesias may precede cranial nerve signs; ptosis, diplopia, dysarthria, dysphagia, loss of facial expression, salivation, descending flaccid weakness, diaphragmatic paralysis, aspiration, and respiratory arrest. Symptoms may be delayed for 12 h or more after some elapid bites.
- ▶ **Myotoxic/sea-snake-like syndrome:** variable local pain, generalized myalgia, trismus, rhabdomyolysis, myoglobinuria, hyperkalemia, and progressive flaccid paralysis.
- ▶ Severity grading useful at bedside:

Grade	Practical definition
None / dry bite	Fang marks only; no local progression, systemic features, or laboratory abnormality
Mild	Local pain/ecchymosis/nonprogressive swelling only

Grade	Practical definition
Moderate	Clearly progressive swelling, systemic symptoms/signs, and/or laboratory abnormality
Severe	Neurologic dysfunction, respiratory distress, cardiovascular instability, or shock

First aid and prehospital care

- ▶ Move the patient away from the snake; keep calm and still; **immobilize the bitten limb** in a neutral position and arrange rapid transport to a facility with airway support, laboratory testing, and antivenom.
- ▶ Remove rings, bangles, anklets, footwear, and tight clothing before swelling progresses. Clean with soap and running water if this does not delay transport; cover with a sterile dressing and splint.
- ▶ **Avoid** incision, suction, electric shock, ice, alcohol, stimulants, tight tourniquets, massage, and attempts to capture the snake.
- ▶ Pressure-immobilization may delay systemic absorption in a reliably identified **primarily neurotoxic elapid bite without significant local cytotoxicity**; it is **not recommended for viperid/cytotoxic bites** because it may worsen local injury.
- ▶ If pressure-immobilization is used by a trained rescuer, Harrison gives approximate wrap pressures of **40-70 mmHg for upper limb** and **55-70 mmHg for lower limb**, with complete limb immobilization and carriage to hospital.

Hospital assessment and investigations

- ▶ Start with **ABC**: early endotracheal intubation for face/neck swelling, bulbar weakness, falling vital capacity, difficulty swallowing, or respiratory insufficiency.
- ▶ Monitor vital signs, cardiac rhythm, oxygen saturation, mental status, and **urine output**. Establish two large-bore IV lines in unaffected limbs; minimize venipuncture and avoid noncompressible sites because coagulopathy may develop.
- ▶ Record time of bite, first-aid methods used, progression of symptoms, comorbidities, drugs, pregnancy, and snake identification if safely available.
- ▶ Mark the leading edge of swelling/ecchymosis/tenderness; measure limb circumference at three points every **15 min** until stable, then every **1-2 h**.
